The increasing winter minimum temperatures for June, July and August to over 8 ºC by mid-century has got negative impacts on apples because they need to be exposed to temperatures below 7.2 ºC for bud break. The increasing annual precipitation is good for apple production and other agricultural crops. However, both increasing temperatures and precipitation can increase the incidences of pests and diseases on apples. Studies in India have shown an increasing number in sprays from 4 -12 per year to control pests resulting economic loss (Signh and Sharma, 2016). With a warmer climate, the region will shift more to the production of sub-tropical fruits rather than temperate fruits. The high chilling requirement apples will not perform well under a warm environment even with special chemical treatments because they would not have received enough chilling to trigger bud break. Such environmental cues may result in misalignment between flowering, pollination and fruiting. Although the projected minimum monthly temperatures will be warmer the chilling hours in other instances will be triggered by extreme events such as the scenario recorded in Marondera in July 2012. The minimum temperatures went as low as -3ºC during early winter. These low temperatures can trigger the low chilling varieties to flower early because they would achieve enough chilling earlier. However, these flowers are prone to mid to late winter temperature extremes which will most times destroy the early flowers before fruiting.

ISSN: 2814-0508

CONCLUSIONS AND RECOMENDATIONS

From the observations and model projections, it can be concluded that in the near future most apple cultivars growing at the Horticultural Research Centre might fail to thrive. The critical parameter of minimum monthly temperature during winter May to August might fail to meet the requirements needed for achieving enough chilling hours sufficient for bud break. Apples need to be exposed to a temperature of About 7.2 ºC for chilling.

ABSTRACT

The survey of hedge plants status and management was carried out Taraba State, in 2006, with the aim identifying the nature, promoters, effects, management practices in the face of increasing climate change. Two hundred structured questionnaires were distributed in six local government areas to elicit relevant information with 83 % return rate. Simple statistics and percentage were used to analyze the data. Results showed that Majority were male (74.4 %) and single (56.9 %), aged 20-30 years old (41.4 %), followed by teenagers (24.8 %) most of whom were applicants (38.8 %) or civil servants (33.3 %). About 97 % are literate, majorly NCE/HND and Secondary school leavers. Horticultural flowers, trees and shrubs were planted by 46.3 %, 38.3 % and 15.4 % of the respondents respectively for beautification and landscaping (47.3 %) and protection of boundary (25.5 %). A higher number of sampled persons planted 1-3 types of hedges (35.5 %), raised from stem cuttings (40 %) and seedlings (37.0 %) at the cost of N20-200/ propagule (85.5 %). Challenges facing hedgerow plants were majorly insect pest, drying out of the plant and fire outbreak as indicated by 32.9 %, 26.2 % and 18.3 % of the respondents respectively. This basic management practices of pruning and watering during dry season were carried out by 79.4 % and 62.6 % respectively. With the involvement of the educated youths and economic potential of raising seedlings, enhanced hedgerow planting culture could be sustained with minimal adverse effect of climate change in the study area.

Key words: Hedge plants, climate, resilience, management

INTRODUCTION

Climate change is a challenge of global dimension that continues to reduce the resource base of any ecology quantitatively and qualitatively. Working against nature, in terms of deforestation for urbanization and industrialization with several fallouts from such unmitigated practice aggravate climate change. Tree planting, afforestation, reforestation and hedge planting are part of the remedies. A hedge is a well arranged shrubs and/or shrublets or short trees, similar species, planted closely together to give a linear strips of vegetation that perform a variety of valuable functions, in a blended scenario where individuality gives way for integrated view of plant set (Hessayon, 1992; Brun and Dinius, 2015). Wilton *et al*. (2014) identified nine sustainable ecosystem services of hedge plants that guarantees a) improvement in water quality, urban air quality, crop water availability, crop pollination, shelter provision for crops and livestock on one hand and b) mitigating flood risk, soil loss/erosion, crop pest impact, climate change on the other hand.

Hedges are known to store more carbon than cropped land mitigating climate change. Trees store more carbon than shrubby hedges because of greater above ground biomass than shrubs and add more carbon into the soil through higher leaf and small branch litter fall. Carbon is sequestered both in woody growth above ground and in roots, leaf litter and other soil organic matter at and below ground level. To have any significant impact upon greenhouse gas levels, carbon needs to be locked up within the hedges and soil over the long-term (Devon, 2014). Hedge plants serve for protection, enhanced security, wind breaks, privacy screens, environmental beautification and management; they make public parks and houses more conducive for relaxation and enjoyment (Okunlola, 2013; Armstrong, 2000; Okunlola, 2013, Mathews *et al*., 2014). After the establishment of hedges plants, maintenance requires watering, weeding, trimming/pruning. The efficiency of hedge plant in playing above-mentioned roles depend on to hedge structure, hedge density, woody species and age. (Devon, 2014)).

In the study area, little information is available on the types, nature and potential of hedge plants to deliver the afore-mentioned soil-water-environmental sustainability services, hence the need to survey the state, for hedge plant need, management practices and challenges which will help the planers and environmentalists harness potentials of hedges for better livelihood.

MATERIALS AND METHODS

Taraba state was zoned into four based on agro-vegetation criteria which could affect hedge plants performance: Semi-temperate zone of Mambila plateau, Forest zone, Southern zone and Northern zone. Six local government areas: Jalingo, Lau, Sardauna, Gassol, Donga and Kurmi were selected. Data were collected with questionnaires, distributed randomly and proportionately to Jalingo, Sardauna (40 each); Gassol, Donga, Kurmi and Lau (30 each) giving a total of 200, out of which 166 were retrieved. Analysis was based on total response to each item and expressed in percentages.

Socioeconomic characteristics of Hedge Plant Users

Table 1 shows socioeconomic characteristics of respondents using hedge plants in Taraba State. A good number (41.4 %) were 20-30 years old, followed by teenagers (24.8 %) and those between 30-40 years. Beyond teen age, the percentage of people that planted hedge plants decreased with age. Fewer older people were involved. Majority were male (74.4 %) and single (56.9 %). About 38.8 %, 33.3 % and 13.9 % of the respondents were applicants, civil servants and farmers respectively. Traders were the least involved. Ninety-seven percent of the respondents have acquired one form of education or the other. The order NCE/HND >Secondary > ND > Degree >Primary > Illiterate was observed. The higher involvement of youths, male, singles and unemployed reflected quest for aesthetic surrounding, high energy and time required for the establishment of the hedge plants which adults, including older farmers and traders could not afford.

Status of hedge plants

The status of hedge plants, utilization, management and challenges in Taraba State is presented in Table 2. Horticultural flowers, trees and shrubs were planted by 46.3 %, 38.3 % and 15.4 % of the respondents respectively for beautification and landscaping (47.3 %), protection of boundary (25.5 %), feeding livestock (17.0 %) and privacy screening (10.3 %) within a compound. Ornamental hedges are a very important part of environmental beautification and management; they make public parks and houses more conducive for relaxation and enjoyment (Day and Loveys, 1998; Okunlola, 2013). Other usage of hedge plants includes provision of shelter/shade for individuals/ family (36.4 %) and construction of local buildings (31.5 %). Its industrial potential of raising electric poles was the least (11.1 %). About 21.0 % sourced fire wood from the hedge plants around them.

Most hedge plants are raised from stem cuttings (40 %) and seedlings (37.0 %). Less than 25 % of the respondents raised theirs from seeds and leave. This reflects the possible low survivability and unavailability of seeds and leave propagules. Most hedge plants are propagated vegetatively. Propagation of hedges by cuttings is an and common technique in horticultural science (Odusanya *et al.*, 2019). Hedge plant choices based on their ease of propagation and early establishment is recommended. Successful

ISSN: 2814-0508

seedling establishment is largely dependent on the capacity of seedling to rapidly initiate roots (Anthony and Douglass, 2005). Rooting through asexual methods of propagation is commonly used (Manica *et al*., 2000; Awan *et al*., 2012; Qadri *et al*, 2018). Haider *et al*. (2015) reported the rate of multiplication through cuttings is higher than for any other vegetative propagation techniques, with the exception of micro-propagation.

About 39.9 % and 28.2 % of the respondents indicated that private sellers and government institutions were the major sources of propagules, followed by friends (19.6 %). Higher percentage of the respondents (43.7 %) paid N20-30/ propagule, while 20.9 % each paid N50-100 or N100-200/propagule. This shows the potential of hedgerow plant propagule as viable business. A higher number of sampled persons planted 1-3 types of hedges (35.5 %), followed by those that planted 3-4 types (24.5 %). The plot size hedged were majorly 2 plots (37.9 %) and 3-5 plots (27.3 %). This was closely followed by those having < 1 plot (19.3 %). The low percentage of individuals that hedged large plots (11.8 %) reflected ownership; amount of planting materials required. Small to moderate plots are easier to be hedged in comparison with large plots. The number of stands/area was in order 20-50 (41.9 %) > less than 20 > 50-100 > 100-200 >500 > 200-500. With about 69.4 % planting <= 50 stands/plot reflected plot size, hedge type and plant spacing. The diversity and density of hedgerow plants reflected needs, purpose and establishment requirements (Haider *et al*., 2015).

Challenges facing hedgerow plants were majorly insect pest, drying out of the plant and fire outbreak as indicated by 32.9 %, 26.2 % and 18.3 % of the respondents respectively. This basic management practices of pruning and watering during dry season were carried out by 79.4 % and 62.6 % respectively. This could be attributed to the nature of hedge plants and scarcity of water (Heritage, 2021). Water is required by plants all year round but mainly between April and the end of September. Trees, shrubs and hedges planted less than five years ago require water to encourage root growth into the surrounding soil to enable the plants to establish and flourish.

Established trees, shrubs and hedges do not generally need watering because they have far spread roots and it is best if they can reach and survive on their own through rainfall. Excessive drought conditions could result in slow growth rate, leaf drop or even die-back so watering in these extreme circumstances is recommended (Odusanya *et al*., 2019). A good number depended on rainfall. About 66.5 % protected the hedge plants using chemical method with insecticide, while 33.5 % used biological method. The reflected the strategic handling of the most important challenge, insect pest that can easily be controlled with synthetic chemicals.

SUMMARY, CONCLUSION AND RECOMMENDATIONS

Most hedge plants are horticultural flowers, trees and shrubs were planted by 46.3 %, 38.3 % and 15.4 % of the respondents respectively. Beautification and landscaping (47.3 %) and protection of boundary (25.5 %) were the main purposes. A higher number of sampled persons planted 1-3 types of hedges (35.5 %), raised from stem cuttings (40 %) and seedlings (37.0 %) at the cost of N20-200/ propagule (85.5 %). Challenges facing hedgerow plants were majorly insect pest, drying out of the plant and fire outbreak as indicated by 32.9 %, 26.2 % and 18.3 % of the respondents respectively. This basic management practices of pruning and watering during dry season were carried out by 79.4 % and 62.6 % respectively. Government should provide insecticides, education on managing fire outbreak and dry season maintenance to general populace at local and state levels for harnessing the potentials of hedgerow plants in the study area.

AN ASSESSMENT OF THE CAUSAL FACTORS OF CLIMATE CHANGE ON FOOD SECURITY: THE WAY FORWARD IN NIGERIA

Agbebaku, H.U.

Department of Environmental Science; Faculty of Sciences

National Open University of Nigeria, Abuja

Corresponding author's e-mail: hagbebaku@noun.edu.ng

ABSTRACT

This paper examines an assessment of the causar factors of climate change and food security. The discursed on climate change and food security have been a major concerned among other global environmental challenges in recent time. Climate change is more to natural than anthrpogenic factors. There exists a corrolation between climate climate, food production and food security and sustainable development of these variables. The differential in food production and pace of food security from region to region is a function of the level of science and technology, innovation and development of the nations involved in food production in commercial scale. The objectives of the paper are to examine the causar factors of climate change and food security and these 2 indices constitutes the conceptual issues of the the study. The study revealed that climate change is caused by both natural and anthrpogenic factors and food security is a function of a combination of factors such as: the quantum of food production, demand and supply for agricultural products, nature of science and technology, innovation and development. The study, therefore, recommends that on climate change, there should be the need for human interferance and control of the effects of: burning and less dependence fossil fuels, greenhouse gases, depletion of ozone layer, environmental degardation, rise in carbon dioxide concentration and practice of afforestation of the earth atmosphere while on food security there is the need for: absolute security in Nigeria on life and property, increase in food production via commercial agriculture, marketing and improved storage facilities, scheme on comparative cost advantage, improved technology, flood control, government incentives and improved budgetry allocation on agricultural products for sustainable development of the teeming population of Nigeria.

Key words: Assessment**,** Causar Factor, Climate Change, Food Security, Nigeria and Way-Forward.

INTRODUCTION

At present the concerned of environmental consultants, health practitioners and agricultural scientists in recent time is how to combat the ramvanging threats of climate change, food production and food security among other environmental challenges as pollution, waste management, erosion, flood, health and increase in human population among other global challenges. Climate change results from changes in climatic variations of the indices of high temperature and global warming (Oyediran *et al*., 2001; Wright and Nebel, 2002; Orimoogunje, 2010). It has been recognized that climate change is a global problem of unique character that could affect every aspect of life on the planet. Secondly, it issues reach far beyond atmospheric and ocean science and thirdly, it issues are increasing pivotal in determining environmental and economic well-being. Furthermore, no matter the level of uncertainties in the knowledge of the characteristics and future trends of climate, climate change and sea level rise will have significant impacts globally, regionally and locally creating problems for sustainable development and resource management (Oyediran *et al*., 2001; Wright and Nebel, 2002; Orimoogunje, 2010; Fadejin, 2010; Agbebaku, 2016). At a global view, while some regions produced food surplus due to their pace of science and technology, innovation and advancement, others produced food deficits owing to their levels of development, financial aids, innovation and level of insecurities. To this end, while areas with harvest surplus have the technology to preserved and ensures food security and sustainability of their agricultural products, the reserves in the case in areas with poor technology and low production and insecurity challenges (Gradi *et al*., 2015; Olayiwola and Arowosegbe, 2021; FAO, 2021). However, in a broad perpecstives, these inadequacies in food in security could be attributed to natural and anthropogenic factors. Food security has been a challenge to primary producers of agricultural crops and government mainly in the developing nations in recent time in the last two decades (Olayiwola and Arowosegbe, 2021). This could be due to a combination of factors such as: (a)poor technology, (b)weak marketing board, (c)inadequate commercial farming, (d)insecurity, (e)envioronmental degradation, (f)epidermic (g)poor human attitude, (h)annual fire outbreak (i)poor government intervention and assistance, (j)poor budgetry allocation, (k)soil infertility (i)differentials in climatic variables among other variables (Ayoade, 2002; Ajadi, Adeniyi and Afolabi, 2011; Olayiwola and Arowosegbe, 2021).

For instance, in Nations such as the United State of America and Sweden, 15% and 9% respectively of their population goes into agriculture and they produced surplus and export for sustainbale development for their teeming population and future use because they have the technology, engaged in research, engaged in commercial production, government assistance and above all have a scheme for agricultural production in place. In essence, the aimed of food security on agricultural crops is the ability to preserved and stored the harvested products without scarity for present and future demands and supply and at a-fixed price whenever the supplied of these products are demanded. But the reverse of these benefits and measures cannote be said in developing Nations in general and Nigeria in particluar as the food supply cannote be guarantee in as much as the price and security of the farmlands where these items area coming from. In addition to these challenges is the issue of: (a) poor technology, (b) less research and development, (c)land tenure challenge and sustenance production, (d) poor government assistance (e) poor scheme on agricultural production and (f)insecurity among others (Oyediran *et al*., 2001; Gradi *et al*.,2015; Clucas *et al*.,2018; Olayiwola and Arowosegbe, 2021). However, there exists a correlation between climate change and food production and food security as the combination of the indices of a favorable climatic conditions enhances food production and possibly food security and vice-versa. There is no doubt that climate plays a crucial role in foof production and harvest of these products needs to be protected for sustainable uses and development hence the concerned of food security accrossed the globe to meet and equate with the demand and supply of these product with the ever increasing population (Orimoogunje, 2010; Olayiwola and Arowosegbe, 2021; FAO, 2021). In view of the above, there is the need for the cross-examination of the causar factors of climate change and food security in Nigeria and examines the ways forward. This informed the reason for this research as the research gap is meant to ascertain the causar factors of climate change and food security and examines ways forward in Nigeria. In order to achieve this, the sole objective of this paper is to examine the causar factors of climate change and food security in Nigeria.

MATERIALS AND METHODS

This paper is purely an experimental survey and a combination of content analysis of articles from journal publications and field survey. The study utilises evidence mainly from secondary sources and observed information from field survey. Primary information was sourced from established survey of literature. Secondary data were sourced mainly from existing literature, academic journals, conference papers, theses, internet materials and archival sources. In a nutshell, secondary data will be sourced from documentary materials from established sources. The descriptive and purposive sampling techniques was used for this study.

CONCEPTUAL ISSUES

Climate Change: This connotes changes in the indices of climatic variables of the earth atmosphere. This concept is used to explain changes in the earth’s climatic system like the theories of polar wandering and continental drift, relief hypothesis, carbon dioxide and variations in polar radiation. In view of these theories and models, climate change is mainly concerned with changes due to an increase in average atmosphere temperature. The incessant features of desert encroachment, glacier melting, irregular wind and wave patterns, environmental in-balance and challenges, tsunamis, drought, overflow of riverbank, epidermis-outbreak and ocean surge are clear indicators that the ecosystem is affected by climate changes. Climate change is a function of environmental challenges and in-balance in the ecosystem (Oyediran *et al*., 2001; Ayo, 2009; Thomas, 2009; Amina, 2013; Agbebaku, 2016). In another perspective, climate change is attributed directly or indirectly to human impact and activities that alters the composition of the physics and chemistry of the global ecosystem and of the natural variability observed over some comparable time periods (IPCC, 2017 as cited by Thomas, 2009). It is now a global concern that the impact of climate change today has been speed up due to increase in human population and spread of socio-economic activities such as; (a) industrialization, (b)agriculture, (c)commerce and mining, (d) technology and (e) man’s quest for comfortability and sustainable development. At the global level, climate change wound directly or indirectly affect (i)food production, (ii) human health and (iii) envioronmental degradation such as: erosion and floods, wind and wave pattern, drought and desertification, settlement and pollution spread among others (Oyediran *et al*., 2001; Ayoade, 2002; Ayo, 2009; Amina, 2013; Agbebaku, 2017).

Food Security: Agriculture was the most important sector in Nigeria before independence in 1960. It accounted for more than 50% of the GDP and more than 75% of export earnings. However, in recent time and due to persistence increase in population growth and the need to sustain the growing population, most agricultural lands have been taken over or reduced for cultivation of agricultural crops hence the inflation of food price, food scarcity and food insecurity. To this end, where the few havested crops are cannot be guaranttee of their presevation owing to poor storage facilities or where government fails to do the needful to meet future demand and supply the challenge of food security comes to play (Ajadi *et al*., 2011; Gradi *et al*., 2015; Agbebaku, 2015; Clucas *et al*., 2018; Olayiwola and Arowosegbe, 2021).

CAUSAL FACTORS OF CLIMATE CHANGE ON FOOD SECURITY

Climate Change: The studies of Oyediran et al (2001), Ayo (2009 as cited by Thomas, 2009), Cunningham and Cunningham (2015) and Agbebaku (2017) revealed that the combination of burning fossil fuels, excessive heat, increase in average temperature, greenhouse gases, heat waves and global warming are major determinants and causar factors of climate change globally. In Africa and Nigeria in particular, hot weather and high temperature as well as wind and wave variabilities are added factors to these global threats in recent time. On the other hand, global warming is caused by deficiencies of greenhouse gases, depletion of ozone layer, dependence on fossil fuel, rise in carbon dioxide concentration and the practice of deforestation. Findings have revealed that global warming is a global phenomenon and experienced in all regions of the globe. For instance, while climate change is caused mainly by the combination of the indices of high temperature and global warming such as the long-term deleterious effects of burning fossil fuels, excessive heat, increase in average temperature, greenhouse gases, heat waves, deficiencies of greenhouse gases, depletion of ozone layer, dependence on fossil fuel, rise in carbon dioxide concentration and the practice of deforestation of the earth atmosphere. Studies have revealed that global warming is largely anthropogenic and there have been a steady rise in used of fossil fuels by man in the past few decades and this have caused an increase in the earth's temperature causing to climate change. Studies have revealed that in the next two decades (probably between 2030 and 2050) that climate change is expected to cause approximately 250, 000 additional deaths per year due to the effect of global warming. These can be felt from the incessant cases of malnutrition, malaria, diarrhea and heat stress. Climate change signified more danger to developing nations like Nigeria and others. These have resulted to about 75% of epidermis diseases or disasters related deaths and environmental challenges of the ecosystem (Wright and Boorse, 2011; Thomas, 2009; Ayo, 2015; Agbebaku, 2017).

Food Security: Studies have revealed that a combination of factors such as (a)urban growth and development (b) attitude of youth towards farming, (c) insecurity (d) land tenure/fragmentation system (e) environmental degradation, and (f) poor government aids to farmers are some of the major reasons and challenges responsible for food insecurity in Nigeria. For instance, the challenge of urban growth and development have drastically reduced the sized of farmlands majorly in human settlement habited areas thereby assembling pressure on agricultural products. There has been a shift of the attitude of youths towards farming as most of them ends up doing white-collar, skilled and miniate jobs as against farming. Furthermore, the indequacies of government to do the needful via: provision of presevation or storage facilities, agricultural loans, fertilizers, chemicals, herbicides and subsisdies as well as the activities of insecurities on the land via; kidnapping, banditary, boko-haram and fulani herdmen are added advantages to reduction in food production hence the threat of food security in Nigeria (Ajadi, Adeniyi and Afolabi, 2011; Gradi, Panagos, Van Liedekerke, Bosco and Brogniez, 2015; Olayiwola and Arowosegbe, 2021).

EFFECTS OF CLIMATE CHANGE ON FOOD SECURITY

Climate Change: Scientists have projected that the effects of climate change could cause the polar regions of the Northern Hemisphere will heat up more than other areas of the planet, and glaciers and sea ice will shrink as a result of global warming. However, the effects of climate change could be observed where (a) storms are expected to be more frequent and more intense in a warmer world. Water will also evaporate more rapidly from soil, causing it to dry out faster between rains. Some regions might actually become drier than before.

Overall, higher latitudes are projected to receive more rainfall, and subtropical areas are projected to receive less (b) weather patterns are expected to be less predictable and more extreme. Storm tracks are projected to move toward the poles, shifting wind, rainfall, and temperature patterns. Heat waves will continue to become more frequent and intense, a trend already observed. Hurricanes, violent storms that draw their force from warm ocean water, are likely to become more severe. The intensity of hurricanes has already increased (c) warming temperatures are already causing significant changes to mountain glaciers around the world, ice sheets in Greenland and the Antarctic, and polar sea ice in the Arctic. From Europe to Africa to Asia to North America, mountain glaciers have receded over the 20th century, and melting is becoming more rapid (d) as the atmosphere warms, the surface layer of the ocean warms as well, expanding in volume and thus raising sea level. The melting of glaciers and ice sheets, especially around Greenland, further swells the sea. Rising sea level will complicate life in many island and coastal regions. Storm surges, in which winds locally pile up water and raise the sea, will become more frequent and damaging. Erosion of cliffs, beaches, and dunes will increase (Oyediran et al, 2001; Thomas, 2009; Ayo, 2009; Cunningham and Cunningham, 2015; Agbebaku, 2017; IPCC, 2017).

In the past two decades in Lagos, Nigeria, studies have revealed that the Bar Beach on Victoria Island has been experiencing ocean surges, flooding kilometers of residential and commercial estates and destroying valuable properties. In addition, the recent flood disasters of 2012 from the over flows of Ladgo Dam in Southern Cameroun into Nigerian rivers and land masses caused more havoc of environmental degradation and challenges in the country. The menace from the flooding covered about 2/3 states in Nigeria, the floods lasted for about two months in some parts of the country. The aftermath effects were the loss of human life, property, agricultural farm lands and products. In addition, there were severe cases of soil erosion, and collapse of socio-economic activities among others that worth trillions of naira. The National Emergency Management Agency (NEMA) states that Nigerian lost about N2.29 trillion to damages caused by these widespread flood in recent time. Findings further revealed that over 3.8 million persons were displaced. The agency further stated that the estimated loss was equivalent to 1.4 per cent of Nigeria Gross Domestic Product. From that incidence 363 deaths were recorded, 5,851 injured, 3,891, 394 people were affected and 3,891,530 were displaced (Owuru, 2012; Ige, 2012; Okechukwu, 2013; Agbebaku, 2015, 2017).

Food Security: In Nigeria, 53% of the population are engaged in agriculture practices yet there is deficit in food production, supply and presevation hence the challenge of food security and dependence on foreign supply to meet with demand. In addition to these indices is the issue of insecurity of their farmlands as well as the citizenry themselves. Agricultural system, food production and security at globe scale is in-line with the climatic patterns and variables of weather and climate of the area. The positive variables such as: (a)humidity (b)trosposheric temperature (c)temperature over ocean (d)sea surface temperature (e)ocean heat content and (f)temperature over land to climate change results to tropical agricultural systems while the negatives variable such as: (a)sea ice (b)snow cover (c)glaciers results to temperate agricultural system. In most states of the North, the positive has led to environmental inbalance, inadequate water and poor soil nutrients for crop cultivation. These effects have resulted to dry and hard nature of the soils (red ferralite), rainfall hardly seeps into the soil due to high temperature but flows across the surface. The implications are the consistent use of traditional and systematic methods, mechanize-irrigation and use of fertilizer applications to revamp the soil nutrient to increase agricultural output. The variation in climatic patterns led to the ease of the production of cereals crops and animal husbandry in the region. In Southern region, the differential in soils (hydro-morphic and juvenile) and climatic patterns have led to variance in crops production as more of roots and tuber crops are cultivated in the region. In addition to these challenges are poor technology on crops presevative measures, poor seedlings, insecticides and herbicides subsidices and annual floodings (Thomas, 2009; Fadejin, 2010; Ige, 2012; Ayo, 2014; Gradi *et al*., 2015).

THE WAYS FORWARD FOR COMBATING CLIMATE CHANGE AND INCREASE IN FOOD SECURITY IN NIGERIA

Climate Change: Though climate change is more of natural than anthropogenic factors. But there should be the need for human interferance on the control of the effects of: (a) burning and less dependence fossil fuels, (b) greenhouse gases (c) depletion of ozone layer (d) control rise in carbon dioxide concentration and (f) practice of afforestation of the earth atmosphere.

Food Security: There is the need for: (a) absolute security in Nigeria (b) increase in food production via commercial agriculture, marketing and improved storage facilities (c) scheme on comparative cost advantage (d)improved technology (e) flood control (f)government incentives and improved budgetry allocation on agricultural products for sustainable development of the teeming population of Nigeria.

IMPACT OF ENVIRONMENTAL INTERACTIONS ON TEA PRODUCTIVITY IN THE CHANGING GLOBAL CLIMATE

ABSTRACT

Tea (Camellia sinensis) is an important beverage crop cultivated in the tropics and subtropics. Tea production impart meaningfully on the economy of several tea-producing countries in Africa and the world generally. Environmental holdbacks, particularly water deficiency due to inadequate or poorly distributed rainfall, limit tea productivity in most of the tea-producing countries in the world. Both atmospheric and intracellular CO2 concentrations are greatly influenced by stomata conductance, which is highly responsive to water availability. Consequently, the CO2 available for assimilation is determined by leaf water status, giving a clear picture about the interrelationship existing between whole-plant photosynthetic capacity and water availability. Agrochemicals with chemical fertilizers used on tea plantations kill many soil-borne beneficial flora and fauna. It has therefore been predicted that global climate change will furthermore have a considerable adverse impact on tea production in the near future. Exhaustive resolution of increasing concerns regarding the quality of tea in this changing climate therefore lies mainly in the effective management of the various environmental conditions that directly or indirectly affect tea productivity.

Key words: Tea, productivity, environmental interaction, climate

INTRODUCTION

Tea (*Camellia sinensis*) belong to the family *Theaceae* and was discovered by the Chinese around 2700BC. It's the most expensively popular nonalcoholic beverage consumed in the world, ranked second after water as the most consumed drink globally and cultivated in 5continents in the world. Besides being a traditional beverage, tea has a more significant role as a health drink. It is produced in 50 countries, with major producers being China, India, Kenya, Sri Lanka, Vietnam, Turkey, Indonesia and Iran. There are over 200 species reported so far of which tea plant is the most economically important. Presently, world production of tea stands at 5.56 million tons, with plantation coverage of 3.80 million hectares (Chen *et al.*, 2007; FAO 2014).

The tea plant is an evergreen woody/bush plant which when under cultivation, is kept at a low level to facilitate harvesting the young shoots, the part from which tea beverage drink is made. The crop attains a height of up to 15 m in the wild. In cultivation, however, the tea plant is maintained at 0.6-1.0 m tall to facilitate harvesting of the leaves (Famaye *et al.*, 2006; de Costa *et al.*, 2007).

Tea has a productive lifespan of over 100 years, but its peak production period is between the 30th and 50th year and can also be grown in low land and high land. Commercially grown teas are hybrids of two distinct ecotypes: The Assam-type (var. *assamica*) and the China-type (var. *sinensis*). The tea plant (*Camellia sinensis*) leaves are light green, short stalked, coriaceous, alternate, lanceolate, serrate margin, glabrous or pubescent beneath, varying in length from 5 - 30cm and about 4cm width. Flowers are white fragrant, 2.5 - 4cm in diameter, found in solitary or in clusters of two or four. Flowers bear numerous stamens with yellow antherand produce brownish red capsules. Fruit is a flattened, smooth, rounded trigonous three celled capsule, seed solitary in each, size of a small nut ((FAO, 2014; de Costa *et al.,* 2007).

ENVIRONMENTAL REQUIREMENTS FOR TEA PRODUCTION

Environmental and climatic conditions determine the rate of shoot expansion and tea yield. Various components of the environment influence the growth and productivity of tea to a different extent in Nigeria. Light, carbon(iv)oxide (CO_2) concentration, temperature and water availability are the most important factors determining tea productivity.

Effect of light environment

The rate of photosynthesis in fully expanded mature leaves of tea shows an asymptotic response to increasing light intensity. Reported values for saturating light intensities range from 600-800 $\mu molm^{-2}s^{-1}$up to 1200-1500 $\mu molm^{-2}s^{-1}$of photosynthetic active radiation. The genotype environment interaction, the effect of light supply, and the stages of the pruning cycle are factors responsible for such variation. This declines during the latter part of the pruning cycle in parallel with an increase in dark respiration rate (Mohotti, 2004).

In a greenhouse experiment, the optimum light intensity for CO2 assimilation was lower for young growing leaves (250 μmolm^{-2}s^{-1}) than that for mature leaves (500 μmolm^{-2}s^{-1}). Because the tea plant originated as an under-storey plant in tropical rainforests, its photosynthetic apparatus is adapted to function with maximum capacity under shade condition. Parameters such as photosynthetic light capture, electron transport, photochemical and non-photochemical energy quenching and carboxylation have shown that the entire photosynthetic apparatus of the tea plant is shade-adapted. The optimum shading level for tea yield is 30-40% (Gamage *et al.*, 2007).

Effect of CO_2 concentration

Variation in the atmospheric CO2 concentration is at least averagely responsible for the spatial and temporal leaf differentiation in tea. In addition, it's important for determining the productivity of tea in response to long-term climate change. A positive, linear correlation has been observed between instantaneous and CO2 concentration. Photosynthesis can be raised temporarily up to 40-60 μmolm^{-2}s^{-1}by CO2 enrichment up to 1500 μmolmol^{-1}around 30 μmolm^{-2}s^{-1}is reached at 1000-1200 μmolmol^{-1}(intracellular CO2) in mature field-grown tea. The corresponding values for young greenhouse-grown tea are 7-10 μmolm^{-2}s^{-1}and 500-600 μmolCimol^{-1}, respectively. The CO_2 response curve of mature field-grown tea is dependent on the shade and harvestable shoot supply levels (Mohotti, 2004).

Apart from the effect of atmospheric CO_2 concentration, intracellular CO_2 concentration is also greatly influenced by stomata conductance, which is highly responsive to water availability. Consequently, the CO2 available for assimilation is determined by leaf water status, and thus the whole-plant photosynthetic capacity is interrelated with water availability.

Effect of temperature

The growth of the tea plant is highly affected by temperature ranges. Tea productivity is sensitive to increased average monthly temperatures, and sustained periods of higher temperatures reduce tea yield. Tea grows well within an air temperature range of about 18-25ºC. It has also been reported to survive within the range of 18-40ºC. Air temperatures below 13ºC and above30ºC have been found to reduce shoot growth. With increasing temperature above the threshold to the optimum temperature, shoot initiation rate increases and thereafter decreases with a further temperature rise up to the maximum value. The threshold temperature for tea shoot extension has been found to vary from 2-7ºC to 15ºC. Interestingly, threshold temperature for shoot extension is 2-3ºC higher than that for shoot initiation and development (de Costa *et al.*, 2007).

The thermal duration determined the growing of tea buds and it need to accumulate about 150ºC-days above a threshold temperature of 12.5ºC to expand the leaves and 450-500ºC-days to produce a harvestable tea shoot. This parameter is needed to determine plucking rounds for different periods of the year. The thermal duration requirement for producing a harvestable tea shoot (three leaves and a bud) varies from 330-370ºC-days at high elevation to 500-600ºC days at low elevation in Sri Lanka (de Costa *et al.*, 2007).

Water availability

Tea growth is mainly controlled by water availability. Drought is responsible for a 14-20% reduction in yield and 6-19% mortality of tea plants. In addition, under drought conditions, photo-inhibition could reduce source capacity and thereby impose a source-limitation on tea productivity. Although the total annual rainfall in most of the rain-fed growing areas is sufficient for tea production, its uneven distribution throughout the year often limits annual tea yield. Under such conditions, the distribution of rainfall throughout the year is distinctly bi-modal due to the seasonality of monsoons and, consequently, these areas experience a continuous dry period of about 2-3 months (Cheruiyot *et al.*, 2008).

In temperate regions that experience less than adequate rainfall, tea plantations must receive additional water from irrigation. Soil water is responsible for shoot extension, leaf area, stem diameter, internode elongation and the numbers of lateral branches of woody plants, including tea, are greatly influenced by soil water deficits. Water uptake is mainly determined by the maximum rooting depth and the water available within the root zone. Tea is generally considered to be a shallow-rooting plant. Wind also have effect on some of the tea-growing regions, especially at high altitudes, experience periods of high wind speeds during certain times of the year. High wind speeds generally tend to increase transpiration rates from extensive tea canopies and thereby accelerate the development of soil water deficits during dry periods. To counter these adverse effects of high wind speeds, wind breaks and shelter belts consisting of several rows of different tree species are being used in tea growing areas. However, reducing wind speed by sheltering increases canopy resistance to water vapour. Daytime temperature of the canopy increases (by 1-2ºC) because of the greater resistance to heat transfer from the canopy to the surrounding air (Carr, 2000; de Costa *et al.*, 2007).

Therefore, sheltering is beneficial for tea plants growing in cooler regions where atmospheric temperature is closer to the threshold temperature for shoot growth, under irrigation and in areas with significant advection of hot dry air onto tea fields from the surrounding areas. Air humidity also have a high ambient vapour pressure deficit also reduces shoot growth in tea even when the soil is irrigated. The critical vapour pressure deficit affecting the growth of tea shoots has been reported to be about 1.2-2.3kPa. Usually, shoot extension is less sensitive to dry weather than leaf expansion. The ambient exerts a significant influence on the transpiration rate of a crop by controlling the water vapour pressure gradient between the leaf sub-stomata chamber and the outside air. A greater leaf-air vapour pressure deficit results in a higher transpiration rate and consequently decreases (Vadez *et al.*, 2014).

Use of Agrochemicals

The chemical inputs applied on tea plantations have had a deadly effect on soil biodiversity while simultaneously polluting river water, killing fish, and harming the animals and people who depend on the rivers for water. Agrochemicals used on tea plantations kill many of the microorganisms that live in soil. Studies have shown that as much as 70 percent of soil biota has been lost on tea plantations as compared to nearby natural habitat, especially in areas that workers and machinery pass over. The use of chemical fertilizers has resulted in a decline in soil fertility. Pesticides used include synthetic pyrethroids, which is quite toxic to fish and downstream organisms (Senapati *et al.*, 2002).

Degradation of Soil

Researchers have found that tea plantation soil contained between one-third and one-half the number of earthworms per square meter as the nearby natural forest soil. However, most earthworms found in tea plantations were not native species to the area (Senapati *et al.*, 2002).

Soil degradation includes factors that reduced cation exchange (a measure of a soil's ability to hold stores of nutrients and release them to plants), reduced water absorption and retention, increased acidity of the soil, nutrient leaching, and accumulation of natural toxins from tea leaves which can begin to alter microorganism soil communities (Senapati *et al.*, 2002),

CONCLUSION

The tea plant very sensitive to prevailing weather conditions across the globe. There are some specific environmental/soil requirements needed for its cultivation and productivity. Besides other environmental factors, CO2 concentrations are greatly influenced by stomata conductance, which is highly responsive to water availability. The CO2 available for assimilation is as a result, determined by leaf water status, giving a clear picture about the interrelationship existing between whole-plant photosynthetic capacity and water availability. In addition, under drought conditions, photo-inhibition could reduce source capacity and thereby impose a source-limitation on tea productivity. Agrochemicals and chemical fertilizers used on tea plantations kill many soil-borne beneficial flora and fauna. Holistic resolution of increasing concerns regarding the quality of tea in this changing climate therefore lies mainly in the effective management of the various environmental conditions that directly or indirectly affect the crop's productivity.

ABSTRACT

One of the pressing environmental issues affecting the world is climate change. Studies have shown that trees provide shading and cooling effects thus leading to a reduction in the accumulation of carbon dioxide (CO_2) in the atmosphere. The study accessed the awareness of Ibadan residents on the environmental benefits of cashew. Agbowo-Bodija was purposively sampled because of its dense population and climate condition that is favourable for the propagation of cashew. A total of 60 respondents were used for this study and vital information on their socio-economic characteristics was collected using well-structured questionnaires. Descriptive statistics were used to analyze the data collected. The result shows that the majority of the respondents are youths (81%) with men of 33.87, the male gender is predominant in the study area (55%) and all the respondents (100%) have a form of formal education. The awareness result shows that majority believes the climate is changing as a result of carbon emission and deforestation. All the respondents believe the tree helps the environment but 34% have no idea where to get cashew seed or seedlings. It is therefore important to encourage schools and institutions to educate people on urban afforestation. CRIN should enlighten people on the environmental use of cashew trees in urban areas and how to get improved cashew seed/seedlings.

Key words: Cashew, environment, awareness, climate change, urban area

INTRODUCTION

Cashew (*Anacardium occidentale L.*) is a tropical tree crop (Nair, 2010), wildly known species of the Anacardiaceae family (Subbarao *et al*., 2011) which is commercially cultivated for its wood, apple and most especially the nut (Adeigbe *et al*., 2015). It is a perennial and evergreen fruit tree with a wildly spread canopy (Toschi *et al*., 1993) which makes it a suitable shade plant. Besides being a shade plant, it also serves as an ornamental tree that is wildly used to control soil degradation (Elijah, 2015). The cashew apple is a rich source of a composite mix of antioxidants, glucose, mineral salts organic acids and vitamin C which is about 4 to 7 times higher than orange (Campos, 2002). It has been observed that consumption of cashew nuts helps in the prevention of cancer, diabetes, weight gain, gallstone, migraine and some heart disorders (Vyavahare *et al.,* 2020). The cultivation of the cashew trees preserves and restores the environment. The planting of cashew is a sustainable remedy for reducing human activities on tree species (Tandjiékpon *et al.,* 2003).

Climate change is gradually rising as one of the most significant universal issues affecting the world (Kangalawe and Lyimo, 2013). Recent studies show that the accumulation of carbon dioxide (CO2) in the atmosphere has increased. CO2 holds heat in the atmosphere leading to an increase in the temperature of the earth surface (Buchdahl, 1999) which contributes to global warming. Besides cooling and shading characteristics provided by tree canopies, rigorous planting of trees to trap CO2 from the atmosphere could help reduce the increasing CO2 accumulation in the atmosphere. Trees are a very important carbon sink and also reduce the effect of climate change in the urban areas thereby controlling the accumulation of CO2 and other atmospheric pollutants (FAO, 2010).

Trees are a principal part of the terrestrial habitat (Lowman, 2009). Trees poise the soil, prevent erosion, control desertification, contribute to climate control and play a major role in the preservation of biodiversity and ecosystem equilibrium (Bellefontaine, 2012). One of the major sources of sustenance in our environment is trees as they provide food, beverages, wood, medicines, wax, fodder, fuel, fertilizers, fibre, rubber and paper (Seth, 2004).

Trees in the urban ecosystem are known to beautify the environment, have a good shade

ISSN: 2814-0508

effect, releases water vapour to the environment via evapotranspiration, purifies the air and reduce carbon emission problems (Yilmaz, 2007). One of the major ways of reducing the effect of climate change is planting trees around the compound at home, privately owned properties open public spaces (Ferrini, 2014). Deliberate planting of shade trees in home areas have been observed to supply considerable energy, long-run cost savings, provides some health benefits and increasing the general environmental quality of the urban area (Akbari, 2001).

So much attention has been placed on the economic importance of cashew crops with little attention on the environmental benefits of the crop. The multipurpose function of cashew trees, most especially the environmental importance makes it a tree suitable and encouraged to be grown in urban areas. Therefore, the objective of this study is to understand the willingness of households to grow cashew in urban areas.

MATERIALS AND METHODS

The study was conducted in Agbowo-Bodija, Ibadan metropolis of Oyo state. The state lies between the derived savannah and rain forest ecological zone of Nigeria. The study area lies between the latitude 7.376736o N and the longitude 3.939786o E. The average annual temperature is 25.9 °C in Ibadan with about 1467 mm rainfall yearly. The whole Ibadan metropolis comprises 11 local governments and it is the capital city of Oyo state. Agbowo-Bodija was purposively sampled because of its dense population and climate condition that is favourable for the propagation of cashew. Agbowo-Bodija was purposively sampled because of its dense population and climate condition that is favourable for the propagation of cashew. A total of sixty respondents were purposively selected for this study based on their location which is Ibadan. A structured questionnaire containing open-ended and closed-ended items was used to interview the respondents. The socio-economic characteristics were analyzed using descriptive analysis techniques such as frequencies, percentages, mean and standard deviation.

RESULTS AND DISCUSSION

Table 1 shows that the majority of the respondents (55%) are male and the age group of 20-35 years were 81.7%. The mean age is 34 years and this shows that the majority of the respondents in the study area are in their productive age and are economically active. This also implies that the majority of the respondents are youth and are capable of taking decisions on their own.

The majority of the respondents are married (51.7%) and all the respondents have formal education (100%). About 26.7% of the respondents were self-employed, 23.3 percent were privately employed and 23.3% of the respondents are public employed. The implication is that majority of the respondents are productive and in their economic age, the decision to plant cashew can be manifested.

Table 2 shows respondent responses to awareness of environmental benefits of cashew trees and climate change. The majority (96.7%) of the respondents agreed that the climate is changing. 51.7% and 61.7% believed that carbon emission and deforestation respectively are responsible for climate change. All the respondents (100%) know that trees help the environment and they are aware that trees can be planted. The majority of the respondents know all the propagation methods of cashew, however, 56.7% have no idea where to get cashew seeds or seedlings. 60 percent of the respondents are aware of the health benefit of cashew tree bark while 61.7% are aware of the cashew leaf health benefit.

CONCLUSION

This study was conducted to assess the awareness of people on the environmental benefits of cashew trees. Cashew as a major cash crop in Nigeria economy has not received the needed attention on the benefits it can accrue to the environment of urban areas and the positive effect it can have on the climate of a densely populated area. Households in urban centres are advised to consider planting cashew trees as this would alleviate the level of environmental degradation in the metropolis and serve as a shade for comfort and recreation. It is, therefore, important to encourage schools and institutions to educate people on urban afforestation. CRIN should enlighten people on the environmental use of cashew trees in urban areas and how to get improved cashew seed/seedlings.

ABSTRACT

The survey aimed at understanding the strategies adopted among cocoa farmers in adapting and mitigating the effects of climate change on pests and diseases prevalence in Cross River State. A multi stage-sampling procedure was used to select 60 respondents from Bendeghe Local Government Area (LGA) and 60 respondents from Ikom LGA, both in Cross River State. Results showed that 96% of the respondents are aware that climate change has a negative effect on cocoa production as a result of high incidence of pest and diseases and that the effect ranges from high to moderate. Majority of the respondents in the study area adopted various adaptation strategies to mitigate the effects of climate change on pests and diseases prevalence. High level of awareness, adaptation and coping strategies adopted by farmers made them less vulnerable to the adverse effects of pests and diseases as a result of the change in climate.

Key words: Mitigation, Adaptation, Pests and Diseases, Climate change, Cocoa farmers

INTRODUCTION

Nigeria has a tropical climate with two precipitation regimes: low precipitation in the North and high precipitation in parts of the Southwest and Southeast (Huma, 2019; Nkechi et al., 2016). The impact of climate change on food supply varies significantly by region and the risk is generally believed to be more acute in developing countries (Okeniyi et al., 2021). Over 70% of the country's population is engaged in agriculture as their primary means of livelihood (Shiru et al., 2018; Nkechi et al., 2016). Nigeria climate has been changing, evident in increases in temperature; variable rainfall; rise in sea level and flooding; drought and desertification; more frequent extreme weather events; affected fresh water resources and loss of biodiversity. Agriculture produce in Nigeria is mainly rain fed and unpredictable rainfall variation makes it difficult for farmers to plan their operations (Anabaraonye et al., 2019; BNRCC, 2011). Evidence from literature and past studied has revealed that the present global warming has influenced agricultural productivity leading to declining food production. Oyekale et al. (2009) and Oseni (2011) showed that climate change greatly affects cocoa production both in hot and wet seasons and during irrigation. According to Raufu et al. (2015), three major phases mostly affected by climate change during field operations include nursery seedlings, field establishment and processing phases. However, the level of public awareness on issues related to climate change in Nigeria is considered low (BNRC, 2011). Mitigation and adaptation are the two main responses to climate change, "Mitigation refers to measures that may either reduce the increase in greenhouse emission or increase terrestrial storage of carbon", while adaptation refers to all the responses of climate change that may be used to reduce vulnerability" (Ifeanyi-obi and Nnadi, 2014). Study showed that Nigerian farmers on their own and with the help of governmental and other intervention agencies are already adapting to climate change using several methods (Ifeanyi-obi and Nnadi, 2014). The adoption of existing and new technologies for adapting to climate change and variability is a high priority for many ecological regions in Nigeria. This includes crop diversification, the adoption of drought-tolerant and early maturing varieties of crops, water harvesting for irrigation, mulching of young seedlings (Okeniyi et al, 2021; Halder, 2019). Climate change also affects bio-physiological processes of both the crop and the rate of development of cocoa pests and pathogens which may result in low cocoa yield (Okeniyi et al., 2021).

MATERIALS AND METHODS

The study was carried out in Cross River State. Two high cocoa producing Local Government Areas were selected for the study. Multi-stage random sampling technique was employed in the selection of 120 respondents from the two purposively selected Cocoa producing Local Government Areas. The selected Local Government Areas include Etung and Ikom. Random sampling was used to select two villages from each of the two LGAs (Etung LGA: Bendeghe and Last motor) and (Ikom: Ajassor 1 and Ajassor mission). Thirty farmers were randomly selected from each of the villages making a total of one hundred and twenty

ISSN: 2814-0508

respondents. Structured questionnaire was used to elicit information from the selected respondents. The information collected from the respondents was analysed using descriptive statistics to describe the socio economic characteristics of the farmers.

RESULTS AND DISCUSSION

The socio-economic characteristics of the respondents in the study area are described in Figure 1. The ages of the farmers ranges between 30 years to over fifty years. Those within the ages of 30 to 50 years were relatively young being 67% of the total population studied while 21% were over 50 years. The implication of this according to Okeniyi et al., 2021, is that the substantial percentage of cocoa farmers in Cross River state are relatively young which is good for cocoa production.

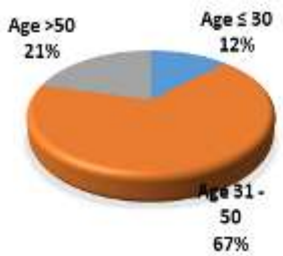

Figure 1: Percentage age distribution of the respondents

75% of the farmers are male while 25% are female this is an indication that men are more involved in the cocoa farming in the study area than the women.

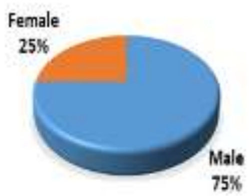

Figure 2: Percentage gender distribution of the respondents

75% of the respondents in the study area are married, 13% single, 8% widowed and 4% divorced. This is a good indication that family labour will be readily available which will reduce the cost of hiring labour.

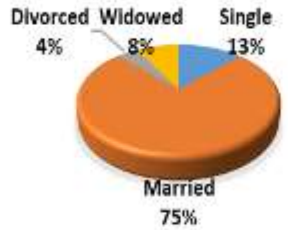

Figure 3: Marital status of the respondents

Majority of the farmers in the study area are 88% are highly experienced on farm work as the proportion has been engaging in cocoa farming for not less than 10 years. Only 12% of the sampled farmers have less than 10 years cocoa farming experience.

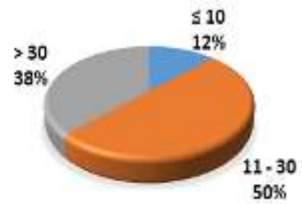

Figure 4: Years of cocoa farming experience

82% of the cocoa farmers in the study area are formally educated though only 17% had tertiary education while 40% completed secondary education. All this are good indicators towards awareness on the effect of climate change and its adaptation.

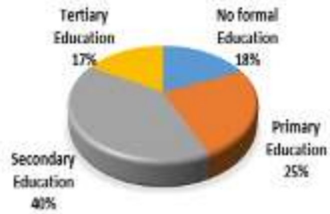

Figure 5: Percentage educational level of respondents

35% of the respondents were of the opinion that climate change resulted in high incidence of pests and diseases, 8.33% believed that the increase in drought experienced was as a result of climate change while 25% understood climate change to have resulted in decline in yield, 18.33% said it resulted into crop failure, 4.17% believed it resulted in excessive rainfall, 23% said it causes high heat waves while 2.5% said it resulted in flooding (Figure 6).

Figure 6: Farmers' perception on climate change

64.2% of the farmers from the sampled area got to know about climate change through radio/television, 19.2% from extension agents, 5% from friends and 11.6% from farmers' association. (Figure 7)

Figure 7: Respondents sources of information on climate change

Result showed that 77.5% of the farmers perceived that climate change negatively imparted on cocoa production while 22.5% perceived the effect to be positive (Figure 8).

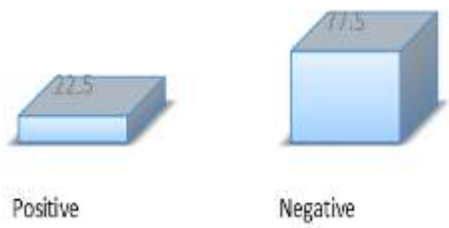

Figure 8: Respondents perception on the effect of climate change on pests and diseases

Effects of climate change on disease prevalence

The result of the study showed that climate change has negatively impacted on Pests and Diseases in the study area. For Black pod disease, 72.1% of the total respondents indicated that change in climate resulted in high incidence of black pod disease, 12.9% indicated that the effect on black pod disease is moderate, 10.4% considered it to be low while 4.6% of the respondents believed the incidence of black pod disease to be low (Figure 9). For Cocoa Swollen Shoot disease, 52.1% of the respondents indicated climate change has no effect on CSSV and so they considered it to be normal. 18.8% believed that climate change had effect on CSSV prevalence but the effect is low, 20.8% considered its effect as moderate while 8.3% indicated that climate change's effect on CSSV prevalence is high (Figure 9). 70.8% of the respondents indicated that the incidence of die back was high as a result of change in climate when compared to the previous years, 10.67% believed that the effect of climate change on die back was moderate, 12.5% considered the effect as low while 6% of the farmers were of the opinion that it was normal (Figure 9). Most of the respondents (64.6%) believed that climate change increased the incidence of Cherelle wilt when compared to the previous years, 15.4% considered its effect to be moderate, 15% considered it low while 5% considered it as normal (Figure 9). For Nematode infection, 32.9% of the respondents believed that infection prevalence increased due to climate change, 29.2% considered it to be moderate, 17.5% considered the rate of infection due to climate change to be low while 20.4% considered it to be normal (Figure 9). 62.5% of the respondents indicated that climate change has greatly influenced the prevalence of stem canker in the plantation, 20.1% considered its effect on Stem canker as moderate 7% believed it prevalence to be low while 10.4% considered the effects on stem canker as normal (Figure 9). Majority of the respondents (72.9%) were of the opinion that climate change had greatly increased the prevalence of yellowing and shedding of leaves in cocoa plantation. 10% of the sampled farmers considered the effect to be moderate, 6.7% considered it as low while 10.4% believed that the rate of yellowing and shedding of leaves remained normal (Figure 9) This report is in tandem with submission of cocoa farmers in Abia State that climate change resulted in high incidence of diseases (Okeniyi et al., 2021).

ISSN: 2814-0508

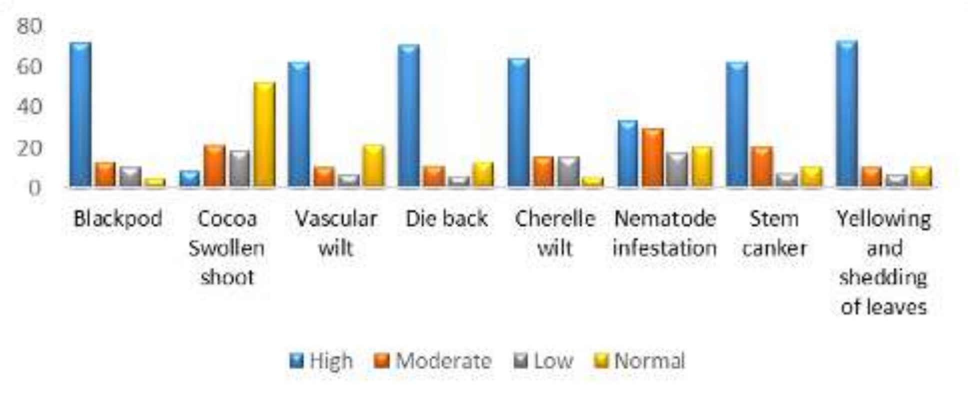

Figure 9: Effects of climate change on Diseases prevalence

Effects of climate change on Pests prevalence in cocoa plantation

67.9% of the respondents indicated that climate change increased the population of Stem borer in the field, 17.1% considered the population has been moderate, 7.5% of the farmers considered it to be low while 7.5% also considered the population of Stem borer due to climate change to be normal (Figure 10). For Pod borer 57.5% of the total respondents were of the opinion that population of Pod borer had increased as a result of climatic change. 25% of the farmers considered the population of Pod borer as moderate, 15.4% considered it to be low while 12.5% indicated that the population of pod borer remained normal (Figure 10). Mirid prevalence due to climate change was considered to be high by 64.6% of the respondents, 18.3% of them considered it to be moderate, 15% of the farmers were of the opinion that Mirid prevalence in the plantation was low while 2.1 % of the total respondents considered it to be normal (Figure 10). 77% of the respondents attributed the prevalence in termite infestation to be due to climate change when compared to previous years, 10% considered the predominance to be moderate, 6.7% believed that termite infestation was low while 6.3% considered it to be low (Figure 10). 64.6% of the farmers indicated that the population of leaf defoliator was greatly increased as a result of change in climate, 15% considered the population of leaf defoliator to be moderate, 18.3 considered it to be low while 2.1% of the respondents believed that the population is normal (Figure 10).

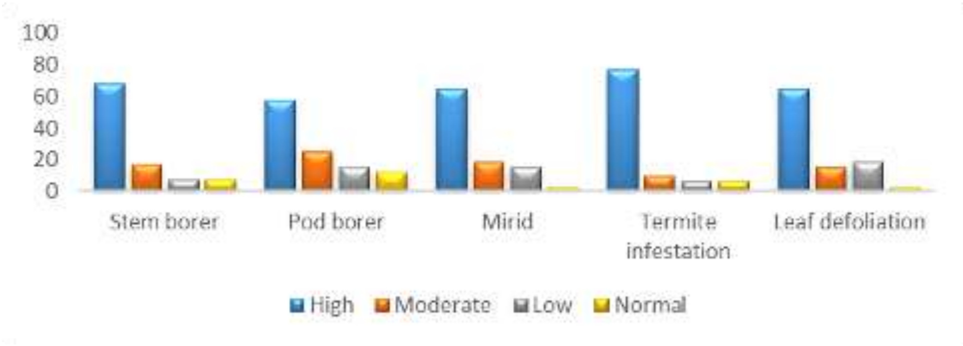

Figure 10: Effects of climate change on Pests prevalence in cocoa plantation

Strategies adopted in mitigating the effect of climate change on Cocoa Plantation

From the result, cocoa farmers in Cross Rivers State adopt different methods to adapt and mitigate the effect of climate during field establishment. 39.2% of the farmers reduced the planting distance in order to ensure that a larger percentage of the seedlings survives. 10.8% of the respondents adopted planting in-situ, 14.2% intercrop with other crops in order to minimize loss, 23.3% planted cassava as shade crop instead of plantain because it is believed that plantain itself cannot survive the effect of climate change. 12.5% of the respondents planted their seedlings in water logged area (Figure 11).

ISSN: 2814-0508

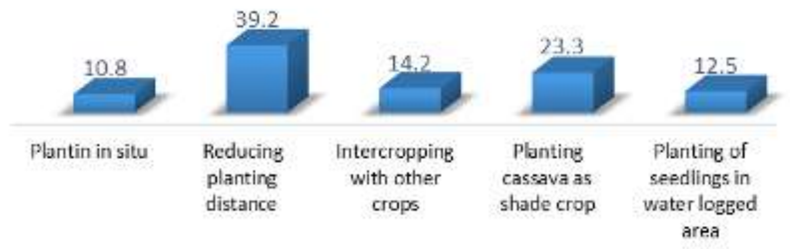

Figure 11: Methods adopted during establishment

Farmers in the study area adopted several methods in mitigating the effect of climate change in their plantation during the farming season. 29.2% harvested rain water for irrigation during the dry period. 25% of the respondents planted drought tolerant cocoa plants, 12.5% mulch the plant to conserve soil water, 10.8% dug well, 5.8% sank borehole while 16.7% conserve soil water (Figure 12).

Figure 12: Adaptation methods adopted by farmers

Mitigation and adaptation methods adopted on the field

In mitigating the effects of climate change on Pests and Diseases among farmers in Cross Rivers State, 35% of the respondents increased the use of chemicals, 16.7% planted resistant varieties, 15% carried out pruning of trees in order to reduce shade, while 25% of the respondents combined more than one chemical during spraying (Figure 13).

Figure 13: Methods for mitigating and adapting to pests and diseases

Most of the farmers in the study area are of the opinion that climate change had greatly affected yield and as such had to mitigate its effect. 33.3% of the respondents applied foliar fertilizer in order to increase yield, 29.2% applied liming, 25% make use of organic amendments while 12.5% of the respondent make use of inorganic fertilizer (Figure 14).

ISSN: 2814-0508

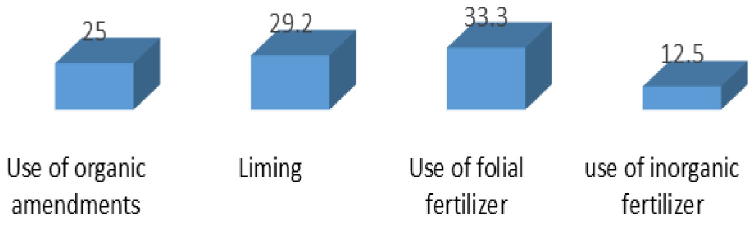

Figure 14: Methods for mitigating and adapting decline in yield

CONCLUSION

This study has revealed the need to incorporate the knowledge and experiences of farmers and indigenous people into the adaptation strategies developed by researchers and disseminate such back to farmers in a more robust way. This will help farmers to develop skills to address the effects of climate change which will allow for more comprehensive measures.

ABSTRACT

A study to determine the inheritance pattern of purple anthocyanin pigmentation on plant shoot, corolla colour and fruit colour of two eggplant species was undertaken at NIHORT, Ibadan, Nigeria in 2013/14. Three selected crosses comprising of two intraspecific crosses Solanum aethiopicum x Solanum aethiopicum (NHS10-22 X NHS10-83), Solanum melongena x Solanum melongena (NHS10-4 X NHS10-49) and interspecific cross Solanum aethiopicum x Solanum melongena (NHS10-22 X NHS10-49) were generated to obtain their F_1, backcrosses and the F_2 generation. The results obtained showed that all the F_1 plants had purple pigmented shoots and backcrossing to the first parents and Chi-square test of goodness of fit of the F_2 data fit the 1:1 and 3:1 ratio, respectively. The phenotypic expression and segregation of the corolla colour revealed that the F_2 data fits 3 white corolla: 1 white corolla with purple tint colour ratio for the intraspecific cross NHS10-22 X NHS10-83 and 3 purple corolla: 1 white corolla ratio for interspecific cross NHS10-4 X NHS10-49. For fruit colour at physiological maturity, the interspecific cross NHS10-4 X NHS10-49 F_2 data fits 3 purple fruit: 1purple stripped fruit with green/white background and at full maturity the F_2 data fits 3 golden yellow: 1yellow fruit colour. Finally, in this study, the $F_1$and F_2 progenies from the two intraspecific crosses (NHS10-22 X NHS10-83and NHS10-4 X NHS10-49) and interspecific cross (NHS10-22 X NHS10-49) revealed that the mode of inheritance of purple anthocyanin pigmentation on the plant shoot, corolla colour and fruit colour at physiological and full maturity are majorly monogenic and simply inherited.

Key words: Intraspecific cross, interspecific cross, Inheritance, anthocyanin pigmentation, phenotypic expression, segregation

INTRODUCTION

Eggplant is an important vegetable crop in the world and belongs to the Solanaceae family. The fruit is classified as a non-climacteric berry, which can grow to various sizes, shapes and colour depending on the genotype. Violet is one of the most common colours: the result of anthocyanins in the epicarp by the presence of chlorophyll pigments in the layers found under the skin (Daunay *et al.*, 2004). For the exploitation of the potentials and the genetic improvement, the gene- character relationship is essential to plant breeders as genes are the building blocks from which new varieties are developed. In eggplant purple anthocyanin pigmentation is a common decimal in the plant qualitative morphology. Anthocyanins are colored water-soluble pigments belonging to the phenolic group which often give red, blue or purple coloration in plants. Yong et al., 2019 reported the total anthocyanin content in fresh purple eggplant and black eggplant peel to be 2.1 and 3.9 mg/g, respectively. The most common anthocyanin linked to purple pigmentation in eggplant is nasunin which is a potent antioxidant and free radical scavenger that has been shown to protect cell membranes from damage.

The colour of shoots, flowers and fruits is caused by the presence of different kinds of pigment belonging to the phenylpropanoid and terpenoid classes whose three major groups are chlorophylls, carotenoids and anthocyanins (Silvia *et al*., 2009). Anthocyanins are an important group of naturally occurring polyphenolic compounds derived from the phenylpropanoid biochemical pathway (Koes *et al*., 2005). They are members of the flavonoid class of plant secondary metabolites and are soluble pigments. Early genetic studies of anthocyanin coloration in eggplant (Halstead, 1918; Nolla, 1932) deal primarily with genes which control the presence or absence of pigmentation in the fruit. Genes involved in anthocyanin coloration are classified into two functionally distinct groups viz; basic colour genes which are required to be in the dominant condition for the development of anthocyanin in the fruit and modifier genes which are hypostatic to the basic colour genes and which quantitatively or qualitatively alter anthocyanin colour (Tigchelaar *et al*., 1968). The objective of the

ISSN: 2814-0508

current study was to determine the inheritance pattern of two intraspecific crosses of two species of eggplant and their interspecific cross.

MATERIALS AND METHODS

Between 2013 and 2014, crossing blocks were set up in Vegetable Research field of National Horticultural Research Institute (NIHORT), Ibadan, Nigeria with four parental accessions consisting of two species *Solanum aethiopicum* (NHS10-22 and NHS10-83) and *Solanum melongena* (NHS10-4 and NHS10-49). Two selected intraspecific NHS10-22 X NHS10-83 and NHS10-4 X NHS10-49 crosses and one interspecific NHS10-22 X NHS10-49 cross were generated. The F_1crosses along with their backcrosses and F_2 plants generated were used to examine the inheritance pattern of anthocyanin pigmentation on three selected traits. The phenotypic expression and segregation of purple anthocyanin pigmentation on young shoot plants, corolla flower colour, fruit colour at physiological and full maturity were observed in the generation of the selected crosses

RESULTS

Phenotypic expression and segregation of plant shoot purple anthocyanin pigmentation in generations of three selected eggplant crosses are shown in Table 1. In crosses NHS10-22 x NHS10-83 (*S. aethiopicum* x *S. aethiopicum*), NHS10-4 x NHS10-49 (*S. melongena* x *S. melongena*) and NHS10-22 x NHS10-49 (*S. aethiopicum* x *S. melongena)*, all the F1 plants had purple pigmented shoot and backcrossing to the P_1 parents gave the ratio 1 purple:1 green while the Chi-square test for F_2 data gave a goodness of fit to the expected 3 purple shoot: 1 green shoot.

The phenotypic expression and segregation of flower colour in generations of three selected eggplant crosses are presented in Table 2. In cross NHS10-22 x NHS10-83, the Chi-square test of goodness of fit to 3 white corolla flower: 1 white corolla flower with purple tint ratio. White corolla colour is associated with green colour of plant shoot. In the inter specific cross NHS10-22 x NHS10-49, the backcrosses and F_2 data fit the 1:1 and the 3:1 ratio, respectively. Purple colour of fruit is dominant over green inherited in 3:1 ratio.

Furthermore, the phenotypic expression and segregation of fruit colour at physiological maturity in generations of three selected eggplant crosses are presented in Table 3. Chi-square test of goodness of fit of the F_2 data in cross NHS10-4 x NHS10-49 also gave a good fit to 3 purple fruits: 1 purple striped fruit with green/white background. Also Chi-square test of goodness of fit of the F_2 data in the same cross NHS10-4 x NHS10-49 at full maturity of fruit also gave a good fit to 3 golden yellow fruits: 1 yellow fruit (Table 4).

DISCUSION

The results of inheritance pattern of plant shoot purple pigmentation, flower colour, fruit colour at physiological and full maturity for 3 selected crosses viz; NHS10-22 x NHS10-83, NHS10-4 x NHS10-49 and NHS10-22 x NHS10-49 showed defined trends which are in agreement with earlier Mendelian reports. The phenotypic expression and segregation observed in all F_2 populations of the 3 selected crosses above for plant shoot purple pigmentation displayed monogenic inheritance pattern in the genetic ratio 3:1 which indicated that purple shoot colour was governed by a single dominant gene. Similar ratio of 3:1 monogenic inheritance gene action observed for cross NHS10-22 x NHS10-83 (white flower x white flower) F_2 populations was also governed by a single dominant gene (white corolla dominant over white corolla with purple tint). It appeared that presence of purple pigmentation is a requirement for white corolla with purple tint to be expressed. The inter-specific cross NHS10-22 x NHS10-49 (white flower x purple flower) F_2 data fit 3:1 monogenic inheritance gene action governed by a single dominant gene (purple corolla dominant over white/ white with purple tint). Similar ratio for flower colour was reported on inter-specific cross *S. melongena* x *S. indicum* by Wanjari and Khapre (1977) and monogenic form of inheritance was reported by Rangaswamy and Kadam Bavananasundran (1973) on inter-specific cross *S. indicum* x *S. melongena*. The fruit colour segregation at physiological and full maturity of fruit in cross NHS10-4 x NHS10-49 also fit 3:1 monogenic inheritance gene action governed by a single dominant gene (purple fruits over purple striped fruit with green/white background at physiological maturity and golden yellow fruits over yellow fruit at full maturity of fruit). However, Daunay et al. (2004) working on *Solanum melongena* reported that anthocyanin presence (vs its absence) is under monogenic dominant gene control. The monogenic inheritance is also in agreement with More and Patil (1982) on inheritance of some characters in brinjal cross, but Khapre *et al.* (1988) working on inter-specific cross *S. melongena* x *S. indicum* reported interaction of 3 non-allelic genes for fruit colour inheritance.

CONCLUSION

ISSN: 2814-0508

The study revealed that the inheritance pattern of plant shoot pigmentation, flower colour, fruit colour at physiological and full maturity of fruit are majorly monogenic and simply inherited.

HERITABILITY STUDIES AND INTER-CHARACTER ASSOCIATION IN SOME TEA (*CAMELLIA SINENSIS L. O. KUNTZE*) GENOTYPES IN NIGERIA

Olaniyi O.O., Oloyede, A.A., Adenuga, O.O., Ayegboyin, K.O., Ebunola, T. E, Sulaimon F.O. and Akinduko, A. K.

Cocoa Research Institute of Nigeria Ibadan, PMB 5244, Ibadan, Nigeria

ABSTRACT

*Tea (Camellia sinensis) is an important medicinal crop. Its young leaves are processed as tea for human consumption due to its health and nutritive values. Tea is grown in all the continents of the world and serves as major economic crop for some countries like China, Kenya, India and Nigeria. Knowledge of inter character association in tea is required for its improvement to suit specific purpose and demand. This research work was carried out to study inter-character association of various morphological and agronomic parameters. The experiment was laid in Randomize Complete Block Design (RCBD). The phenotypic correlation analysis shows that plant height showed significant positive correlation with number of leaves 0.73**, number of branches 0.74**, harvestable point 0.49*, stem diameter 0.70**, leaf breadth 0.54* and yield/plant 0.40*. Yield showed significant positive genotypic correlation to all the characters except caffeine with value of 0.38. Meanwhile, fewer characters showed significant environmental correlation than both genotypic and phenotypic correlations. Plant height had significant positive environmental correlations with number of leaves 0.64, number of branches 0.57** and stem diameter 0.41*. Plant heightand number of leaves combined high heritability with moderate genetic advance 70.95, 30.25 60.17, 34.85 respectively. Qualitative analysis showed variability for all characters except leave petiole colour and mature leaf colour. Therefore, there is presence of character association among the traits studied.*

Key words: Character, Association, Heritability, Germplasm and Correlation

INTRODUCTION

Tea is an important crop based on its health and economic benefits (Xia et al. 2020). It originated from China and spread to all continents of the world. Its medicinal use was first reported by the Chinese (Mandal 2007). It remains the oldest non alcoholic caffeine containing crop in the world and its consumption is next to that of water. According to Oloyede et al. (2014), consumption of green tea may help reduce the risk of cardiovascular disease and some form of cancer, reduce blood pressure, improve antibacterial and antiviral activities and promote oral health. Crop improvement depends greatly on the extent of variability to which selection for further development can be made by the breeders. Tea yield is a quantitative character simply because it is influenced by many other characters. Knowledge of inter-character association is important to know the extent at which one character is affecting other characters either positively or negatively. To determine the extent of relationship between two characters, correlation analysis is employed which the result may be positive or negative. Correlation produce is highly effective when selecting superior genotypes (Akinyele and Osekila, 2006). It is important to note that when there is positive association between major yield components simultaneously, selection becomes difficult. Therefore, the objective of the work is to investigate inter-relationship of tea yield attribute in view of identifying the traits contributing to its yield.

MATERIALS AND METHODS

Thirty-four genotypes of tea (*Camellia sinensis*) were obtained from Cocoa Research Institute of Nigeria tea germplasm and they have their origin from China except C143, C318 and and C357 that were originated from Kenya

Location of the experiment: The experiment was carried out in 3 environments (1) Cocoa Research Institute of Nigeria headquarters Onigambari, Ibadan latitude 7°12' N, longitude 3°51' E. and altitude 457m above sea level. The land preparation was done manually using hoe and cutlass and Randomized Complete Block Design was employed. The experiment included three blocks, each containing 34 single-row plots, representing each of the tea genotypes. The Spacing of 0.6 m X 1.0 m within and between rows with 12 plants per plot (7.2 m^2), making the total land area to be 870.4 m^2. Weeding and other cultural maintenance practices were done as and when necessary. The scoring of the qualitative traits was done according to IPGRI now (Biodiversity international) descriptor for tea.

Quantitative Characters

Internodes length (cm) Measured with meter rule between 3rd and 4th nodes

Length of mature leaf (cm) Measured with meter rule from leaf base to the apex

Width of mature leaf (cm) Measured with meter rule at the middle of the leaf

Plant height (cm) Measured from ground level to the tip of the plant

No of branches Recorded by counting number of branches

Shoot weight (g) Measured using electric weighing balance

Stem diameter Measured at the ground level with vernier caliper

Number of leaves Recorded by counting number of leaves

Number of flower buds Recorded by counting number of flower buds

Data analyses

Data were subjected to analysis of variance and means were separated using Duncan Multiple Range Test (Duncans, 1955) at 5% probability level (P$\leq$ 0.05). Genotypic and phenotypic variances were determined according to Okelola *et al.,* (2007). The Variance components were used to compute the genotypic and phenotypic coefficient of variability, heritability (in the broad sense) and genetic advance according to the method of Burton (1952), (Johnson *et al.*, 1955) and (Kumar *et al.*, 1985). Other analyses carried out were Correlation, Genotypic Coefficient of Variability $\{100 * \left(\frac{\delta g}{N}\right)\}$ and Phenotypic coefficient of variability $\left\{100 * \left(\frac{\delta ph}{N}\right)\right\}$ Where δph and δg are the phenotypic and genotypic standard deviations respectively and $\boxed{N}$ is the grand mean of the character under consideration.

The genotypic and phenotypic variances were calculated according to (Adewale *et al.*, 2010).

$$MSe = \delta^2\text{e}$$

$$MSy = \delta^2\text{e} + r\delta^2\text{g}$$

Genotypic variance $(\delta^2\text{g}) = \frac{Msy - Mse}{r}$ where error mean square (MSe) = error variance (δ^2e)

Phenotypic variance ($\delta^2\text{p}) = \delta^2\text{e} + \delta^2\text{g}$,

r = number of replicates.

Heritability was calculated in its broad sense.

$$Hb(\%) = \frac{\delta^2\text{g}}{\delta^2\text{p}} x100$$

Genetic Advance was also estimated using

$$G.A = \frac{\delta^2\text{g}}{\delta^2\text{p}} kx100$$

Where k = selection differential of 2.06 at 5% selection intensity according to (Adewale *et al.*, 2010). Estimates of genotypic and phenotypic correlation coefficients among the characters were obtained using the formula of Miller *et al., (*1958)

$r_{x,}y = \frac{Cov(x, y)}{\sqrt{(\delta x)^2(\delta y)^2}}$

.where

r_x,y is either genotypic or phenotypic correlation between variable x and y;

Cov (x,y) is the genotypic or phenotypic covariance between two variables;

δx is the genotypic or phenotypic variance of the variable x;

δy is the genotypic or phenotypic variance of the variable y.

Environmental correlation coefficients were determined according to Falconer (1996).

Quantitative Characters

Internodes length (cm) Measured with meter rule between 3rd and 4th nodes

Length of mature leaf (cm) Measured with meter rule from leaf base to the apex

Width of mature leaf (cm) Measured with meter rule at the middle of the leaf

RESULTS

Morphological characterization

The qualitative characters evaluated for each tea genotypes used in this study are presented in table 1 below. The leaf shape was lanceolate for all the genotypes except for NGC 55, 357 and NGC 47. The leaf base shape for the genotypes was attenuate apart from NGC 55 which was round. The leaf margin varies from biserrulate to serrulate and finally to entire for NGC 6 and C357. All the genotypes evaluated were indifferent in terms of leaf petiole colour which was green as well as mature leaf colour which was dark green. All the genotypes had medium leaf size except for genotype C357 with large leaf size. The leaf apex habit was between straight and recurve while the leaf venation for the genotypes evaluated ranged between indistinct and distinct. However, the immature leaf colour showed a vast range of variability from dark green observed in NGC 40 to green in NGC 6 and lastly to yellowish brown in NGC55.

Table 1. Qualitative description of tea genotypes

Heritability

Estimate of mean, phenotypic variance, genotypic variance, environmentalvariance, phenotypic coefficient of variability, genotypic coefficient of variability, heritability and genetic advances expressed as percentage of the mean in three environments are presented in Table 2. Tea genotypes showed considerable variation for plant height, number of leaves, number of flower buds, as well as number of branches. The genotypic variance ranged from 0.03 for caffeine to number of leaves (2193.23). Phenotypic variance also followed similar trend with genotypic variance. The phenotypic variance ranges between caffeine and number of leaves with 0.09 and 2149.29 respectively. The genotypic coefficient of variation from 2.76% for crude fibre to 54% for number of flower buds. Meanwhile, phenotypic coefficient of variation ranges from 3.69% for protein to 92.83% for number of flower bud. The mean value also ranges from 2.19 for caffeine to 164.87 for number of leaves. Considering heritability and genetic advance simultaneously, plant height, number of leaves combined high heritability with moderate genetic advance. Internodes length, leaf length, leaf breadth, crude fibre and caffeine had moderate heritability and low genetic advance. It was noted that the yield/plant combine low heritability and low genetic advance while high genetic advance and moderate heritability was observed for number of flower buds.

Phenotypic Correlation

The Phenotypic Correlation Coefficients of thirteen character of tea are presented in Table 3 below. Plant height showed positive significant correlation with number of leaves (0.73**), number of branches (0.74**), harvestable point (0.49*), stem diameter (0.70**), leaf length (0.46*), leaf breadth (0.54*) and yield/plant (0.40*), while it showed insignificant correlation with internodes length (0.37) and number of flower bud (0.30). The number of leaves (NL) exhibited significant positive correlation with number of branches (0.83**), harvestable point (0.45*), stem diameter (0.68**), number of flower bud (0.45*) and yield/plant (0.57**). Number of branches also showed positive correlation with harvestable point (0.54*), stem diameter (0.65**) and yield/plant (0.48*.)

Harvestable point was significantly correlated to stem diameter (0.41**), leaf breadth (0.42) and yield/plant (0.61**). There was positive correlation among stem diameter and the following traits; leaf breadth (0.67**) and yield/plant (0.44*). Internodes length showed no significant correlation to all the characters measured. Also, the leaf length showed no significant correlation to all the characters measured except for plant height (0.46*). It was observed that leaf breadth showed no significant correlation to number of flower bud and yield/plant with the following values (0.25) and (0.34) respectively. The number of flower bud was only significant to number of leaves (0.45*) among all the traits observed. Protein and crude fibre showed positive significant correlation to caffeine with values of 0.40* and 0.42* respectively.

Genotypic Correlation

The results of genotypic correlation among thirteen characters in tea are presented in Table 4. Generally, more characters showed genotypic correlation among themselves than the phenotypic correlation. It was observed that plant height showed strong positive genotypic correlation to all characters with the values of 0.87**, 1.08**, 0.85**, 1.06**, 0.72**, 0.64**, 0.69**, 0.56* and 1.65** for number of leaves, number of branches, harvestable point, stem diameter, internodes length, leaf length,

ISSN: 2814-0508

leaf breadth, number of flower bud and yield/plant respectively. Similarly, number of leaves showed positive genotypic correlation for all the characters except for internodes length, protein, crude fibre and caffeine with the correlation coefficients of 0.30, 0.29, 0.01 and 0.05 respectively. The results also showed that number of branches was positively correlated with harvestable point 0.58**, stem diameter 1.37**, leaf length 0.81**, leaf breadth 0.58** and yield/plant 1.27. The number of branches was not significantly correlated with internodes length 0.14 and number of flower bud 0.38. It was also observed that harvestable point exhibited negative genotypic correlation with internodes length -1.04**. Harvestable point was positively correlated with stem diameter, leaf breadth, number of flower bud, yield/plant, protein and crude fibre with the genotypic correlation coefficients of 1.61**, 0.64**, 0.68**, 0.57**, 0.58** and 1.12** respectively. Also, stem diameter was positively correlated with leaf breadth 1.25**, number of flower buds 0.73**, yield/plant 3.06**, protein 0.49*, crude fibre 0.43* and caffeine 1.01**. It was found that internodes length was negatively correlated with yield/plant -0.66** and crude fibre -0.47*. The leaf length showed positive correlation with number of bud 0.53**, yield//plants, 0.46* but showed significant negative correlation with protein -0.54* and crude fibre -0.66**. Number of flower buds showed positive genotypic correlation for protein 0.72**, and crude fibre 0.43*. Yield/plant exhibited significant genotypic correlation for protein 0.61** crude fibre 1.36** and caffeine0.91**. Protein exhibited positive genotypic correlation for crude fibre 0.55** and caffeine 0.85**. Finally, positive genotypic correlation exists between crude fibre and caffeine with value of 0.79**.

Environmental correlation

The environmental correlation coefficients among thirteen characters are presented in Table 5. Generally, fewer characters showed significant environmental correlation than both the genotypic and phenotypic correlations. Environmental correlations of plant height were highly significant and positively correlated with number of leaves 0.64**, number of branches 0.57** and stem diameter 0.41* It was observed that there was no significant environmental correlation between harvestable points for all possible combined characters except for number of leaves 4.09**. Leaf breadth, number of flower bud, yield/plant and crude fibre showed no significant environmental correlation to all the characters. Stem diameter showed significant environmental correlation to leaf length 4.64**. It was noticed that caffeine recorded positive environmental correlation to number of branches and crude fibre with values of 1.07** and 0.41*, respectively. The PH (0.40*, 1.68**), NL (0.57**, 1.09**), and NB (0.48*, 1.27**) were phenotypically and genotypically correlated with yield, respectively.

DISCUSSION

The significant phenotypic correlation of yield/plant with plant height, number of leaves, number of branches, harvestable point and steam diameter suggest that these characters possessed greater practical values for selection than component characters.

The significant positive plant height and number of branches implies that tea plant with good height tend to produce more harvestable leaves from the buds of the new branches. Positive phenotypic correlation between number of leaves and number of branches implies that tea plant with more number of branches produce more leave directly increasing the yield since the first two new leaves and the bud is harvested as yield. It is pertinent to say that positive correlation between harvestable point and leaf breadth also determined the quantity of yield harvested. The positive correlation between plant height and stem diameter showed that plant with good height and strong stem tends to produce more yield. Plant height, number of branches, harvestable point and stem diameter were phenotypically and genotypically correlated with the yield/plant. The characters that are genotypically correlated but not phenotypically correlated will not be of practical value in selection, since selection is often based on the phenotypic performance of the characters (Adebisi *et al*., 2004)

The significant negative genotypic correlation between internodes length and yield /plant indicate that the longer the internodes length the lower the yield/plant. Similarly, harvestable point is negatively correlated with internodes length i.e. the longer the internodes length the fewer the bud harvested. This may be due to the effect of partitioning of assimilates between the internodes and bud (harvestable point). Characters with moderate to high value of genotypic coefficient of variability such as number of flower bud might be further improved through varietal selection (Aremu 2005; Omoighi *et al.,* 2006). Therefore, genotypic coefficient of variability gave information on the genetic variability present in the various quantitative characters; it is not enough to offer full scope to estimate the variation that is heritable or environmental. Hence along with PCV and GCV estimates, the estimation of heritability and genetic advance became necessary. (Janaki *et al*., 2017). The low heritability value obtained for yield/plant was a confirmation of Adebisi *et al*., (2004) who reported low heritability for grain yield in soya bean. As yield is a product of complex characters liable to have more environmental influences compared to all other traits. Characters that are highly heritable are important to a plant breeder as they enable him to base his selections reliably on the phenotypic performance and extent to which improvement is possible through selection (Priyanka *et al*., 2017). High heritability observed for plant height, number of leaves, number of branches and leaf breadth indicated that the expression of these traits was more of genotype than environmental effects and therefore, there is possibility of positive response to selection Joshi (1986).

The nine qualitative characters studied confirmed that relationship exists among the studied characters of the genotypes. Leaf shape, leaf margin, leaf size, leaf apex habit and leaf venation seems to be controlled by few genes action. Adeoluwa and Kehinde (2011) found out in their work that some variations in okra such as leaf colour and spine in the fruits surface are inherited in a simple fashion. For leaf petiole colour and mature leaf colour, the gene controlling these traits are probable dominant as no variation was expressed among the genotypes.

CONCLUSION

There is presence of association among the traits studied which led to the resultant variability. Therefore, further improvement of tea is possible in Nigeria.

CORRELATION AND PATH COEFFICIENT ANALYSES OF YIELD-RELATED TRAITS IN CACAO (*THEOBROMA CACAO* L.)

Adenuga, O.O., Adepoju, A.F., Sobowale, I.O., Olaniyi, O.O., Areola, O.J. and Nyamkyume, T.F.
Plant Breeding Section, Cocoa Research Institute of Nigeria, Ibadan, Nigeria

ABSTRACT

The cacao tree (Theobroma cacao L.) produces the cocoa bean, a major source of foreign exchange earnings for most West African countries and many smallholder farmers. Declining yield of cacao is a major limitation to cocoa production in Nigeria. This study aimed at determining the correlations of the phenotypic traits that were related in the yield of the cacao genotypes. Nine cacao hybrids were produced from some high-yielding parents in the research farm of Cocoa Research Institute of Nigeria, Ibadan and evaluated in the field in Owena (7^0 11'N, 5^0 1'E), Ondo State, Nigeria. Character Correlations and Path Coefficient Analysis were used in the description of the performance of the genotypes. The study concluded that significant genotypic and phenotypic correlations existed among many of the pairs of the fruit and bean characters with one another and with pod index, suggesting the contribution of these characters either positively or negatively to growth and yield in the cacao genotypes, and that fruit and bean traits are determinants of yield in cacao.

Key words: Cacao, Genotypes, Correlation, Phenotypic traits, Path coefficients

INTRODUCTION

The importance of the cacao crop is very enormous to farmers and government in the producing countries. Cocoa bean, the main ingredient used in the manufacture of chocolate, other beverages, is the major product obtained from the cacao tree. Declining yield is, however, a limiting factor in cacao cropping in Nigeria (Adenuga *et al*., 2018). The cocoa bean yield is the primary focus of any cacao farming venture, and is indicated essentially in the 'pod index', which refers to the number of cocoa pods (fruit) required to produce one kilogramme (1kg) of dry cocoa beans. Among other factors, cocoa bean yield is influenced by variety and age of plant (Goenaga *at al*., 2018). A number of factors are, therefore, observed to be correlated with pod index in cacao.

Correlation is a measure of the degree of relationship between variables and a plant breeder should know whether the improvement of one character will result in simultaneous change in other characters through estimates of inter character correlations (Falconer, 1989). Estimates of genotypic, phenotypic and environmental correlations among characters can provide the basis of planning of more efficient breeding programmes. A positive genetic correlation between two desirable traits simplifies the breeder's job of crop improvement. As yield, being a complex and polygenic trait, is influenced even by fluctuations in environmental factors, a knowledge of the nature and magnitude of the traits that influence yield in cacao can provide a basis for genotype selection many characters that improve yield. Beyond the influence of climate, an often complex inter-relationship of plant traits is an important determinant of yield in cacao (Adenuga *et al*., 2018). This study was therefore carried out to understand the association among yield and the related traits in cacao so as to improve on the crop.

MATERIALS AND METHODS

Nine new early-bearing cacao hybrids produced at the Cocoa Research Institute of Nigeria which fruited at the Owena sub-station (7^0 11'N, 5^0 1'E) of the Institute, with harvest period ranging from 104 through 124 weeks after field ploanting (Table 1) were used this study. Thirty (30) individual seedlings were established per genotype as ten (10) seedlings per plot in three (3) replications in a Randomized Complete Block Design (RCBD). Prior to fruit harvest, data were collected (at three months' interval) on plant height, stem diameter, number of leaves, time to jorquette, jorquette height, tree circumference, fruiting and cherelle wilt. Five uniformly matured and ripe cocoa pods were harvested per genotype in each of three replications, giving a total of fifteen pods (fruits) per genotype. The time to fruit harvest (being the time of fruit maturation) was recorded in weeks. Each fruit was weighed, and the fruit length and width measured using a vernier calliper. The fruits were carefully broken and pod husk thickness was estimated as the difference between the outer (ridge to ridge) and the inner diameter of the fresh pod husk using the venier calliper. The number of rows, number of beans per row and number of beans per pod was counted and the weight of the beans was recorded per fruit, while the weight of one bean was recorded as the average of the weight of ten beans randomly selected per fruit. The beans from each fruit were extracted and fermented in trays. The beans were weighed after fermentation and the weight recorded per fruit and per individual bean as the average of ten fermented beans weighed. The fermented beans were sun-dried, and the pod value recorded as the weight of the total dried beans obtained per fruit. The weight of one dried bean was also recorded as the average of the weight of ten dried bean per fruit. Dried bean length and width were recorded by as an average of the values of ten dried beans using the vernier calliper. Pod index was calculated from the weight of dried beans from each pod as the number of pods required to produce one kilogramme of dry cocoa beans. In all, a total of fourteen quantitative traits were used to assess the nine genotypes. The means from the sampling unit per genotype were used to estimate the phenotypic, genotypic and environmental correlation coefficients using the formula of Miller *et al*. (1958) thus:

$$\mathbf{r}(\mathrm{x,y}) = \frac{\mathrm{Cov\,(xy)}}{\sqrt{(\delta \mathrm{x})^2 . (\delta \mathrm{y})^2}}$$

Where $r_{(x,y)}$ is either genotypic or phenotypic or environmental correlation between variables x and y;

$Cov_{(xy)}$ is the covariance of variables x and y;

$(\delta_x)^2$ is either the genotypic or phenotypic or environmental variance of variable x;

$(\delta_y)^2$ is either the genotypic or phenotypic or environmental variance of variable y.

The significance of the correlation coefficients was tested using the non-directional probability in the software of Lowry (2009). The direct and indirect Path Coefficients were calculated to reveal the strength of the relationship among pod index and the yield-related characters by solving a series of simultaneous equations as suggested by Dewey and Lu (1957)

RESULTS

The phenotypic correlation coefficients among fourteen vegetative and fruit characters of the nine cacao hybrids are presented in Table 1. Plant height was positively and significantly correlated with stem diameter (0.83), tree circumference (0.60), presence of fruits (0.46), fruit width (0.41) and pod index (0.56), but negatively correlated with time to fruit harvest (-0.47). Time to jorquette was positively ($P \leq 0.05$) correlated with time to fruit harvest, (0.43) and fruit weight (0.53) but negatively correlated with pod index (-0.40). Presence of fruit was positively significantly correlated with cherelle wilt (0.57) and pod thickness (0.96). Cherelle wilt was positively significantly correlated with pod thickness (0.55). Time to fruit harvest was positively significantly correlated with fruit weight (0.41), fruit length (0.71), but negatively correlated with fruit width (-0.91) and pod index (-0.83). Number of beans per row was negatively correlated with pod index (-0.71).

Table 1: List of nine cacao genotypes used in the study

S/N	Genotypes	Pedigree	Weeks to Harvest
1	P_1 x P_{10}	($T_{82/27}$ x $T_{12/11}$) x ($T_{65/7}$ x $T_{57/22}$)	122
2	P_1 x P_{11}	($T_{82/27}$ x $T_{12/11}$) x ($T_{53/5}$ x $N38$)	117
3	P_2 x P_{10}	(P_7 x $T_{60/887}$) x ($T_{65/7}$ x $T_{57/22}$)	124

The genotypic correlation coefficients among fourteen vegetative and fruit characters of the nine cacao hybrids are presented in Table 2. Plant height was positively significantly (P≤0.01) correlated with stem diameter (2.84), time to jorquette (1.29), tree circumference (2.29), presence of fruit (2.24), fruit width (27.68), pod thickness (19.82), and pod index (4.27) but negatively correlated with number of leaves (-1.62), jorquette height (-1.06), cherelle wilt (-4.09), time to fruit harvest (-2.19), fruit weight (-1.07), fruit length (-0.47) and number of rows (-0.82). Time to jorquette was also highly significantly (P≤0.01) correlated with the rest of the characters except jorquette height. The highly significant correlations of time to jorquette with these characters was however negative with fruit width (-9.98), number of rows (-0.53) and pod index (-0.99). Jorquette height was significantly (P≤0.05) correlated with the rest of the characters except fruit weight, fruit length and pod thickness. The highly significant correlations of jorquette height with these characters was however negative with presence of fruit (-0.68), Cherelle wilt (-1.42), time to fruit harvest (-0.41) and number of rows (-0.41). Tree circumference was positively significantly (P≤0.01) correlated with fruit width (7.96), pod thickness (1.84) and pod index (0.72) but negatively correlated with cherelle wilt (-1.27), time to fruit harvest (-0.42) and number of rows (-0.37). Presence of fruit was positively significantly (P≤0.01) correlated with cherelle wilt (0.57), pod thickness (10.60), and pod index (0.47) but negatively correlated with fruit length (-0.47). Cherelle wilt was also positively significantly (P≤0.01) correlated with time to fruit harvest (0.54), pod thickness (9.52) and pod index (0.54) but negatively correlated with fruit width (-3.76). The correlation of pod index was negative with each of time to fruit harvest (-1.09), fruit weight (-0.75), fruit length (-0.92) and number of beans per row (-0.56). Fruit width was positively correlated with pod index (12.26).

The environmental correlation coefficients among fourteen vegetative and fruit characters of the hybrids are presented in Table 3. Plant height showed positively significant (P≤0.05) correlations with stem diameter (0.65), number of leaves (0.63), jorquette height (0.54), tree circumference (0.42) and cherelle wilt (0.60). Stem diameter showed positively significant (P≤0.05) correlations with number of leaves (1.13), tree circumference (0.98) and cherelle wilt (0.64). Time to jorquette was negatively significantly (P≤0.01) correlated with tree circumference (-0.86) and cherelle wilt (-0.44). Jorquette height was positively significantly correlated with cherelle wilt (0.73) but negatively correlated with time to fruit harvest (-0.55). Tree circumference had positively significant correlations only with the presence of fruit (0.37) and cherelle wilt (0.91). Presence of fruits had positively significant correlation only with cherelle wilt (0.63), but a negative correlation with pod thickness (-0.92). Cherelle wilt was positively significantly (P≤0.01) correlated with number of rows (0.40) but negative correlations with pod thickness (-0.58) and pod index (-0.79). Time to fruit harvest was negatively significantly correlated with number of rows (-0.43). Fruit weight was negatively correlated with number of rows (-0.78). Fruit width and number of beans per row were negatively significant with pod index (-0.39 and -0.90 respectively).

The direct and indirect path coefficients that estimate the strength of the relationship between pod index and the vegetative and fruit characters using the genotypic correlation values is presented in table 4. Fruit length had the largest positive direct effect (4.5487) on pod index, with its largest indirect effect through time to jorquette (1.6755). The largest negative indirect effect of fruit length on pod index is through time to fruit harvest (-7.5772). Cherelle wilt also had a notably large positive direct effect (3.5830) 0n pod index, with its largest indirect effect also through time to jorquette (5.0864). The largest negative indirect effect of cherelle wilt on pod index is through time to fruit harvest (-4.5974). Time to fruit harvest had the largest negative direct effect (-8.5137) on pod index, with its largest indirect effect through fruit length (4.0484). The negative direct effects of jorquette height (-0.4375), and plant height (-0.2087) on pod index are also noteworthy. Jorquette height had its largest indirect effect also through time to fruit harvest (3.4906). Though the number of characters used in the path coefficient analysis was large, the residual factor was 1.7558.

DISCUSSION

The mutual association among characters is often expressed by the phenotypic, genotypic and environmental correlations (Searle, 1961 and Ariyo, 1989). Phenotypic correlation is a composite of genotypic and environmental correlations. In this study, the genotypic correlation coefficients were in most cases higher than the corresponding phenotypic correlation coefficients and the environmental correlation coefficients. This has been ascribed to reduced values of environmental correlations between the corresponding characters implying reduced influence by the environment (Searle, 1961). This implies that the genotypic factor had a greater contribution in the development of the character association (Arshad *et al*., 2006). The low values of the environmental correlation coefficients imply that the phenotypic correlation coefficients would be good indicators of genotypic correlation coefficients (Ariyo, 1995).

Selection of the genotypes based only on inter-character associations which are genotypically correlated but not phenotypically correlated may not be of practical value since selection is mostly based on the phenotypes of the characters. Such a selection will be unrepeatable and unreliable (Ariyo, 1995). This applies to the pairs of characters that exhibited this kind of relationship in the study, such as stem diameter, fruiting and wilted fruits with pod index.

The significant genotypic and phenotypic correlations of many of the pairs of the vegetative and fruit characters with one another and with pod index suggested that these characters contributed either positively or negatively to growth and yield in the cacao genotypes. Such inter-character associations can therefore be used as criteria for selection of the genotypes that particularly exhibit good yield. This relationship applies to plant height, time to jorquette, time to fruit harvest, fruit length and fruit width with pod index. Significant correlations of yield-related characters in young cacao plants were reported by Santos *et al* (2018).

The direct and indirect relationships between pod index and the vegetative and fruit characters of the nine cacao genotypes indicated that plant height, jorquette height, fruiting, time to fruit harvest, fruit weight and fruit width all had a negative direct effects on pod index. These relationships are very desirable. It implies that an inverse relationship exists between each of these traits and pod index, i.e. an increase in the value of each of these results in a corresponding reduction in the pod index. Since pod index refers to the number of cocoa pods required to produce 1.0kg of dry cocoa beans (Wood and Lass, 1985), the lower the value, the more desirable the genotype. Any character whose incremental value will reduce the numerical value of pod index is therefore of utmost importance.

The valuable negative indirect effects of these plant traits on pod index include their effects through fruiting, cherelle wilt, fruit length and fruit width (for plant height); fruit wilt, fruit weight and fruit width (for jorquette height); plant height, stem diameter, time to fruit harvest and fruit length (for fruiting); stem diameter, tree circumference, fruiting and fruit weight (for time to fruit harvest); stem diameter, jorquette height, tree circumference, time to fruit harvest and pod thickness (for fruit weight); and plant height, time to jorquette, cherelle wilt, fruit length and pod thickness (for fruit width). Each of plant height, jorquette height, fruiting, time to fruit harvest, fruit weight and fruit width can therefore be considered along with any or all of each of the other traits that enhance their negative expression in the screening or selection of these cacao genotypes for desirable pod index. Initial increase in the tree circumference can result in better yield (pod index), when tree circumference is considered in association with jorquette height, fruiting, cherelle wilt, fruit length and fruit width, which all had negative indirect correlations with pod index. The other traits such as stem diameter, time to jorquette, cherelle wilt, fruit length and pod thickness which had positive direct effect on pod index (which is not desirable in this context) can also be considered in conjunction with the traits which had negative indirect effect on pod index. The significant value of the residual factor in spite of the large number of characters used in the path coefficient analysis may be due to the fact that correlations are mere estimates, and may also be due to rounding-off errors.

CONCLUSION

Significant association existed among most traits under consideration, and such traits significantly determined yield as indicated by pod index in cacao. These traits, therefore, are important for consideration in further yield improvement procedures in cacao.

ABSTRACT

This study was undertaken to evaluate morphological variations in Saba fruits sourced from Kabba, Okoro, Unosi and Oforachi in Kogi State. The morphological variation in fruits was evaluated by sampling fruits and assessing their characteristics. Five fruits per accession were selected for this study and were replicated five times. The experiment was a completely randomized design (CRD). Results of the analysis of variance revealed variability in most fruit traits of Saba across the accessions. Oforachi and Okoro accession had the widest fruit base shape of 5.0 (IPGRI, 1995) which did not differ statistically from the value (4.8) recorded from Unosi accession. The widest fruit circumference (25.3 cm), widest diameter (7.8 cm), heaviest fruit weight (283.0 g) and thickest pulp (1.0 cm) were obtained in Oforachi accession. Values for fruit circumference and fruit diameter obtained in this accession were not statistically different from 25.0 cm and 7.4 cm obtained in Kabba accession, respectively. Kabba accession gave the longest fruit length (14.0 cm), heaviest fresh weight of seeds with mucilage (148.6 g) and pulp weight (99.6 g). The diversity found between locations is vital for selection and domestication of this wild species. This could provide basis for genetic improvement of Saba.

Key words: Accession, *Saba senegalensis*, fruit traits, variability

INTRODUCTION

Human cultivates a number of plant species with different direction of use – seeds, fruits, roots, leaves etc. Market requirements enforce fruits to be attractive for consumers, traders and for processing industry according to appearance, size and weight (Todorova, 2007). Quantitative fruit characters – length, diameter, pericarp thickness, average weight and usable part are of great importance in describing of fruits and genotypes (varieties), respectively. They also have strong effect for economic significance of each variety. Saba is gaining popularity and may soon take its place in domestic and international market. The fruit is highly prized and in parts of Africa, they are important to the rural economy and are openly hawked in the cities (TPD, 2020).

Saba senegalensis (A.DC.) Pichon is an African indigenous large, woody plant that belongs to the family Apocynaceae (Arbonnier, 2000). In Nigeria, it is found largely in North central and Southern parts of the country (Baiyeri *et al.,* 2019). It is a climber that usually seeks support from other plant species to rest upon and grow. The species growing in various ecological conditions (from 100 mm to 1300 mm annual rainfall). It is known as 'Utu' by the Igbo of southeastern Nigeria, 'Ibo' by Okun-Yoruba of north central Nigeria (Baiyeri *et al.,* 2019). *Saba senegalensis* has the potential to contribute in feeding and treating hundreds of diseases in rural populations (Sarr *et al*., 2018). The pulp is tasty, sweet sour with yellow colour when ripe and can be consumed as such or can be processed into puree, nectar and jams (Arbonnier, 2000; Tanor, 2001). The fruit is rich in vitamin A, vitamin C, dietary fiber and contains minerals such as potassium, magnesium and calcium (Fatim *et al.,* 2019).

Earlier studies focused on biochemical evaluation of Saba fruit pulp but not on fruit characterization and as such there is limited information on the characterization of Saba fruit in Nigeria. Therefore, the main aims of this study was to investigate the natural variation in fruit traits of Saba. Furthermore, to identify accession with specific fruit traits that will increase the market value, encourage the cultivation of this wild species and prevent it from going into extinction.

MATERIALS AND METHODS

Fully matured *Saba senegalensis* fruits (Fig. 1) for this experiment were harvested from the wild in four Local Government Areas (LGAs) purposively selected, they are Kabba in Kabba Bunu LGA, Okoro in Ijumu LGA, Unosi in Ajaokuta LGA and Oforachi in Igala Mela/Odollu LGA of Kogi State. The experiment was a completely randomized design (CRD). Five fruits per accession were selected for this study and were replicated five times. This corresponds to a total of 100 fruits sampled used for assessing and analyzing morphometric data for Saba. The fruits were cut into two halves and the measurements taken. De-pulping was done by pouring the seeds containing mucilage in a cloth and saw dust added, folded and squeezed gently till the pulp is removed from the seeds. The seeds were poured in a basket rubber with smaller mesh size compared to the size of seeds, washed in a bowl filled with clean water and used for other measurements. Most of the measurements taken were done as stated in descriptors for avocado (IPGRI, 1995).

Figure 1: *Saba senegalensis* whole fruit and yellowish fruit pulp with seeds

Data collection

Fruit apex position, fruit base shape, fruit shape and seed shape were determined using descriptors for Avocado as described by IPGRI (1995). Fruit circumference (cm) was measured round the fruit from the apex to the base using measuring tape, fruit length was determined in cm by measuring the fruit from the apex to the base using measuring tape, fruit diameter was measured in cm at the broadest part of the fruit by a measuring tape, fruit weight was determined in (g) by weighing each fruit with sensitive scale and the average recorded, pulp thickness was taken using a Vernier caliper, fresh weight of seeds per fruit with mucilage was determined in gram by using weighing balance, pulp weight was calculated by subtracting the weight (g) of seed with mucilage from the weight of seed without mucilage and the average recorded (pulp + seed – seed), according to De Smedt *et al.* (2011). Fresh seed weight per fruit without mucilage was determined in gram by using weighing balance and the average recorded and number of seeds per fruit were counted and the average also recorded.

Data analysis

Data were collected across the accessions and subjected to the analysis of variance (ANOVA) in completely randomized design (CRD) using GENSTAT Discovery edition 3 Release 7.22 DE (GENSTAT, 2008). Significant treatment means were compared using least significant difference (LSD) at 5 % level of probability.

RESULTS

The fruit traits varied with the accessions except fruit apex position, fruit shape, fresh seed weight per fruit without mucilage and number of seeds per fruit (Table 1). Oforachi and Okoro accession had the widest fruit base shape of 5.0 which did not differ statistically from the value (4.8) recorded from Unosi accession while the thinnest (2.4) was obtained in Kabba accession. The widest fruit circumference (25.3 cm), widest diameter (7.8 cm), heaviest fruit weight (283.0 g) and thickest pulp (1.0 cm) were obtained in Oforachi accession. Value for fruit circumference and fruit diameter obtained in this accession were not statistically different from the value (25.0 cm and 7.4 cm) obtained in Kabba accession, respectively. Kabba accession gave the longest fruit length (14.0 cm), heaviest fresh weight of seeds with mucilage (148.6 g) and pulp weight (99.6 g) while the shortest fruit circumference (19.0 cm), fruit length (11.0 cm), diameter (5.6 cm), least fruit weight (113.0 g), tiniest pulp (0.6 cm), least fresh weight of seeds per fruit with mucilage (58.2 g) and least pulp weight (33.4 g) were attributed to Unosi accession.

DISCUSSION

The differences in fruit traits studied may be related to the variability between the four studied accessions, climatic conditions and nature of the soil in each location of collection. Todorova (2003) established that the systematic factors manifest a proven effect on the phenotypic variability of length, diameter, weight and usable part of the fruit. Stoffella *et al.* (1995) report similar results for fruit weight in Bell peppers. The fruit length and fruit diameter obtained in this study varied from (11.0 to 14.0 cm and 5.6 to 7.8 cm) respectively. These were similar with the report of Sarr *et al.* (2018) who observed that the fruit of *Saba senegalensis* is a globose shell, 7 to 10 cm long, 6 to 8 cm wide. Also, fruit length recorded in this work varied from 11.0 to 14.0 cm, fruit weight ranges from 113.0 to 283.0 g, weight of pulp varies from 33.4 to 99.6 g and number of seed per fruit ranged from 25.0 to 47.8. The results are similar to the findings of Nafan *et al.* (2013) who reported that the length of Saba fruit varied from 6.7 to 12.3 cm; the weight of the whole fruit ranged from 173.8 to 491.14 g; the weight of the pulp varied from 63.47 to 216.53 g and the number of nuts by fruit swung from 10 to 45. The weight of pulp observed in this present study is lower when compared to the value obtained in their study.

Table 1: Effect of accession on fruit traits of *Saba senegalensis*

ACCESSION	FAP	FBS	FC	FL	FD	FW (g)	PT	FS	SWM	PW	SWWM	NSPF
KABBA	5.0	2.4	25.0	14.0	7.4	265.0	0.8	4.4	148.6	99.6	49.0	47.8
OFORACHI	5.0	5.0	25.3	13.0	7.8	283.0	1.0	2.2	132.6	89.8	42.8	31.2
OKORO	5.0	5.0	23.0	12.0	6.8	199.0	0.7	3.4	110.6	72.0	38.6	40.2
UNOSI	4.8	4.8	19.0	11.0	5.6	113.0	0.6	3.4	58.2	33.4	24.8	25.0
LSD (0.05)	NS	0.4	3.0	1.7	0.9	88.0	0.1	NS	58.0	40.0	NS	NS

FAP=fruit apex position, FBS=fruit base shape, FC=fruit circumference, FL=fruit length, FD=fruit diameter, FW=fruit weight, PT=pulp thickness, FS=fruit shape, SWM= seed weight with mucilage, PW=pulp weight, SWWM= seed weight without mucilage and NSPF= number of seeds per fruit.

CONCLUSION

It was evident that differences existed in fruit traits of four accessions of *Saba senegalensis* from Kogi State, Nigeria, indicating great potential for domestication of this crop. This information could provide basis for genetic improvement of this wild species.

ABSTRACT

Physicochemical and chemical properties are very important in the determination of fruit quality in tomato. Twelve selected tomato genotypes were established at the Vegetable research field of National Horticultural Research Institute, Ibadan, Nigeria. Wholesome ripe fruits were selected for each genotype and all laboratory analysis were carried out following standard procedures. The results revealed significant variation for all the physicochemical and chemical properties examined in the twelve tomato genotypes. NHSL4, NHSL11, NHSL20 and NHSL21 had the highest lycopene content, ranging from 0.32 to 0.35 mg/100g out of the twelve genotypes; NHSL20 and NHSL21 had the highest beta-carotene (0.27mg/100g each respectively); NHSL12 and NHSL20 recorded the highest Vitamin C (0.151 and 0.148 mg/g respectively) while the highest value for fruit firmness (5.03 Pascal) was recorded for NHSL11. In conclusion, NHSL4, NHSL11, NHSL21, NHSL20 and NHSL12 with highest carotenoid content, Brix, Vitamin C and firmness can be selected as genotypes with high quality fruits for health and commercial purposes. They can be used for crop improvement in future breeding programme.

Key words: Breeding, physicochemical, tomato, lycopene, quality

INTRODUCTION

Tomato is one of the vegetable fruits consumed worldwide. This is due to its ability to reduce the incidence of chronic degenerative diseases such as some types of cancer (Giovannucci, 1999) and cardio-vascular diseases (Pandey *et al*., 1995). It has been reported that tomato fruit contains 92.5 – 95 % water and 5 – 7.5 % dry matter (DM). The DM consists of 48 % sugars (glucose and fructose), organic acids, 13 % citric and malic acids; minerals mainly N, P and K (18 %) and small fractions of vitamins and anti-oxidant pigments (e.g. lycopene) (Carvalho, 1980). Lycopene, ascorbic acid (vitamin C) and potassium contents are part of nutritional value derived from tomato and they are of great importance to human health (Caliman, 2010). Vitamin C which is useful for the prevention of scurvy and maintenance of skin and blood vessels can also be found in fruits (tomato) and vegetables in form of ascorbic acid and is equally important to human health (Lee and Kader, 2000). Due to the health benefits derived from tomato and its importance to human well-being, studying the level of the physico-chemical and chemical properties in different genotypes cannot be over-emphasized. The objectives of the study were, therefore, to determine the variation in the quality of properties in fruits of twelve selected tomato genotypes and to select genotypes with best fruit quality in terms of physical and nutritive content.

MATERIALS AND METHODS

Twelve genotypes of tomato selected from an on-going breeding programme were used in this study. These were established on the Vegetable field of National Horticultural Research Institute, Ibadan using a completely randomized block design with three replications. The spacing used was 0.5 m between plants and 0.6 m within rows with 12 plants per plot. Wholesome fruits used for the study were harvested on sampled plants at red ripen stage. Each sample used for the analysis comprised of 2 - 4 fruits depending on the fruit size of each genotype. The samples used were cut, freeze-dried, powdered and stored at -20°C for determination of the physicochemical properties.

Determination of physicochemical properties in tomato at red ripen stage:

Total Titratable acidity (TTA) (%): This was obtained by titrating 5 ml of sample powder with 0.1 N NaOH up to pH 8.1. The result was expressed as grams of citric acid per 100 g of dry sample weight (AOAC, 2000).

Brix or Total Soluble Solid (TSS) (°C): Total soluble solids (TSS) were determined for each sample according to AOAC (2000) method using an Atago DR-A1digital refractometer (Atago Co. Ld., Japan) at 25 ° C and expressed as percentage.

Fruit firmness: The fruits firmness for the twelve tomato genotypes was measured by the use of manual fruit penetrometer by pressing the tip of the penetrometer on the side of the fruit until the reading was taken. This was done on three fruits per genotype and the average measurement was recorded. The result obtained was subjected to analysis of variance while means were separated using Duncan's Multiple Range Test (DMRT).

ISSN: 2814-0508

Determination of the chemical properties in tomato at red ripen stage

Beta-carotene: About 0.5 g of homogenous sample was extracted with 5 ml cold Acetone and 5 ml ethanol, until the total loss of pigmentation. 3 ml of distilled water was added which was later partitioned with 10 ml petroleum ether. The ether phase was passed through Neutral Alumina (activity III) packed column. The column was eluted with petroleum ether and the first band was collected into 25 ml volumetric flask. The extract was read at 450 mm, to determine beta-carotene content calculated were as follows:

$$C(\mu g/g) = \frac{A \times \text{Volume (ml)} \times 10^4}{A1\ \% \times 1\ \text{cm} \times \text{sample weight (g)}}$$

Where A = Absorbance, A1 % = absorption coefficient of beta –carotene in PE (2592) (Rodriguez-Amaya and Kimura, 2004).

Lycopene: Out of the stored dry samples, 0.5 g was extracted with 5 ml cold Acetone and 5 ml ethanol, until the total loss of pigmentation. 3 ml of distilled water was added which was later partitioned with 10 ml petroleum ether. The ether phase was passed through Neutral Alumina (activity III) packed column. The column was eluted with petroleum ether and the first band was collected into 25 ml volumetric flask. The extract was read at 510 mm, to determine lycopene content calculated were as for beta-carotene.

Total carotene = Lycopene + beta carotene.

Vitamin C: Five ml of standard solution of ascorbic acid was pipetted into 100 ml conical flask. 10 ml of oxalic acid was added and the solution titrated against the dye (V_1 ml) until a pink colour persisted for 15 seconds. The dye consumed is equivalent to the amount of ascorbic acid.

The amount of vitamin C in analyzed samples was determined by titration using the method described by Pongracz *et al*., (1971) with slight modifications. About 0.5 g of each sample was soaked for 10 min in 40 ml meta-phosphoric acid-acetic acid (2 % w/v). The mixture was centrifuged at 3000 rpm for 20 min and the supernatant obtained was diluted and adjusted with 50 ml of bi-distilled water. 10 ml of Oxalic acid was added to 5 ml of the mixture above. 10 ml of this mixture was titrated to the end point with dichlorophenol-indophenol (DCPIP) 0.5 g/L. The volume of the dye used was recorded as (V_2 ml):

$$\text{Ascorbic acid (mg/100g)} = \frac{0.5\ \text{mg} \times V_2 \times 50\ \text{ml} \times 100}{V_1 \times 5\ \text{ml} \times W}$$

Where W = sample weight (Pongracz *et al*., 1971).

RESULTS

Tomato fruits of 12 genotypes were estimated for important physicochemical and chemical characteristics. The analysis of variance for these properties of 12 tomato genotypes is presented in Table 1. There were significant differences for all the parameters observed in this study. Table 2 presents the descriptive statistics for the physicochemical and chemical properties in twelve selected tomato genotypes. The TTA (%) content ranged between 0.05 to 0.22 %. The highest content was observed in NHSL2 while the lowest was recorded in NHSL14. The average value for TTA was 0.08 %. Brix or Total Soluble Solid (TSS) (0^o) content also varied and ranged from 4.07 to 5.77 mg/100g. The highest Brix was recorded in NHSL11 (5.77 mg/100g) while the least was observed in NHSL13 (4.07 mg/100g). Beta-carotene content in 12 tomato genotypes ranged from 0.07 to 0.27 mg/100g. The highest β-Carotene content was recorded in NHSL21 (0.27mg/100g) followed by NHSL20 (0.27mg/100g) which were statistically similar to each other while the least content was recorded in NHSL19 (0.07 mg/100g). The range of lycopene content was between 0.15 to 0.35 mg/100g with the highest recorded in NHSL4 (0.35 mg/100g) followed closely by NHSL11 (0.34 mg/100g) which were statistically similar while the least was recorded in NHSL23 (0.31 mg/100g). The Vitamin C content observed in the tomato genotypes at full ripen stage ranged from 0.088 to 0.151 mg/g. NHSL12 (0.151 mg/g) recorded the highest Vitamin C content while the least content was obtained in NHSL13 (0.088 mg/g).

The firmness of 12 selected fruits at five days after harvesting at full ripeness was measured by manual fruit penetrometer by pressing the tip of the penetrometer on the side of the fruit until the reading is taken. This was done on three fruits per genotype. The readings showed variation across the 12 genotypes under studied. The highest fruit firmness (very firm) was recorded in NHSL11 (5.03 Pascal), followed by NHSL14 (4.80 Pascal) while the lowest firmness (very soft) was observed in NHSL4 (3.23 Pascal).

Table 2: Descriptive statistics for the physicochemical properties and firmness in twelve selected tomato genotypes

Property	Mean	Coefficient of Variation (%)	Range
TTA (%)	0.08	32.81	0.05 - 0.22
Brix (0°)	4.71	1.67	4.07 - 5.77
B-Carotene (mg/100g)	0.18	6.75	0.05 - 0.27
Lycopene (mg/100g)	0.26	3.12	0.15 - 0.35
Vitamin C (mg/g)	0.12	2.68	0.08 - 0.15
Firmness (Pascal)	4.12	20.54	3.23 - 5.03

DISCUSSION

Physicochemical and chemical properties are very important when determining the quality of tomato fruits. The significant differences observed among these parameters in tomato genotypes is an indication that there is wide variability within the genotypes and this enhances large scope of selection in future breeding programme. Four (NHSL4, NHSL11, NHSL20 and NHSL21) out of twelve genotypes in this study had high lycopene content while two (NHSL20 and NHSL21) had high beta-carotene content. These two are the total carotene recorded in this study and these contain anti-cancer agents which help in the fight against cancerous diseases. This is an indication that consumption of these genotypes can reduce the risk of cancerous diseases. This is in conformity with the work of Frusciante *et al.*, 2007 who studied the antioxidant nutritional quality of tomato. NHSL12 and NHSL20 had high Vitamin C content which helps in the fight against scurvy and maintenance of skin. This implied that these two tomato genotypes can help in reduction of the risk of scurvy in human and in maintenance of human skin.

The firmest fruit was NHSL11 followed by NHSL14. This indicated that these genotypes can store longer under room temperature and can be selected for the preparation of salad due to low moisture content. This is in conformity with the work of Lesage and Destain, 1996 who worked on measurement of tomato firmness by using a non-destructive mechanical sensor.

CONCLUSION

NHSL4, NHSL11, NHSL21, NHSL20 and NHSL12 with highest carotenoid content, brix, vitamin C and firmness can be selected as fruits with high quality for health and commercial purposes. These can be used for crop improvement in future breeding programme.

ABSTRACT

Due to absence of improved varieties and lack of pure seed supply are among major challenges of production. Therefore, the study is to evaluate performance of pepper accessions for environmental adaptability and high yielding. Thirty-one pepper accessions were planted in randomized complete block design (RCBD) with three replicates during the year 2020. The seeds were raised in the nursery and transplanted to the field at five weeks after sowing. The accessions were grown in the field with spacing 50 cm by 50cm. Data were collected on growth and yield attributes of pepper accessions. Data collected were subjected to analysis of variance and significant means were separated using Least Significant Difference at P≤0.05. Pepper accession varied significantly in term of vegetative growth and yield trait. In conclusion pepper accession V11R1 had the highest yield follow by V4R2-1, V17R2, V1R2-1 and V3R3-3. These can be used for crop improvement in future breeding programme.

Key words: Growth, pepper accession, fruit characteristics yield, Rainforest agro-ecological zone of Nigeria

INTRODUCTION

Pepper (*Capsicum annuum L)* belongs to the family *solanaceae*, under the genus *Capsicum* (Russo, 1996). The crop is a native of Tropical South America especially Brazil which is thought to be the original home of Peppers (Islam *et al*., 2010). The genus Capsicum contains about 20 species but the popularly cultivated species are sweet pepper (*C. annum*) and hot pepper (*C. frutescens*) both serving as a food and cash crops in Nigeria and other countries. Pepper yields obtained by peasant farmers in Nigeria are often very low (Adigun, 2001). Pepper thrives in a wide range of soil types, but good drainage is essential. Is the most precious and valuable form of spices in the world (Usman, 2019). It is the 3rd most added ingredient in food among the wide range of spices, India is one of the largest producers of pepper, after China and Vietnam. Pepper has played a pivotal role in India's international trade and it is said that the Europeans came to India primarily for this pepper spices (Grubben, 2004). It is also used in industry as an ingredient for numerous foodstuffs, and also in certain cosmetic and pharmaceutical products (Grubben and El Tahir, 2004).

The world fresh chilli and sweet pepper production was 27.6 million tons in 2010, to which West Africa contributed 888,400 tons or 3.2%. In 2011, it was estimated that Nigeria produced 50% of total production in Africa (Adesina *et al,* 2014) and ranked 8th while Ghana ranked 13th producing country in the world (FAOSTAT, 2012). However, farmers use to grow mostly local selections, because there are shortages of improved varieties. Most farmers produce seeds from harvested fruit or source from local markets. Such seed lots are often mixed with different varieties and the impurities harboring pathogens. Thus, the objective of this study is to evaluate performance of pepper accessions for environmental adaptability and high yielding.

MATERIALS AND METHODS

The field trial was carried out during dry (October 2020 – March 2021) seasons at block 3 Vegetable Research Field of the National Horticultural Research Institute (NIHORT), Ibadan (Latitude 7° 22' N and Longitude 3° 50' E at 234m above sea level), located in the forest agro-ecological zone of Nigeria. The experimental site had been under continuous cultivation for many years. Top soil was collected and sterilized by heating to 100^{0}C in a metal drum and was allowed to cool. The sterilized soil was filled into nursery trays after which seeds of pepper accession were sown. Regular watering and monitoring was carried out in the nursery for five weeks. The trial was laid out in randomized complete block design (RCBD). The treatments consisted of 31 pepper lines. The land was ploughed and left for two weeks to allow buried weeds to decay and ploughed followed by harrowing. Pepper seedlings were transplanted at 5 weeks after sowing (WAS) at the spacing of 50 x 50 cm. The plot size was 2 x 2 m, alley of 1.0 m within plots and 1.0 m between replicates. NPK 20 10 10 at the rate of 15g per plant (two splits) was applied 8 weeks after transplanting. Weeding was carried at 4 weeks' interval Cypermethrin was applied at 2ml to 1 liter of water to control insect.

Data were collected from five randomly selected tagged plants within the plot for growth and yield attributes; plant height, number of leaves, number of fruit per plant, fruit weight, fruit length, fruit width, pedicle length, number of seeds/ fruit and seed weight All data collected were subjected to the analysis of variance (ANOVA) using Gen-Stat Discovery Edition 4 (2013). Significant means were separated using least significant difference (LSD) at five per cent (5%) level of probability ($P \leq 0.05$).

RESULTS AND DISCUSSION

The result in table 1 shows significant difference among the treatments in plant heights the tallest plant height was recorded from variety NHTatase (51.30 cm) followed by V6R3-4 (47.90 cm) followed by V12R3-4 (45.20cm). The shortest plant height was attained from variety V1R2-1 (16.70 cm) at 6 WAT. This result is in agreement with the works of MARC (2005), which reported that varieties Weldele and Melka Zala showed the tallest plant height of 61 and 62 respectively among the evaluated varieties at three locations. The significant variation of plant height in pepper accession maybe attributed to genetic potential as well as environmental factor and ability to absorb nutrients. This result is in agreement with work done by Eghaarevba and Law-Ogbomo (2007) El-Tahomy et al, Alizadeh and Carapetian (2006) Vos and Frinking 1997 and Mastro (2007) who reported significant differences in plant height in other crop due to genetic and environmental condition.

There were significant differences among the treatments at 2 and 6WAT (Table 3). Pepper accession tagged with V2R1-1 and V11R1-1 had the highest number of leaves (29.00 and 87.00) while V12R1-1 and V13R3-2 recorded least value of 6.36 and 22.50 respectively. In contrary at 4WAT, V6R3-1 had the highest value while V12R3-6 and V12R1-1 had the lowest number of leaves of 12.08. Significant differences were observed among the evaluated pepper accessions for some of the quality and yield trait. Table 4 shows that V11R1-1 had significantly higher fruit length, fruit width, number of seeds, pedicle length, fruit yield in gram and fruit yield in ton/ha, except in number of fruits and seeds weight. Fruit length was significantly differed among the pepper accessions. V11R1-1 had the longest fruit length (69.1cm) followed by V17R2-1 (61.5cm) and V4R2-1(56.8cm) while the shortest fruit length was recorded in T26.

Fruit width had highly significant effect among the pepper accessions. The highest fruit width was produced by V11R1-1 (177.4cm), followed by T2 (128.5cm) and T28 (124.4cm) while T26 had the least fruit width. Similarly, number of fruits was significantly differed among the pepper accessions. NH TATASE had highest number of fruits per five plants (81.0) while the least number of fruits per five plants was recorded from T26. The variations in fruit development among accession could also be due to the temperature stress of the growing environment and the capability of each variety to withstand the stress specially on the reproductive development, which is more sensitive to high temperature stress (day and night temperature) than vegetative development. This result is inline with the work of Sato (2005), who reported that, the reduction of fruit set under moderately elevated temperature stress was mostly due to a reduction in pollen release and viability in tomato plant. Number of seeds had highly significant effect among the pepper accession. The highest number of seeds (1642.0) was recorded from V11R1-1, follow by V17R2-1 (1380) and V1R2-1 (1149.0) respectively while the least number of seeds per five plants was observed from T26. This report was inline with Russo (2003) and Aleemulah *et al*. (2000), who observed positive relationship between seed number and pod size, where fruit weight increased linearly with seed number in sweet pepper. Pedicel length was highly significant differ among the accession. V11R1-1, V5R3-2 and V17R2-1 produced the longest pedicel length of 38.9cm, 37.3cm and 32.3cm respectively whereas T26 produced the shortest pedicel length. The pepper seed weight had significant effect among the accession. The highest seed weight (20.94g) was obtained from V1R1-2, followed by V17R2-1 and V4R2-1 and the least seed weight was gotten from T26. Bosland and Votava (2000) reported that, in some cultivars of chili pepper seed, it contains up to 60% of the dry weight of the fruit which makes it an important economic part of the crop. There was significant variation in the fruit weight/g and fruit weight in tons/ha observed among the pepper accession. V11R1-1 V1R2-1 and V17R2-1 respectively recorded the highest fruit weight while least fruit weight was observed from T26. The significant differences in fruit yield among the pepper accessions may be due to genetics and environmental factors (Wasiullah *et al*., 2003 and Tsegaye *et al*., 2007).

CONCLUSION

There is variation in vegetative growth, fruit quality and fruit yield characters in the pepper accession during the late cropping season. Thus, based on the findings of present investigation, it can be

ISSN: 2814-0508

concluded that pepper accession V11R1-1 recorded highest fruit yield during late cropping season. Accession V4R2-1, V17R2, V1R2-1 and V3R3-3 yielded relatively well. These can be used for crop improvement in future breeding programme.

ABSTRACT

Nine accessions of fully ripe tomato fully ripened Nsukka yellow peppers from nine F5 breeding lines were harvested and analyzed for their physico-chemical properties including pH, Total Titratable Acidity (TTA), Total Soluble Solids (TSS), β-carotene, Vitamin C, Capsaicin and Piperin. The highest pH was recorded in 59-2-1-5 variety, (5.62) while the lowest was 31-1-3-5 (5.06). The Vitamin C content was observed to be high in 34-1-2-5 variant (86.06mg/100g) and the least being 06-5-5 variant (33.90mg/100g). Among the various lines, the highest TTA value was found in 53-1-2-5 breeding line (0.31%) and others lines are of same values (0.16%). Among all the accessions, 59-2-1-5 had the highest capsaicin value of 0.86 mg/g, follow by 59-3-1-5 variant with 0.85 mg/g whilst the lowest value was reported in D2-1-5. The highest β-carotene was found in 59-3-1-5 variety, with 6849.29 µg/100g while the lowest was 06-5-5 of value (3801.44 µg/100g). The Piperin content was recorded to be high in 34-1-2-5 variant (66.70 mg/100g) and the least being D2-5-5 variant (20.32 mg/100g). Midst the breeding lines, 63-1-2-5 had the highest brix value of 9.08% and the least is 06-5-5 line of 6.58%. Most of the generational lines showed better performance than their parents and thus can be selected for further breeding work. In conclusion generational lines; 59-3-1-5, 34-1-2-5, 63-1-2-5 and 59-2-1-5 obtained from the various parents were found to have more desirable traits compared to their parents.

Key words: Nsukka yellow pepper; variant lines; pH; capsaicin, piperin

INTRODUCTION

One of the most practical ways of managing free radical activity in the body is through diet. Dietary antioxidants may play an important role in protecting against cell damage caused by free radicals by acting as radical scavengers, reducing agents and quenchers of singlet oxygen formation, and by forming complexes with pro-oxidant metals (Ademoyegun *et al*., 2013).

Carotenoids impart orange and red colors in vegetables. The carotenoids in peppers include capsanthin and carotene. Nsukka yellow pepper is predominantly yellow color of peppers, and the carotene is formed by *α*- and *β*-carotene, zeaxanthin, lutein and *β*-cryptoxanthin (Anyaoha *et al*., 2019). Beta-carotene is a hydrocarbon carotenoid found widely in the chloroplasts of higher plants, and exercises pro-vitamin A and powerful antioxidant activities. Carotenoids' cancer-preventive activities have been associated with their antioxidant properties. Perera and Yen reported that consumption of carotenoid-rich foods reduces the incidence of several disorders such as cancers, cardiovascular diseases, age-related macular degeneration, cataracts, diseases related to compromised immune function, and other degenerative diseases.

Phenols function as antioxidants with properties similar to vitamins C and *β*-carotene, and have received extensive study. A wide variety of spice-derived phenolic compounds, such as capsaicin, possess potent antimutagenic and anticarcinogenic properties (Adetula and Olakojo 2006). Phenolic compounds cannot be produced by the human organism and are acquired mainly through diet. Knowledge about the nutritional and therapeutic role of dietary phenolic antioxidants is essential for development of functional foods, which are conventional foods with augmented health benefits (Ademoyegun *et al*., 2011).

Ascorbic acid is a required human nutrient, and functions primarily as an antioxidant in biological systems, preventing common degenerative processes. Testing of ascorbic acid derivatives on cancer cells showed ascorbic acid esters to have promising anticancer activity. Ascorbic acid as found in most fruits and vegetables also protects against heart disease, high cholesterol, high blood pressure and cancer (Idowu-Agida *et al*., 2011).

Nigeria is one of the principal centers of origin and domestication of the genus *Capsicum*. Some variants in Nigeria are known and used primarily in certain regions. For example, *Nsukka yellow pepper* variants are common, grown in Eastern part of Nigeria. *Nsukka yellow pepper* fruit is known to be an excellent source of aromatic favor. Hot chili peppers are widely consumed in Nigeria, with an average annual per capita intake of approximately 7 to 9 kg, making it the second most consumed vegetable after tomatoes. Such a widely consumed vegetable with various potential health benefits merits characterization of its bioactive compounds content to better understand their possible applications and increase consumer awareness of these benefits (Baiyeri *et al*., 2016). The present study objective was to quantify polyphenols, carotenoids and ascorbic acid levels, and measure capsaicin level of *Capsicum annum var Nsukka yellow* Genotypes commonly grown in Eastern zone, Nigeria.

MATERIALS AND METHODS

All analyses carried out were of standards procedures and performed in triplicate.

Statistical Analysis

All parameters carry out among genotypes were subjected to a one-way Analyses of Variance (ANOVA) using IBM SPSS Statistics 20 software and means were separated using Least Significant Different Test (LSD).

RESULTS AND DISCUSSION

pH and Total Titratable Acidity (TTA)

The lowest pH value for the samples analysed was 5.06 (31-1-3-5 variant), however the highest value was 5.62 which was higher than the values with 5.62 (59-2-1-5 variant). This is an indication of stronger acidity in the samples worked on than the samples worked on by Antonious et al., (2009), however, this gave rise to the second least TTA, a higher pH is expected to give rise to a lower TTA value, but this was not the case in the 31-1-3-5 line, and this might be due to other factors. A higher pH should give rise to a lower TTA. This was due to the lower percentage of citric acid present in this line. The highest TTA value was recorded in 53-1-2-5 0.31% but was significantly different ($P > 0.05$) from the others hybrid (0.16 to 0.20%) (Table 1.).

Total Soluble Solids (TSS)

The highest TSS (9.08%) was observed in 63-1-2-5, whilst the lowest was observed in 06-5-5 (6.58%). The highest TSS observed in 63-1-2-5 might be due to the high carbohydrate (sugars and nonsugars) content. Significant differences ($P < 0.05$) were detected in the TSS values among the various breeding lines (Table 1). However, no significant differences ($P > 0.05$) were detected among the total soluble solid values of 53-1-2-5 and 31-1-3-5 lines, also no significant differences ($P > 0.05$) were detected among the total soluble solid values of 59-3-1-5, 59-2-1-5 and D2-5-5 lines which might be due to similar carbohydrate content in these samples. The lowest observed TSS was in 06-5-5 (6.58%), which implies low carbohydrate content and the conversion of acids to sugars in the glycolytic pathway.

Carotenoids are fat-soluble antioxidants found in many fruits and vegetables and are required for human epithetlial cellular differentiation. Carotenoids content in the studied *Nsukka yellow* accession genotypes ranged from 3147.63 to 6849.27 µg/100 g sample (Table 1). No differences (p > 0.05) were identified among four lines of accession, the carotenoid levels in 53-1-1-5, 31-1-3-5, D2-5-5 and D2-1-5. Carotenoids are terpenoid compounds formed by the condensation of eight isoprene units. Specific chemical groups present at the chain terminus determine carotenoid chromophore properties and allow their classification into two families based on color: red and yellow/ orange. *Capsicum* fruit owe their intense coloring to carotenoid pigments, which coincides with the high carotenoid content observed here in all nine studied genotypes. Ademoyegun *et al*., stated that carotenoids can act as antioxidants, with functions that include protection of membranes against damage by free radicals and retardation of ageing processes. In their analysis of carotenoids content in mature *C. chinense* fruit from 63 accessions, Antonious *et al*., found that accession PI-355817 (from Ecuador) contained the highest *β*-carotene concentrations (8,000 µg/100g fresh fruit). 59-3-1-5 accession line can be identified as potential candidates for mass production of antioxidants with health-promoting properties. Differences in carotenoids content are probably due to the influence of genotype and maturity stages. Carotenoids are known to play an important role in preventing oxidative damage, which is caused by free radicals in age-related diseases such as cancer. Most current carotenoids research is focused on their probable function as lipid antioxidants, which can protect against oxidation and other destructive processes mediated by singlet oxygen and free radicals, although more specific immune system effects are also receiving attention.

Peppers have the highest ascorbic acid content of the vegetables; for example, consumption of 100 g fresh weight of peppers provides 100% - 200% of the recommended dietary allowance of ascorbic acid. Ascorbic acid content in the nine studied *Nsukka yellow* genotypes ranged from 33.90 to 86.06 mg/100 g sample (Table 1). The genotype had the highest level is 34-1-2-5 and the 06-5-5 the lowest. The high ascorbic acid content of peppers is one of their primary nutritional qualities. Factors such as genotype, environment and fruit maturity affect levels of ascorbic acid and other nutritional compounds.

Table 1. pH, total soluble solid, titriable acidity, β – carotene and Vitamin C (ascorbic acid) content of Nsukka yellow breeding lines pepper fruits

BREEDING LINES	pH	TOTAL SOLUBLE SOLID	VITAMIN C	BETA-CAROTENE	TITRICABLE ACIDITY
59-3-1-5	5.50 ± 0.10a	7.67 ± 0.14c	49.00 ± 1.00b	6849.27 ± 39.60a	0.16 ± 0.02c
53-1-2-5	5.35 ± 0.05b	8.08 ± 0.14b	43.00 ± 1.00c	5439.81 ± 30.86b	0.31 ± 0.03a
06-5-5	5.54 ± 0.04a	6.58 ± 0.13d	33.90 ± 2.07d	3801.44 ± 46.51d	0.16 ± 0.02c
59-2-1-5	5.62 ± 0.03a	7.67 ± 0.15c	56.59 ± 2.32b	4938.27 ± 38.58c	0.16 ± 0.02c
31-1-3-5	5.06 ± 0.06d	8.08 ± 0.16b	37.54 ± 1.60	5389.39 ± 81.00b	0.16 ± 0.02c
63-1-2-5	5.41 ± 0.01b	9.08 ± 0.17a	47.00 ± 1.40c	4633.44 ± 70.50c	0.16 ± 0.01c
D2-5-5	5.39 ± 0.03b	7.50 ± 0.25c	39.80 ± 1.41d	5666.64 ± 65.37b	0.16 ± 0.02c
34-1-2-5	5.24 ± 0.04c	7.50 ± 0.25c	86.06 ± 2.02a	3147.62 ± 45.21e	0.17 ± 0.01c
D2-1-5	5.17 ± 0.06c	6.83 ± 0.14d	50.78 ± 2.45b	5395.55 ± 38.34b	0.20 ± 0.02b

Ascorbic acid levels were low in all the studied genotypes, which coincides with reported high in ascorbic acid content as some pepper fruit varieties. Carotenoids, ascorbic acid, flavonoids, phenolic acids and other chemical constituent concentrations increase as peppers. These authors concluded that the high variability in ascorbic acid content among breeding samples may have been due to differences in growing conditions, maturity and particularly post-harvest handling. In the study of the mature fruit of 63 *C. chinense* accessions by Antonious *et al*., they reported that accessions PI-152452 (Brazil) and PI-360726 (Ecuador) contained the highest ascorbic acid concentrations (1.2 and 1.1 mg·g−1 fresh fruit, respectively).

Capsaicin is an important parameter in peppers that indicate the hottest of pepper, Nsukka yellow pepper of breeding line 59-2-1-5 had the highest pungent value of 0.86 mg/g, follow by 59-3-1-5 variant of 0.85 mg/g and lowest value with D2-5-5 (0.42 mg/g) (Figure 1**)**. *Nsukka yellow* pepper is containerized aromatic pepper. The piperin in pepper is responsible for the flavor with a distinct aroma, which enhance is accessibility. The breeding line with highest piperin is 34-1-2-5 with value 66.70 mg/g and lowest is D2-5-5 with 20.32 mg/100g valve (Figure 1**)**. From the research results their no distinct relationship or correlation between the capsaicin and piperin in *Nsukka yellow pepper*. These accessions were identified as potential candidates for mass production of antioxidants with health promoting properties.

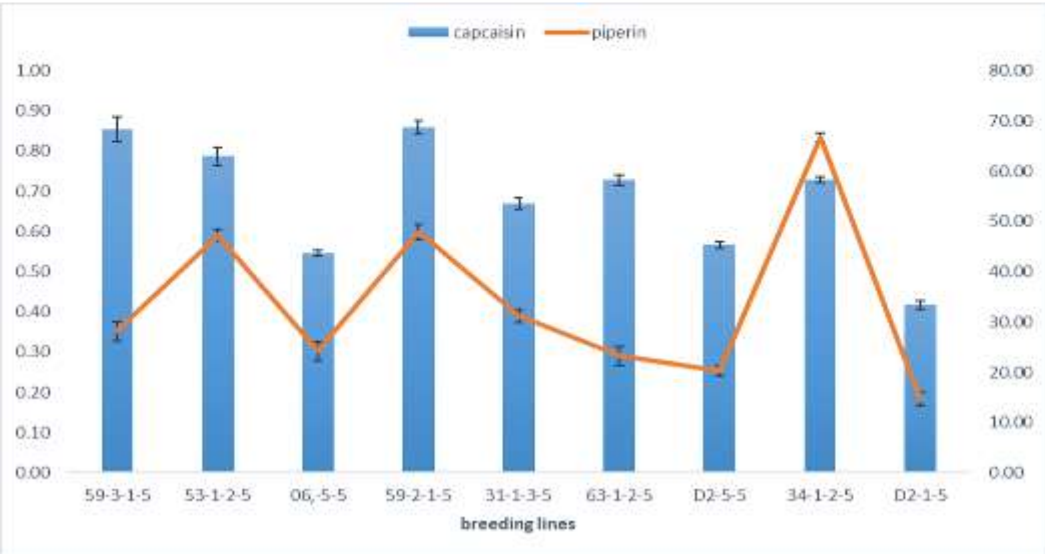

Figure 6: Capcaisin and Piperin contents of nine breeding lines of Nsukka yellow pepper

CONCLUSION

In terms of vitamin C, 34-1-2-5 was superior as compared with others. This is an indication that 34-1-2-5 had high vitamin C content which can meet the daily uptake of by man. 34-1-2-5 breeding line had the highest content of vitamin C and piperin as compared with all the others. The fruits with the highest content of capsaicin were the lines of 59-2-1-5 and 59-3-1-5, an indication of high levels of pungency as compared to that of the other lines, which was also seen in the β-carotene for the line 59-3-1-5. The offspring performed better than their parents and possessed traits which can be used in further breeding works.

ABSTRACT

Pepper is an important vegetable crop and played significant role in development of food in Africa. However, the production in Southern Nigeria is still short of what is demanded therefore there is need to increase and advance pepper research and production through quality and vigorous seeds for higher yields. This study was conducted at the screen house in vegetable research of National Horticultural Research Institute (NIHORT), Ibadan, Nigeria. Pepper were collected from agro-ecology zone of Nigeria and sorted into thirty accessions. The seeds were sown into nursery trays, watered and monitored for six weeks at nursery before hardened. Data were collected on daily emergence from six – fifteen DAS, plant height and number of leaves were recorded at transplanting. Data collected were subjected to analysis of variance and means were separated using LSD. The results showed significant different among pepper accessions. Acc 30 had the tallest seedling (14.2cm), while highest number of leaves was recorded in Acc 27 (12.67). Highest percentage germination rate was recorded and observed in Accession 30, which also germinated rapidly and attained 90% germination at 6 DAS, then obtain total germination percentage of 100% at 8DAS, therefore Acc 30 can be considered for further study.

Key words: germination%, vigour, pepper accession, seedling

INTRODUCTION

Pepper generally originates from Central America. *Capsicum annum* is from middle America (Mexico) while *Capsicum frutescens* (Bosland *et al.,*1993, Khali *et al* 2019) is from the northern half of south America to part of central America and Caribbean area. Pepper played a significant role in food production in Africa. Pepper is one of the most important vegetable crops in the world (FAOSTAT, 2018). There is need to increase production as indicated by the demand for pepper throughout the year. Germplasms collection and screening for desirable traits are essential for crop genetic enhancement (Idowu-Agida and Ajayi 2012). It is mainly used for adding flavour and imparting the pungency to cooked vegetables and meals. Pepper is often described as the "king of spices," and it shares a place on most dinner tables with salt (Alabi, 2006).

The vast majority of crops produced in world agriculture begin with the sowing of a seed to establish a new plant in the field. Successful seedling establishment is the first critical step for crop production, and determines the success or failure of the future harvest (Finch-salvage *et al*., 2015). Seeds germinate best at 25-30°C. Optimal temperatures for productivity range between 18-30°C. Peppers are tolerant to a wide range of soil conditions. However, fertile medium loams and well-drained soils with a pH of 5.5-6.8 are generally considered most suitable (Brandenberger *et al*., 2012). Seed quality is an essential trait for crop production and food security, particularly during the increasing uncertainty due to climate change (Finch-salvage *et al*., 2015). There is need to increase and advance horticultural crops for research and production. This study therefore investigate thirty accessions of pepper collected from Southwest Nigeria for seedling emergence and field establishment.

MATERIALS AND METHODS

The experiment was conducted at the screen house of Vegetable Research (NIHORT), Ibadan, Nigeria. Seeds were extracted from long cayenne and hot pepper collected from thirty locations respectively of agro- ecologies of South West Nigeria. The seeds were air-dried, bulked, and packaged as accession from each location. Top soil was collected and sterilized by heating to 100^{0}C in a metal drum and was allowed to cool. The sterilized soil was filled into perforated nursery trays. Thirty accessions of pepper seeds were sown in nursery trays filled with steam-sterilized top soil. Twenty seeds were counted and sowed from each accession at 2cm depth, regular watering and monitoring was carried out in the nursery for six weeks. The following data were collected during the early growing stage; seedling emergence counts, seedling height (cm) was determined as the distance between the soil surface and the uppermost collar using meter rule and number of leaves, germination percentage was computed as: Germination percentage = $\frac{(No\ of\ emerged\ seedling)}{No\ of\ seed\ sowed} x100\%$

Analysis: Data recorded were subjected to Analysis of Variance (ANOVA) using the Genstat 12th edition package while means were separated using least Significance Difference (LSD) at 5% probability level. Treatments means were considered significantly different at *p*<0.05.

RESULTS

The mean maximum number of leaves (12.67) was observed in Accession 27, followed by Accession 30 (10.69), and Accession 29 which had the same value with accession 28 (10.33). Similarly, the tallest seedlings were observed from Accession 30 (14.17cm) and Accession 10 (12.67cm) (Table 1). However, lowest number of leaves (4.67) was observed in Accession 26 followed by Accession 25 and Accession 24 with the same mean value (5.33). Meanwhile, the shortest seedling was observed in Accession 24 (Table 1).

DAS= Days After Sowing, Acc = Accession.

DISCUSSION

In the study, accession 30 gave the highest seedling, and was the second accession with more leaves which are indications of good seedling vigour. Vigour is the properties of seed that determines the potential level of activities and performance of seeds during germination and seedling emergence (ISTA 2015; Finch-salvage 2016). These results conformed with the findings of (Jeremi Kolodziejek 2017), who reported that, both shoot biomass and root biomass of the seedling from the seeds on the primary umbel were significantly higher than those of the seedlings from seeds on the secondary umbels. In addition, the total percentage germination differed significantly (p-value<0.01) than others, also has rapid germination, similar results were found by Ajala *et al.,* (1985) and Jeremi Kołodziejek (2017) who observed that seed mass and germination percentage of *Angelica archangelica* were higher in seeds on the primary umbel than in those on secondary, tertiary, and quaternary umbels. This can be attributed to seeds because seeds carry the full genetic compliment of crop production and improvement (Perry 1980).

The study revealed that accession 2, 8 9 and Acc 18 emerged lately, it does not emerge until 12th DAS with poor germination rate, number of leaves and seedling height respectively, which might have been as a result of aging during storage. Sheppard *et al., (*1995), reported that seeds undergo aging during storage, the extent of which depends on the moisture content and temperature. The deterioration manifested by aged seeds includes reduced emergence. This is similar to the findings of Jeremi, (2000) who suggested that seed size can affect germination percentage as well as seedling establishment, growth survival and can be due to their sources and vigour. Powell *et al.* (1984) and Finch-salvage (2015) also reported low vigour grain of legume seeds due to increased leakage of solutes that attract fungi, and the presence of dead tissue that provides a food base for infection.

CONCLUSION

In conclusion, it was discovered that variation existed among the thirty accessions of pepper under the present study. When selections of new accessions are the objective in future breeding and agronomy work, Acc 30, Acc11 and Acc29 can be considered.

ABSTRACT

Seventeen amaranth (Amaranthus spp.) accessions were planted at the Teaching and Research Farm of the Federal University of Agriculture, Abeokuta to determine their genetic variability for yield and related traits as well as contribution of each character to variation. The field experiment was laid out in randomized complete block design with three replications. Data were collected on plant height (cm), number of leaves, leaf length (cm), leaf width (cm), stem girth (mm), 1000-seed weight (g) and seed yield (kg/plant). Analysis of variance revealed that the seventeen amaranth accessions differed significantly with respect to all characters except leaf width. The first principal component analysis (PCA) had the highest contribution of 34.1% to the total variation. The small difference between the phenotypic coefficient of variation and genotypic coefficient of variation observed for most characters indicated that the variability was primarily due to genetic differences. Meanwhile, heritability was highest for number of leaves (H_B = 95.62) and was lowest for leaf width (H_B = 6.10). It was concluded that variability exist among the seventeen amaranth accessions used in this study and number of leaves with high estimate (95.62%) of Broad-sense heritability could be used as a criterion for selection in a future breeding programme.

INTRODUCTION

Amaranth is an herbaceous annual belonging to the family *Amaranthaceae* that originated from central and South America. The genus *Amaranthus* consists of approximately 60 species worldwide which is characterized by a high degree of diversity and a wide spectrum of adaptability to different agro ecological conditions (Snezana *et al.,* 2012; Malaghan *et al*., 2018). The cultivated amaranths are utilized as leafy vegetables, food grains and forage crops in diverse geographic areas (Stallknecht and Schulz-Schaeffer, 1993; Popa *et al*., 2010). Amaranth leaves are rich in dietary fiber, protein, vitamins and minerals (Shukla *et al.,* 2004). The seeds are rich in protein (17–19%) with very good balanced amino acids, particularly lysine, which is often limited in other cereal grains (Popa *et al*. 2010; Oduwaye *et al*., 2016).

The first step in the development of high yielding varieties is assessing the genetic variability of available genotypes for yield and its components (Rahman *et al*., 2016). This information will guide in choosing genotypes to be included in a breeding programme. Genetic parameters, such as, co-efficient of variation, heritability and genetic advance provides information on the extent of variability and efficiency of selection of genotypes based on their phenotype, in a diverse population. Hence, this study was carried out to determine genetic variability among seventeen Amaranth accessions.

MATERIALS AND METHOD

Seventeen accessions of amaranth used for this study were collected from the Nigeria Institute of Horticultural Research (NIHORT), Ibadan. These include; NGB01234, NG/SA/DEC/07/0423, NGB0124g, NGB01276, NG/AO/11/08/042, NG/SA/DEC/07/0412, NG/AA/03/11/010, NG/AO/11/08/039, NG/AA/MAY/09/027, NG/TO/02/12/154, NHAM15, NHAM22, PI477913, PI576460, PI576478, PI576454 and PI511719. The experiment was conducted between Nov 2014 and February 2015 in the Teaching and Research Farm of Federal University of Agriculture, Abeokuta (Latitude 7°15′ North, Longitude 3°25′ East and altitude 159 m above sea level) within the Forest – Savannah transition zone in Southwestern Nigeria. The experiment was laid out in a randomized complete block design with three replicates. The Amaranth seedlings were transplanted to the main field 3 weeks after sowing in a double row plot at a spacing of 50cm by 25cm. Weeding was done manually and no fertilizer was applied. A total of 16 plants were maintained in each plot and data were collected on five selected plants for Plant height (cm), stem girth (mm), leaf length (cm), leaf width (cm), number of leaves/plant, 1000-seed weight (g) and seed weight (g). The data collected were subjected to analysis of variance (ANOVA) to test for significance among the accessions. Genotypic coefficient of variability (GCV), Phenotypic coefficient of variability (PCV) and heritability (broad sense) were calculated (mohsin *et al*.., 2009). Also, contribution of each character to variation was determined using principal component analysis.

RESULTS AND DISCUSSION

There were significant differences among the seventeen amaranth accessions for number of leaves, stem girth, plant height, leaf length, 1000-seed weight and seed yield (Table 1). This suggests that there is sufficient variation in the materials studied.

Table 1: Mean squares of seven traits measured in seventeen Amaranth Accessions

Source of variation	Block (df = 2)	Accession (df = 16)	Error (df = 32)
Number of leaves	91.29**	506.16**	22.19
Stem girth (mm)	3.91*	5.33**	0.93
Plant height (cm)	212.45*	296.86**	54.01
Leaf length (cm)	0.80	2.47**	0.61
Leaf width (cm)	11.80	15.50	14.55
1000-seed weight (g)	0.01	0.02**	0.00
Seed yield (kg/ha)	0.07	3.43**	0.24

The means, variances, phenotypic coefficient of variation, genotypic coefficient of variation and broad sense heritability of seven traits in seventeen accessions of amaranth were presented in Table 2. The values of phenotypic coefficient of variation were higher than those of genotypic coefficient of variation for all the traits studied. Similar results in amaranth were reported by Ramesh *et al*., (2013) and Lokeshkumar & Murthy, 2017. Number of leaves (32.37) and seed yield per plot (30.24) showed high estimates of GCV revealing that emphasis should be given on these characters during selection of improved genotypes because these characters have high range of genetic variation, hence, a better scope of improvement through selection. It is not possible to determine the amount of variation that is heritable with GCV alone. The GCV together with heritability estimates would give reliable indication of the expected amount of improvement through selection (Johnson *et al.,* 1955).

Table 2: Estimates of variances, phenotypic coefficient of variation, genotypic coefficient of variation and heritability

Character	Mean	Phenotypic variance	Genotypic variance	EV	PCV	GCV	Heritability %
Number of leaves	39.24	167.72	161.32	7.40	33.10	32.37	95.62
Stem girth (mm)	5.93	1.78	1.47	0.31	22.48	20.43	82.63
Plant height (cm)	57.87	98.95	80.95	18.00	17.19	15.55	81.81
Leaf length (cm)	6.74	0.82	0.62	0.20	13.45	11.69	75.49
Leaf width (cm)	3.92	5.17	0.32	4.85	57.95	14.32	6.10
1000-seed weight	0.45	0.00	0.00	0.00	13.96	12.75	83.33
Seed yield (kg/ha)	3.41	1.14	1.06	0.08	31.38	30.24	92.88

The fact that most of the traits evaluated had relatively high estimates of broad-sense heritability confirmed that there existed a large genetic differences among the accessions and that the traits can be used as selection criteria in future breeding programme. The result also indicated that the effect of the environment on the expression of most characters was low. However, high heritability estimate of 95.62% and 92.88% recorded for number of leaves and seed yield respectively indicated a large contribution from genetic factors compared to environmental factors. The knowledge of genetic variation and relationships among accessions will help breeders in developing appropriate breeding strategies to solve problems of low yield in amaranth.

Table 3 presents the eigen values, variance proportion and factor scores of yield and related traits in seventeen accessions of amaranth. The output of the PCA revealed that different characters contributed differently to total variation. The first four component axis had 2.731, 1.860, 1.158 and 0.868 eigen values respectively and together accounted for 82.7% of total variation.

The characters that contributed significantly to variations in the PC1 include 1000-

seed weight, plant height, stem girth and number of leaves. In PC2, seed yield, leaf length, leaf width and plant height were the most effective traits. Thus, the characters associated with these principal components should be used in differentiating the Amaranth accessions.

Table 3: Eigen values, variance proportion and factor scores of yield and related traits in seventeen accessions of amaranth

	PC1	PC2	PC3	PC4
Eigen value	2.731	1.860	1.158	0.868
Proportion (%)	0.341	0.232	0.145	0.109
Cumulative (%)	0.341	0.574	0.719	0.827
Character				
Number of leaves	0.443	-0.075	-0.041	0.491
Stem girth (mm)	0.532	0.237	-0.084	-0.026
Plant height (cm)	0.438	0.463	-0.101	0.153
Leaf length (cm)	-0.005	0.602	0.267	-0.243
Leaf width (cm)	-0.241	0.316	0.555	-0.112
1000-seed weight (g)	0.370	-0.238	0.475	-0.120
Seed yield (kg/ha)	0.237	-0.445	0.518	-0.135

CONCLUSIONS

The current study has shown that variability exists among the seventeen amaranth accessions and such variation or much more could exist among the entire collections of this accessions being held at NIHORT. High genotypic coefficient of variation and high heritability is helpful in making selection of superior genotypes. Number of leaves with highest broad-sense heritability estimate can be used as selection criterion for amaranth improvement.

ABSTRACT

The study was conducted on okra (Abelmoschus esculentus (L.) Moench) collected from National Horticultural Research Institute, Ibadan. Twenty (20) genotypes of Okra were evaluated in a randomized complete block design with three (3) replicates to assess the degree of genetic variability and qualitative traits among the genotypes in 2019 and 2020 cropping seasons. The results revealed that the okra genotypes had significant variation in days to first flowering, plant height, fruit length, fruit width, internode length, and number of pods per plant. Mean performance for pod per plant shows that Prof x Clemson-59 produced the maximum number of pods per plant which was significantly higher among the other genotypes, followed by Prof x Clemson-9, LD88, and 47-7. Variability for pod yield per plant had its traits correlation effect mainly with pedicel length, plant height, days to first flowering and fruit width. This indicates that a selection procedure base on these traits may be effective in improving fruit yield. Prof x Clemson-59 with early days to first flowering and high pod yield per plant could be utilized in hybridization for future Okra breeding programmme for developing superior varieties.

Key words: Okra, variability, correlation and Pods yield per plant

INTRODUCTION

Okra (*Abelmoschus esculentus* (L.) Moench) belongs to the family *Malvaceae*. The fruits are a green capsule containing numerous white seeds when immature and the upright plants and flowers give okra an ornamental value. Okra fruit varies in fruit shape which could be angular or circular (Chaudhary *et al*., 2006 and Varmudy, 2011). It is a very important vegetable crop grown in tropical and subtropical parts of the world. It's proposed to be originated in Tropical Africa and it is native to North Eastern Africa in the area of Ethiopia and Sudan from where it extensively spread to Asia, America, Southern Europe, and other countries (Aladele *et al*., 2008 and Anyaoha *et al*., 2018). It is self-pollinated, mainly propagated by seeds with a duration of 3 to 4 months. It is a rich source of fats, fibres, proteins, carbohydrates, minerals, and vitamins. The unripe green finger-like seed capsule of okra, usually called "pod," is processed and consumed as stews, salads, soups, sliced, boiled, and fried vegetables. (Barrett, 2013; Duzyaman, 1997).

Okra is a traditional crop in southern, western, and northwestern Nigeria. The crop is cultivated from landraces over the years in the country. Geographic distances and environmental differences are the two major causes of genetic diversity among plant populations (Anyaoha *et al*., 2018; Alade *et al.,* 2008). Evolutionary forces like selection, mutation, migration, and genetic drift are the basis of crop genetic diversity. In this regard, morphological characterization involves both the quantitative and qualitative traits' performance of plants under study. Progress and gain from the selection in any breeding program depend upon the magnitude of useful variability present in the population and the degree to which the desired traits are heritable. (Adeoluwa *et al*., 2011 and Rahman *et al*., 2012)

In Nigeria, despite the increase in demand for okra cultivars that present good quality and high yield, the yield of okra is still low (2.7 t/ha) compared to other countries such as India (10.50 t/ha), Sudan (10.2t/ha), Egypt (15.7 t/ha), Pakistan (7.6 t/ha), Saudi-Arabia (11.5 t/ha) and Ghana (5.5 t/ha) (Varmudy *et al*., 2011, and Oyelade, et al., 2003) Therefore, it is essential to study the variability and the quantitative traits of the different Okra genotypes for yield and crop improvement programme (Ariyo, O.J. 1990). This study was carried out to assess the degree of genetic variability and qualitative traits among twenty okra genotypes to provide input for okra variety, crop improvement program and its conservation in Nigeria.

MATERIALS AND METHODS

The research was conducted at the research farm of the National Horticultural Research Institute, Ibadan (Latitude 7 ° 24’ 26” N, and longitude 3°50’43” E), during 2019 and 2020 wet season. Ibadan has bimodal rainfall distribution, which peaks in June/July and September. (Olaniyan et al 2001). Twenty Okra genotype were selected for this study from The National Horticultural Research Institute (NIHORT) Ibadan. Selection was based on fruit traits such as shape, size and colour of fully-developed fruit

Experimental Design:

The experiment was laid out in Complete Randomized Block Designed in 3 replications. The seeds of the Okra were planted three (3) per hole. Plants were spaced 60 cm between and within rows. Plants were thinned down to one per stand, three weeks after seedling emergence, giving a total plant population of approximately 27, 778 plants/ ha. Agronomic maintenance carried out included manual weeding at two weeks after planting; NPK 15:15:15 fertilizer was applied in split at 60 Kg/ha first at three weeks after planting and later at flowering.

Data Collection:

Data was collected on three (3) plants per genotype per plot on the following agro- morphological quantitative traits according to (IPGRI, 1998) descriptors for Okra (Abelmoschus esculentus (L.) Moench) on the following agronomic attributes: Number of days to flowering, plant height (cm), number of pods per plant, internode length (cm), fruit length (cm) and fruit width (cm).

Data analysis

Each genotypes, the mean values of the data collected were subjected to Analysis of Variance to determine significant differences of the traits using Duncan Multiple Range Test (DMRT) at 5% probability level.

The relationship among the fifteen traits were investigated for each environment using phenotypic correlation coefficients between traits X and Y (rp XY) calculated from mean values of traits using the procedure outlined by Miller *et al.* (1958) thus

rpXY = $\frac{CoVpXY}{\sqrt{((\delta 2gX)(\delta 2gY))}}$

Co VXY = Phenotypic covariance of traits X and Y

$\delta^2 gX =$ Phenotypic variance of Traits X

$\delta^2 gY =$ Phenotypic variance of Traits Y

RESULTS AND DISCUSSIONS

The result of the analysis of variance showed that highly significant (P<0.01) genotypes effect was observed for days to first flowering, plant height, internode length, and number of pods per plant (Table 1). Fruit length and pedicel length were also significantly (P<0.05) different among the genotypes. Non-significant (P>0.05) genotype effect was observed in fruit width. The result suggests the presence of variation among the twenty genotypes evaluated except for traits that were not significant. The presence of wide genetic variability provides an indication of a better scope for genetic improvement. Similar results were reported by other workers (Ariyo, O.J. 1990; Ade-Oluwa and Kehinde, 2011; Binalfew *et al*., 2016) who also investigated genetic variability in okra and found significant cultivar effect in all the studied traits.

Table 1: Mean squares of traits evaluated in twenty genotypes of okra

Source variance	DF	Days to first flowering	Fruit length (cm)	Fruit width (cm)	Pedicel length (cm)	Internode Length (cm)	Plant height (cm)	No pods Per plant
Block	2	39.18	0.02	0.28	0.21	2.69	97.38	2.55
Accessions	19	7.99**	5.89*	3.31	0.61*	10.53**	238.87**	0.68**
Error	38	0.94	0.78	0.27	0.10	0.43	1.94	0.19

Days to first flowering: The result of the mean performance shows significant variations among the genotypes studies pertaining to days to first flowering. (Table 2). The result revealed that genotypes; Prof x Clemson-59 and 47-4 significantly had the earliest days to first flowering at 46 days but genotype Benue Local had late days to first flowering at 61 days. The differential performance of the genotypes to flowering may have been influenced by their unique genetic characteristics. The results are supported by previous works (Rahman *et al*., 2012; Demelie *et al*., 2015; Anyaoha *et al*., 2018).

Table 2: Mean performance of morphological traits studied on twenty-five accessions of pepper for quantitative traits

Mean with the same alphabets within the column are not significant different at 5% probability level from one another

Plant height (cm): Table 2 shows that significant genotypes effect was observed for plant height. Maximum height (73.60 cm) was recorded in Prof x Clemson-9, whereas Prof 10 (34.60 cm) gave the minimum height. Khan *et al*. (2002) and Mohammed *et al.* (2017) also reported significant differences for plant height among okra varieties evaluated.

Internodes length (cm): Fruit internodes showed significant genotype effect. The genotype Ik11 and Ik7 had the maximum internode length at 11.82cm and 11.75 respectively while the minimum occurred in the Prof x Clemson-34 and PROF x CLEMSON-35 at 4.7 and 4.95 respectively. (Table 2). The study also revealed that internode length has positive correlation with fruit yield per plant. This result is in line with the findings of Raji *et al.* (2002) and Akortkar *et al*. (2010).

Fruit width (cm): No significant genotype effect was recorded with respect to fruit width. It showed that the genotypes did not differ in fruit width. However, the genotype Ik11 recorded the largest width of (12.15cm) and Prof 10 (11.35cm) whereas the least was observed in the Prof x Clemson-9 (7.50cm). (Table 2). Khan *et al*. (2002) and Temam *et al*., 2020 also observed a non-significant cultivar effect on fruit size in their study.

Fruit length (cm): Significant genotype effect was observed in the fruit length. The genotype Prof x Clemson-59 had maximum fruit length of (13.85 cm) and Clemson had (10.65cm) while the minimum occurred in the 47-7 (6.39 cm). (Table 2). However, the fruit length for plots sown with Clemson, Prof 2 and Prof x Clemson-34 were not statistically different indicating that they did not differ in terms of fruit length. This result is in line with the findings of Chaudhary *et al.* (2006) and Akortkar *et al*. (2010).

Number of pods per plant: Number of pods per plant showed significant effect among the okra genotypes. Table 2 revealed that genotype Prof x Clemson-59 produced the maximum number of pods which was significantly higher among the genotypes evaluated. The number of pods per plant produced by Prof x Clemson-9, LD88, and 47-7 were 5.60, 5.52, and 5.00, respectively. This result suggest that these three genotypes possessed similar fruiting potentials. This finding corroborates the reports of other authors; (Bello *et al*., 2006; Akortkar, et al., 2010; Rahman *et al*., 2012 and Simon et al. 2013) who also had significant effect of number of pods per plant in different okra cultivars. However, this result contradicts the findings of Khan *et al*. (2002) who had noted a no significant effect of cultivar on number of pods per plant in Pakistan.

Correlation: Expressive significant phenotypic correlation coefficient was observed for most of the traits studied (Table 3). The phenotypic correlations between pedicel lenght and number of pods per plant was positive and significant (r = 34*). The result also shows that the correlation between days to first flowering (r = 0.08), fruit width (r = 0.09) and plant height (r = 0.30) with number of pods per plant was positive but negatively with fruit length (r = -0.07). Days to first flowering had significant and positive correlation with plant height (r = 0.48**) and number of pods per plant (r = 0.08). This result showed that early flowering genotype have advantage over late flowering ones as it allows for a longer duration of fruiting which ultimately influences number of pods per plant. Ariyo, O.J. (1990); Mihretu *et al.,* 2014 and Anyaoha *et al*. (2018) also reported a positive relationship between number of pods per plant and days to flowering, fruit length and plant height. The positive association of number of pods per plant with pedicel length (r = 0.34*), days to first flowering (r = 0.08), fruit width (r = 0.09) and Plant height (r = 0.30) indicates that genotypes with these traits may be selected for increase in okra fruit yield.

Table 3: Correlation Coefficient between traits in 20 Okra genotypes evaluated

Traits	Days to first Flowering	Fruit Length (cm)	Fruit Width (cm)	Pedicel Length (cm)	Internode Length (cm)	Plant Height (cm)	No of pods Per Plant (cm)
Days to First Flowering	1.00	0.18	0.22	0.25	-0.13	0.48**	0.08
Fruit Length	0.18	1.00	0.07	0.34*	-0.11	0.14	-0.07
Fruit Width	0.22	0.08	1.00	0.29	0.15	-0.04	0.09
Pedicel Length	0.25	0.34*	0.29	1.00	-0.02	0.19	0.34*
Internode Length	-0.13	-0.14	0.15	-0.02	1.00	-0.16	0.23
Plant Height	0.48**	0.12	-0.04	0.19	-0.16	1.00	0.30
No of fruit Per Plant	0.08	-0.07	0.09	0.33*	0.29	0.30	1.00

**. Correlation is significant at the 0.01 level. *. Correlation is significant at the 0.05 level.

CONCLUSION

Significant ($P \leq 0.01$) variations were observed among the okra genotypes for all the morphological quantitative traits studied. The result revealed wide variation for days to first flowering, plant height, fruit length, fruit width, pedicel length, internode length and number of pods per plant. It also revealed the relationship between number of pods per plant and its components as they affect pod yield. It shows the superiority of Prof x clemson-59, Prof x clemson-9, LD88, and 47-7 in terms of early days to flowering, fruit length, fruit width and yield potentials under South West Nigeria and soil condition. This genotypes could be utilized in hybridization for breeding programmes for development of superior okra varieties. Hence, the result of this study is an indicator for the presence of a higher chance to develop okra varieties that could be highly preferred by farmers, consumers and for further plant breeding program through selection/ crossing of okra genotype.

ABSTRACT

Coffee is one of the most economic important tree crops worldwide. Response to selection and success of hybridization in Coffee depends majorly on the natural diversity and how well the magnitude of the genetic diversity is harness for future improvement. This study was conducted to estimate some genetic parameters of the seeds and growth habits of young plants of Robusta coffee accessions in order to provide baseline information for breeding programs. The experiment was conducted in a Randomized Complete Block Design with three replications at Owena, Ondo State of Nigeria. Cherries of coffee accessions collected from different farm locations were characterized before processed for onward planting. Fifteen qualitative and quantitative agro-morphological traits were evaluated and data were taken on the plants for two consecutive years. Result of the analysis revealed that phenotypic coefficient of variation (PCV) was higher than genotypic coefficient of variation (GCV) across all the traits. High phenotypic coefficients of variation were observed in seed traits and plant growth habit traits. High PCV was recorded in leaf number (103.72); fruit shape (49.42) and the lowest PCV in leaf length (30.08) and dried seed weight (12.67). High GCV were observed in leaf number (75.34) and fruit shape (41.22) whereas, lowest GCV were recorded in plant height (22.34) and fresh cherry weight (8.51). Heritability estimations for all traits ranged from medium in plant height (32.72) to relatively high in fruit shape (69.57). These findings revealed a high genetic variability for most of the morphological traits coupled with high heritability for most of the traits which can be utilized in future coffee improvement programs.

Key words: Coffee accessions, Seeds characterization, Coefficient of variation, Broad sense heritability, Genetic diversity

INTRODUCTION

Coffee is one of the most important tree crops worldwide. One of the utmost decisions to be taken by farmers is the choice of variety to plant that will produce the best results and this has always been a challenge to farmers. Coffee growers have been selecting plants with specific traits for many years either consciously or unconsciously with the aim of achieving high productivity. With this effort made by farmers, it is of priority to identify available cultivars for selection of desirable traits in coffee breeding programme (Cubry*et al*., 2008). According to Partelli*et al*. (2019, 2020), efforts of selection and identification of cultivated cultivars of coffee, had led to development of new coffee genotypes in the recent past with some desirable traits. However, much is still needed to be done to identify cultivars with desirable agronomic characteristics and well adapted to different environmental conditions as this will bring about competitiveness, sustainability and increase in coffee production. This necessitate determinant of level of variation among the cultivated robusta coffee, identification of homogeneous genotypes and those with stable traits among the cultivars for commercial coffee production (Gichimu and Omondi, 2010).

Coffea canephora is an allogamous and diploid species, with self-incompatible gametophyte (Tran *et al.* 2017; Moraes*et al.* 2018). This inferred that C. *canephora* is of natural reproduction, which makes propagation of coffee by seeds to be of highly diverse, wherein each plant may differ from others in relation to its architecture, shape and size of grain and leaves, maturation pattern, and susceptibility or tolerance to biotic and abiotic factors, among others. The magnitude of genetic variability present in the coffee population determines the success of the breeding program for crop improvement. Getachew *et al.* (2017) evaluated genetic parameters in Arabic coffee and reported significant variations on growth characters among the accessions. Genetic variability in a population can be achieved by introducing new genetically diverse lines in to the population. It is important to increase variability in the population in order to bring the genetic improvement in the characters for economic benefits. In view of this, concerted efforts were made in this study for ex-situ collection of robusta coffee accessions, in order to consolidate on increase in genetic diversity of existing genotype of robusta coffee in Nigeria. Therefore, it is imperative to characterize the available robusta coffee accession for future selection and improvement programme. Evaluation of the collected accessions for genetic variability would be of use in future for improvement purposes.

MATERIALS AND METHODS

Plant materials

A total number of 15 *Coffea canephora* accessions were collected and used for this study, of which 3 were from CRIN coffee germplasm as a check and the remaining 12 were collected from various coffee farms. Ripe coffee cherries were harvested from heavy-bearing healthy trees for seedlings establishment and for onward transplanting into the field. Each accessions collected were numbered and named based on the location of collection. Pulps were removed with the use of pestle and mortar after fermentation. After then the parchment coffee seeds were air dried under the shade until ready for planting at pre-nursery. Harvested coffee cherries were characterized before process into seeds. The experiment was conducted at CRIN Owena substation in Ondo State under rain fed condition, in randomized complete block design with 3 replications and six plants per plot representing population of each accession.

Data collection and analysis

Data on 15 agro-morphological parameters were taken for two years. Among data recorded, 13 were quantitative traits and the remaining 2 parameters were qualitative traits and scored based on physical observation as described in descriptors of coffee by International Plant Genetic Resources (IPGR) (1997). Data were recorded on: plant height; stem girth; leaf number; internodes length; number of plagiotropic branches; leaf length; leaf width; colour of matured fruit; fruit width; fruit length; fruit shape; fresh cherry weight; dried seed weight; germination % and days to 50% germination. Data of 15 different characters' traits were subjected to statistical analysis. Analysis of variance (ANOVA), was generated from data, using SAS 9.1.3 Version (2004). Multivariate analysis (MANOVA) was performed from the variance components, in which the following parameters were estimated for each characters: phenotypic variance (PV); genetic variance (GV); environmental variance (EV); genotypic coefficients of variation (GCV); phenotypic coefficient of variation (PCV); environmental coefficient of variation (ECV); heritability estimates in broad sense (H^2b) and expected genetic advance (GA); and genetic advance as percentage of mean (GAM%). Cluster analyses were performed using word method to plot hierarchical clustering.

Genotypic and phenotypic variation was calculated based on the formula given by (Singh and Choudhary, 1985). Phenotypic coefficient of variation (PCV %) and genotypic coefficient of variation (GCV %) were estimated following the formula given by (Sivasubramanian and Madhava, 1973). It was categorized as follows Less than 10% = low, 10-20% = Moderate, More than 20% = High. Heritability (H^2b) was estimated based on the formula given by (Falconer, 1981). Heritability was classified as low (below 30%), medium (30-60%) and high (above 60%) as suggested by (Johnson *et al.,* 1955). According to Singh (2001), heritability values greater than 80% are regarded as very high value, from 60-79% moderately high; 40-59% as medium and values less than 40% as low. Estimation of genetic advance Genetic advance (GA) and percentage of mean (GAM) and selection intensity (k) at 5% (2.06) was used in accordance with the formula described by (Johnson *et al*., 1955). Genetic advanced was classified as between 0% and 10% for low, 10% and 20% for intermediate, and more (>20%) for high, following the formula given by (Johnson *et al*., 1955: Juangsamoot*et al*., 2012).

RESULTS

The result of analysis showed genetic variations in plant morphological traits, with phenotypic variance (PV) being higher than the genotypic variance (GV) in all the traits for the two years combined (Table 1). The highest phenotypic variance value recorded was for leaf number (103.72), number of plagiotropic branches (95.13), internodes length (56.36), and stem girth (45.84), likewise the intermediate phenotypic variance was leaf length (30.08), leaf width (34.87); and plant height (39.06). Highest genetic of coefficient of variation was expressed by leaf number (75.34), number of plagiotropic branches (51.89), similarly intermediate genetic coefficient of variation (GCV) was observed in plant height (22.34), stem girth (31.44), internodes length (32. 87) and leaf length (22.96). Heritability estimates in broad sense ranges from medium in plant height (32. 72) to high in fruit shape (69. 57) for all the fifteen traits. Genetic advance as percentage of mean ranged from intermediate (10.84) to high (70.82).

Genetic variability was observed among the seed traits (Table 1). The value of phenotypic coefficient of variation was higher than genotypic coefficient of variation for all the characters studied.

Fruit shape (49.42%) shows high phenotypic coefficient of variation while dried seed weight (12.67%) shows lowest phenotypic coefficient of variation. Intermediate to high phenotypic coefficient of variation was observed in seed width (21.88%), length of seed (21.38%), and days to 50% germination (15.59). Genotypic coefficient of variation recorded value ranging from 8.51% (fresh cherry weight) to 41.22% (fruit shape). Low to high genotypic coefficient of variation was exhibited by fruit colour (10.19%), dried seed weight (9.35%), seed width (13.84%), and length of seed (21.38%), germination percentage (18.61%), and days to 50% germination (10.84%).

Broad sense heritability was estimated from PCV and GCV values. It is observed that heritability ranged from 33.33% in length of seed to 69.57% in fruit shape. High heritability was recorded for germination percentage (65.16%). Moderate heritability was revealed by dried seed weight (54.39%), days to 50% flowering (48.37%), seed width (40.00%) and fresh cherry weight (38.25%). Genetic advance estimated shows value range from low to intermediate of genetic advance for seed character which was 0.11 for seed weight to 12.59 for germination percentage. Low genetic advance value was recorded on fruit colour 0.75, fresh cherry weight 7.84, fruit shape 1.54, dried seed weight 3.38, length of seed 0.12, and days to 50% germination 7.82. Genetic advance as percentage of means magnitude value ranges from intermediate to high with values ranged from 10.84% for fresh cherry weight to 70.82% in fruit shape. Intermediate genetic advance as percentage of means was observed in fruit colour (15.74%), dried seed weight (14.20%), germination percentage (14.32%), length of seed (14.68%), days to 50% germination (14.68%), and seed width (18.03%).

The relationships among the 15 robusta coffee accessions based on the quantitative traits were assessed as shown by clustering (Fig.1). The result revealed 15 robusta coffee accessions were distinct from each other with some grouped based on morphological similarity. Cluster dendrogram constructed based on morphological traits to estimate the diversity among the fifteen coffee accessions, grouped them into three main clusters. Cluster group 1 comprises of five accessions which shows that (33.3%) of the accessions were of shortest plant height, cluster group 2 comprises of six accession representing (40%), of the accessions that are of tallest plant height, while cluster group 3 comprises of four accessions representing (26.7%) of the accessions that are of moderate plant height.

DISCUSSION

Improvement programme in crops depends majorly on the magnitude of genetic variability and heritability of traits studied. Coefficient of variation studied indicated that phenotypic coefficient of variation (PCV) was higher than the genotypic coefficient of variation (GCV) for all the traits. Getachew *et al*. (2017) reported same in Arabica coffee, implying the influences of environmental factor on all the traits, with low genetic variability. Similar finding was reported in *C. arabica* by Resende *et al*. (2001) and in C. *canephora* by (Bayisa and Ney, 2017). Bhadru *et al.* (2012), also reported same finding in rice. Genetic diversity is reliant on the heritable variation within and between populations as it is useful in predicting genetic gain from selection (Paikhomba *et al*., 2014), as increase in heritability contribute to increases in genetic gain (Mckeand *et al*., 2008). This study was able revealed moderate to high heritability in the traits studied suggesting that the traits studied are heritable. Moderate to high heritability would guarantee transfer of heritable characters to their offspring by parents (Jansson, 2005). This gives high level of confidence in the phenotypic values which serve as a guide for the genetic value in selection of the accessions for improvement programme. High to moderate genetic advance as percentaage of mean revealed by all traits indicated that all the traits are under genetic control suggesting that selection from them can be achieved through their phenotypic performance. Also moderate to high genetic advance as percentage of mean is a useful indicator of the progress that can be expected as result of exercising selection on the pertinent population. High heritability value together with good genetic advance as percentage of means value, would give a more reliable index for selection with desirable characteristics (Ajmal *et al*., 2009: Johnson *et al*., 1955). Clustering due to morphological traits shows that such accessions are morphologically similar, with low genetic variation within the accessions. Similar grouping based on similar morphological traits has been reported in *C. canephora* (Aluka, 2013) and in *C. arabica* (Gesseseet *al*., 2015). Close proximity observed among the accession from CRIN germplasm (M36) from south west and farmer's varieties (DAC and ORA1) collected from north central of Nigeria explained the similarity and relationship between the accessions, implying there is likely possibility of being related genetically. This required stringent evaluation of these accessions using molecular markers. Deductively, this finding has suggested that morphological traits could be used to select superior accessions without assessing of the yield components, this has been reinforced by report of Freitas*et al*. (2007) on coffee. Moreover, this study is in agreement with the previous work stating that morphological diversity is more important factor rather than variation in geographical origin as an indicator of genetic diversity in coffee (Bayetta, 2001). However, the use of morphological markers to studied genetic divergence in coffee is of equally important as it has been reported by (Gichimu and Omondi, 2010; Guedes *et al*. 2013: Baba Nitsa *et al*. 2020) which also provide genetic information and opportunity for plant breeders to develop new high-yielding crop varieties (Govindaraj *et al*., 2014).

Conclusion

Result obtained from this study was able to emphatically establish the important of morphological parameters for genetic evaluation and grouping of accession into mean full cluster for identification of best accession with desired heritable traits. Information from this study will guide in the management and planning for coffee improvement strategies in Nigeria. Further study is needed to explore more accessions and also to relate the observed diversity to other traits with the aim of identifying best parental for breeding programs. The traits could be incorporated into intensive molecular characterization for quality related traits (caffeine content) and use of coffee plants for aesthetics value.

ABSTRACT

Nine cocoa clonal materials AMAZ 15, MAN 15, UF 676, ICS 95, PA 150, SCA 6, N 38, SPEC 54 and IMC 47 were selected from 25 clones at the International Cocoa Clonal Germplasm of Cocoa Research Institute of Nigeria, Ibadan. After self-pollinated, the resultant true-to-type seeds were raised into seedlings and transplanted into a field in Ibadan. Data were collected on the Plant height, Stem diameters and Leaf Relative Water Content (LRWC) to determine the influence of LRWC on the growth performances of these cocoa materials over two separate dry and wet seasons in the first two years of establishment. There was variation in the performances of the variables measured with SCA 6 and PA 150 have higher growth values than some clones like N 38, ICS 95 and AMAZ 15.

Key words: Cocoa, establishment, plant height, stem diameter, relative water content

INTRODUCTION

Cocoa is a tropical crop that grows in areas with high annual rainfall and its production is prone to periodic drought due to seasonal rainfall patterns that sometimes include a long dry season. In West Africa where over 70% of the global cocoa beans are produced, the cocoa plant is still majorly grown as a rainfed crop with its vegetative and reproductive growth mainly controlled by a range of environmental factors. At some levels of water stress and high temperature conditions, cocoa shows adaptations to various physiological levels for its survival and growth. For dry weather to affect cocoa plant, the amount of rainfall must lead to a soil water deficit and ultimately to a plant water deficit situation. Despite the fact that drought negatively impacts the survival and growth of the crop (Abo-Hamed *et al*., 1985, Razi *et al*., 1992, Belsky and Siebert, 2003) selection of cocoa clones based on how they respond physiologically to drought has been meagre (Zuidema *et al*., 2005) and very little research has been directed towards the identification and development of drought tolerant traits in the cocoa germplasm (Balasimha *et al*., 1988, Bae *et al*., 2008). In fact, much of the little research work on how cocoa react to stress are carried out under artificial stress conditions of which the results of plants response may not be representative of the crop response in the field conditions. Therefore, on-the-site research is needed to gain basic understanding of the effects of drought stress on cocoa and reduce the chances of crop failure since such experience is needed to ensure improvement of crop and soil water management to develop drought tolerant cultivars (Ayegboyin, 2012). This present experiment was then carried out to study the effect of leaf relative water content on the plant height and stem diameter in young cocoa trees across two different dry seasons and two wet seasons in Ibadan, Nigeria.

MATERIALS AND METHODS

Nine cocoa clonal materials namely AMAZ 15, MAN 15, UF 676, ICS 95, PA 150, SCA 6, N 38, SPEC 54 and IMC 47 were selected from the 25 cocoa clones established at the International Cocoa Clonal Germplasm of Cocoa Research Institute of Nigeria, Ibadan. Hand pollinated seeds of the nine selected clones were produced and later raised into seedlings which were true-to-type with their parental clones. Five stands per cocoa clone were planted in 3 replications to make up 135 experimental cocoa stands established on the field using a completely randomized block design. The plant height, stem diameter and leaf relative water content (LRWC) were determined for the cocoa plants during the 1st two years of establishment which cut across 2 dry seasons and 2 wet seasons. The plant height and stem diameter were measured in-situ. While the height of cocoa was measured with 1-meter rule, the stem diameter was determined with the aid of a digital vernier caliper. The LRWC was determined in the laboratory using various procedure. First, about 20 leaf discs of diameter 10mm per disc were removed from each sample leaf and the fresh weight (FW) of the discs was determined. Later, 40ml of distilled water was added to the discs in each petri-dish and left to float for specific temperature for complete 24 hours to allow them reach full turgor and their turgid weight (TW) was determined. The discs were then transferred into clean brown envelopes before

ISSN: 2814-0508

being dried in the oven at 65⁰C for 3hrs to determine their dry weights (DW). The LRWC plant was then calculated in % using the method of Turner (1981) while all the procedures adopted had been fully explained in Ayegboyin, 2012.

RESULTS AND DISCUSSION

There were significant clone season interactions at 6, 15 and 18 MAT, representing later part of the 1st dry season and full 2nd dry season after establishment. Values were not significant (NS) at 9, 12, 21 and 24 MAT (1st and 2nd wet seasons). This shows that cocoa growth during the experimental period varied with seasonal water availability while clones are prone to varied osmotic adjustment during water deficit. SCA 6 and PA 150 plant heights were significantly higher than those of the N 38 during the 1st and 2nd dry seasons which is an indication that some cocoa clones tolerate soil water deficit than the others (Table 1).

Table 1: Mean plant height during the first two years of establishment (cm)

	Months After Transplanting (MAT)							
	1st dry season		1st wet season		2nd dry season		2nd wet season	
	3	6	9	12	15	18	21	24

Values represent the means of three replicates (two trees per replicate) while NS means Not Significant

The stem diameters of cocoa across all seasons showed genotypic differences between clones. There were significant clone*season interactions in the dry seasons with SCA 6 and PA 150 having significantly higher stem diameter than ICS 95 and N 38 at 6 and 18 MAT (Figure 1). This confirms that increase in cocoa stem diameters had similar features with increase in the cocoa plant heights with both parameters showing the influence of genes and environmental factors on their performances (Balasimha, 2011).

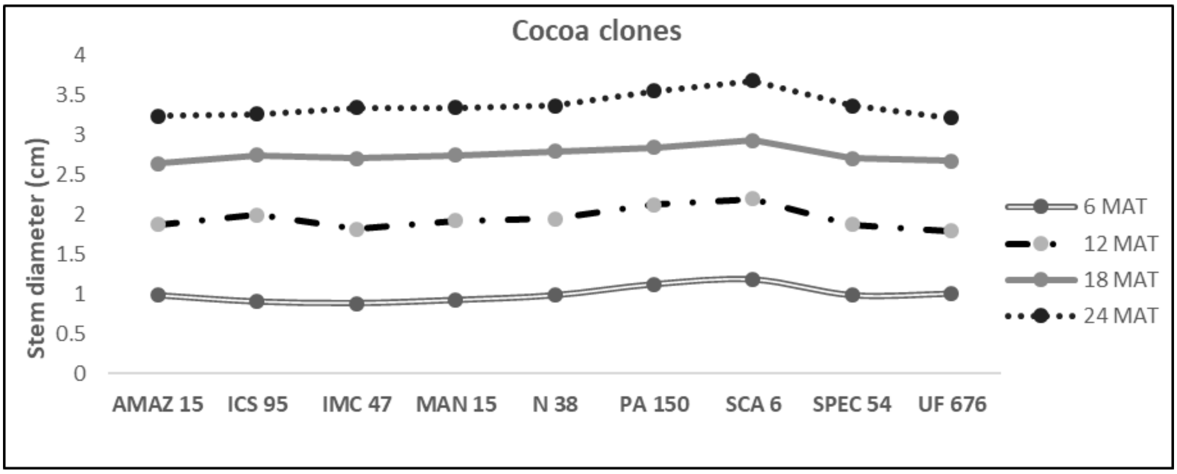

Figure 1: The stem diameters of cocoa clones during the 1st two years of establishment. Values represent the means of three replicates (two trees per replicate) and MAT means Months After Transplanting.

ISSN: 2814-0508

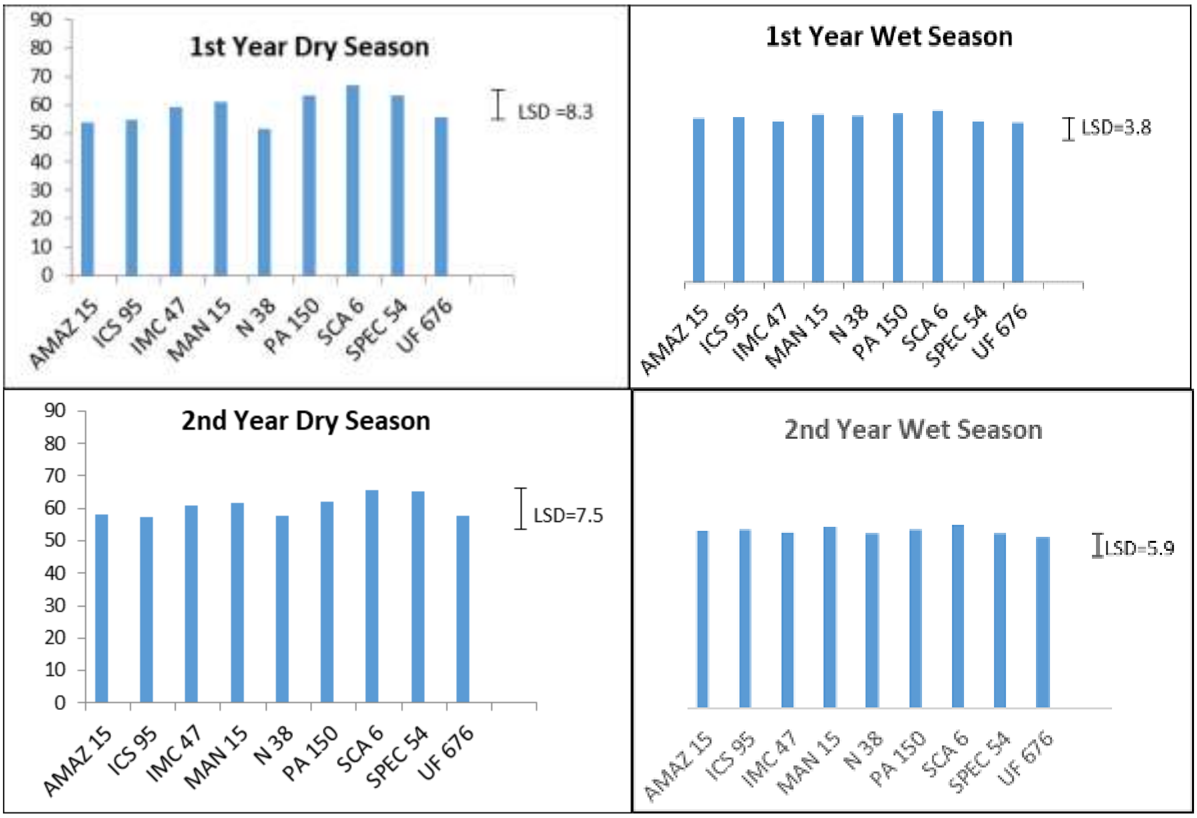

Figure 2: Leaf Relative Water Content (LRWC) of cocoa clones during the 1st two years of establishment. Values represent the means of three replicates (two trees per replicate) and two measurements. Bars shows the Least Significant Differences (LSDs).

The LRWC showed significant cocoa clone*season interactions during the 1st and 2nd year dry seasons with SCA 6 and PA 150 having significantly higher values than ICS 95 and N 38 at 6, 9, and 15 MAT. Wet seasons recorded higher LRWC values than dry seasons thereby revealing varied osmotic adjustment by cocoa clones during water deficit. The values of cocoa LRWC were not significantly different among clones during the two wet seasons. Similar reports of relative decrease in LRWC among cocoa clones during dry season condition had been made by Abo-Hammed *et al.* (1985), Balasimha *et al*. (1988) and Ayegboyin (2012). Although, Abo-Hammed *et al*. (1985) reported LRWC of 80 % as the lowest value in cocoa, the present study in Nigeria showed that overall highest LRWC in cocoa was 79% which is similar to those obtained in Ghana by Acheampong (2010). One explanation to this is that since Nigeria and Ghana shared almost similar climatic features, the LRWC of cocoa is not only dependent on genetic and seasonal variability, but also on many other climatic factors like temperature and relative humidity which are determinants of water potential of cocoa trees. This reports confirms the position of Balasimha (2011) that LRWC of cocoa cultivars is not only genetic but also dependent on soil-water potential, air relative humidity and daily mean temperature. The ability to keep the LRWC high during the period of water deficit might be one of the traits responsible for SCA 6 and PA 150 to maintain normal activities like photosynthesis and produced significantly higher plant heights and stem diameters than N 38 during dry seasons. This confirms that for plant cells to exhibit normal activities and growth during growth, its leaves must maintain high turgor under low plant-water availability while such turgor pressure are governed by osmotic adjustment (Chimenti *et al*., 2002; Martínez *et al*., 2007).

The sustenance of a reasonable growth in dry seasons by some cocoa clones showed that those cocoa trees had relatively enough LRWC for optimum leaf turgor despite soil water deficit situation during those dry seasons. One explanation for this is that due to their genetic capabilities, the soil water deficit in dry seasons could not affect the provision of enough plant-water potential sufficient to avoid significant loss of water from the leaves in such cocoa clones. This confirms the fact that while LRWC and many other metabolic processes are negatively affected during increase intensity of drought (Balasimha, 1985), the reduction of plant water potential is not a product of loss of soil water in plant (Martínez et al., 2007). The present study showed that cocoa LRWC, plant height and stem diameter were not just a function of genetic capabilities but are influenced by many environmental factors such as weather and soil conditions of an area (Ayegboyin[1], 2019). The superior performance of SCA 6 and PA 150 than some other clones showed that these clones were less affected by water stress. Such drought tolerant clones possess stronger abilities to maintain some good photosynthetic rates under many precarious conditions that negatively affect other clones (Ayegboyin, 2019).

ABSTRACT

An experiment was carried out between December 2019 and April, 2020 at the screen house of Centre of Excellence in Agricultural Development and Sustainable Environment (CEADESE), Federal University of Agriculture, Abeokuta. The experiment was conducted to evaluate the effects of shade and water stress on growth of two varieties of cocoa. It was a 2 x 2 x 2 factorial experiment. Factor-1 was shade provision: Shaded and un-shaded, factor-2 was volume of water supplementation: 600mls/plant/week (no stress), and 150 mls/plant /week (stressed) and Factor-3 was cocoa variety: CRIN TC-1 and CRIN TC-2. The experiment was laid out in Completely Randomized Design replicated three times. The effects were monitored by collection of data on growth components which include, plant height, stem girth, total leaf area and dry matter production of leaf, stem and root. Data generated were subjected to Analysis of Variance and means separated using Least Significant Differences (p<0.05). Shade significantly enhanced stem girth and leaf area of cocoa in the nursery. Cocoa grown under shade had significantly (p<0.05) thicker stem girth, larger leaf area surface and higher root weight value compared to those without shade. Cocoa that received 600mls/plant/week water had significantly (p<0.05) taller, thicker girth, larger leaf area surface as well as higher leaf, stem and root weight compared to those that received 150 mls/plant/week. Variety CRIN TC-1 had significantly taller plant compared to CRIN TC-2 while CRIN TC-2 was superior with respect to stem girth and higher root weight value compared to CRIN TC-1. The interaction of shade x water supplementation rate x variety significantly affected growth of cocoa. CRIN TC-1 that received 600mls/plant/week grown under shade produced the tallest plant with larger leaf area surface. This study indicated the importance of shade and the supply of 600mls/plant/week water for growing of cocoa during the dry season. CRIN TC-1 is recommended as better cocoa variety.

Key words: Cocoa variety, Water stress, Shade, Growth

INTRODUCTION

Cocoa is one of the most important tropical crops in the world. Africa contributes 75% of the world's cocoa production and production is cantered in West Africa with Ivory Coast (2,034,000 t/ha), Ghana (883,652 t/ha), Nigeria (328,263 t/ha) and Cameroon (295,028 t/ha) being the first, second, fifth and sixth respectively in the world rankings of producers (FAOSTAT, 2017). Cocoa powder is used in baking cakes, biscuits, cocoa beverage, cocoa mixes, other confectioneries, baking, dairy products, including ice cream, soft drinks and in pharmaceutical and food preparations (Opeke, 2005).

Cocoa growth is highly sensitive to water and light availability (Zuidema *et al.*, 2005; Carr and Lockwood, 2011). Gateau-Rey et al. (2018) explained that drought stress can have substantial negative impacts on plant growth until the death of plant up to 15%. Drought stress has detrimental effects on the growth and yield of cocoa are well documented (Gateau-Rey *et al.,* 2018; Schroth *et al.,* 2016). Under drought stress, Medeiros *et al.* (2012) reported that the inflow of water reduces due low water avail-ability in soil, which potentially affects the physiological processes dependent on turgor pressure because of low water status in plant. Drought stress also inhibits the activity of enzymes, such as nitrate reductase (Mandi *et al.,* 2018). Then, it also causes the degradation of photosynthetic pigment, such as chlorophyll. The degradation in the concentration of photosynthetic pigments causes damage in photochemical activity. The present study aimed to examine the effect of shade and drought stress on the growth of cacao two cocoa varieties.

MATERIALS AND METHODS

The experiment was carried out at the at the screen house of Centre of Excellence in Agriculture Development and Sustainable Environment (CEADESE), Federal University of Agriculture, Abeokuta, Nigeria. This research was conducted from December 2019– April 2020. Each polybag was fulfilled with 3 kg soil. It was 2 x 2 x 2 factorial experiment, Factor 1 was shade at 2 levels (Shaded and un-shaded), factor 2 was irrigation volume at two levels 600mls/plant/week (no stress), and 150 mls/plant /week (stressed) and Factor 3 was cocoa variety at two levels (Crin T-c 1 and Crin T-c 2). Average monthly temperature ranges between 34.3- 36.80C in the shaded area and 41.2-44.50C in the un-shaded area (Figure 1). The average monthly relative humidity ranges between 41-46 % for the shaded area and 10-31% for the un-shaded area (Figure 2) while Average monthly light insolation ranges between 750 and 946 Lux for the shaded area and 18460-32600 lux for the un-shaded area (Figure 3). Data on shoot height, number of leaves, stem girth, number of branches were collected on at two-week interval. Dry matter accumulation was determined at 20 weeks after sowing (WAS) by carefully uprooting one plant per plot in and oven dried to constant weight at a temperature of 750 C. Data collected were subjected to Analysis of Variance (ANOVA) using GENSTAT (12th Edition) and treatment means separated using Least Significance Difference (LSD) at 5% probability.

RESULTS

Vegetative growth

Shade does not significantly influence plant height of cocoa. Although not significant, shaded seedlings were taller than the one without shade (Figure 4). However, the effect of irrigation volume had profound effects on plant height of cocoa was significant. Plants that were irrigated with

ISSN: 2814-0508

600mls/plant/week were significantly taller compared to those that received 150mls/plant/week from 8-20 WAS (Figure 5). Also, Crin-Tc 1 variety were significantly taller compared to Crin-Tc 2 from 8-20 WAS (Figure 6).

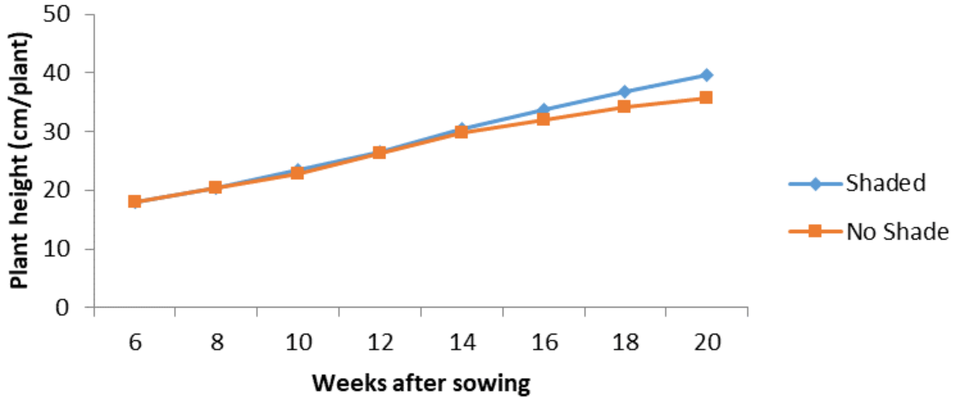

Figure 4: Plant height of cocoa as affected by shade

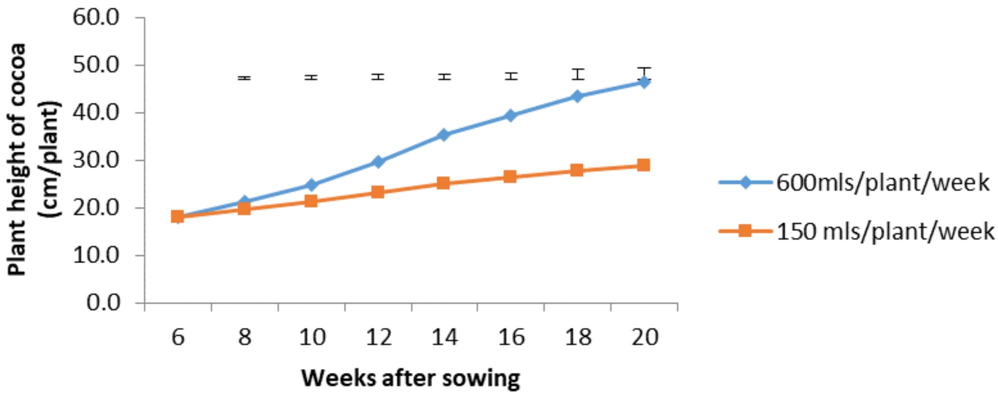

Figure 5: Plant height of cocoa as affected by irrigation rate

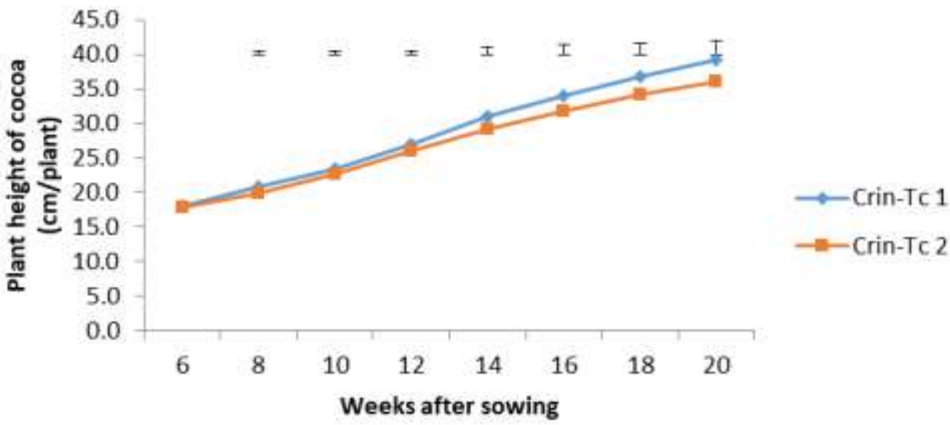

Figure 6: Plant height of cocoa as affected by variety

The interaction of shade x irrigation volume x variety was significant on plant height of cocoa from 14-20 WAS. Cocoa raised with water volume of 600mls/plant/week were significantly taller irrespective of shade and variety compared with those that received 150mls/plant/week. Crin-Tc 1 variety irrigated with 600mls/plant/week raised under shade were tallest compared with other treatment while the shortest plant height was recorded in Crin-Tc 2 irrigated with 150mls/plant/week with shade (Table 1).

Table 1: Interaction of shade, irrigation rate and variety on plant height of cocoa

Treatments			Plant height of Cocoa (cm/plant) Weeks after transplanting							
Shade	Water rate	Variety	6	8	10	12	14	16	18	20
No-Shade	600mls/plant/week	Crin-Tc 1	18.2	22.4	24.8	30.3	36.0	38.3	41.2	43.0
		Crin-Tc 2	17.8	20.3	24.1	29.4	35.4	39.2	42.9	45.5

Stem diameter of cocoa was influenced by shade significantly. Cocoa seedlings grown under shade had wider stem girth from 8-20 WAS compared to those without shade (Figure 7). Similarly, the effect of irrigation volume significantly influenced stem girth of cocoa. Cocoa seedling irrigated with 600mls/plant/week had significantly wider stem girth compared to seedlings that received 150mls/plant/week from 10-20 Weeks after Sowing (WAS) (Figure 8). Crin-Tc 2 variety elicited significantly wider stem girth compared to Crin-Tc 2 from 12-18 WAS (Figure 9). The interaction of shade x irrigation volume x variety was not significant on stem girth of cocoa. Although not significant, cocoa seedlings raised under shade and received application of 600mls/plant/week had wider stem girth (Table 2).

Shade significantly influenced leaf area of cocoa. Cocoa seedlings raised under shade had significantly higher leaf area value from 12-20 WAS compared to those without shade (Figure 10). Cocoa seedlings irrigated with 600mls/plant/week had significantly higher leaf area value compared to those that received 150mls/plant/week from 8-20 WAS (Figure 11). However, variety does not influence leaf area of cocoa (Figure 12).

The interaction of shade x irrigation volume x variety was significant on leaf area of cocoa from at 8, 10, 18 and 20 WAS. Generally, Cocoa seedlings raised under shade and received 600mls/plant/week had significantly higher leaf area value compared with those that received water volume of 150mls/plant/week (Table 3). Crin-Tc1 raised under shade and received 600mls/plant/week had significantly higher leaf area value while the least leaf area value was recorded in Crin-Tc 1 raised without shade irrigated with 150mls/plant/week (Table 3)

Dry matter production

The effect of shade was significant on dry root weight of cocoa seedlings. Seedlings resided under shade had higher dry root weight value compared to those without shade (Table 4). The effect of irrigation volume was significant on dry leaf, stem, root and total weight of cocoa seedlings. Cocoa seedling that received 600mls/plant/week of water had significantly higher dry leaf, stem, root and total weight compared to seedlings that received 150mls/plant/week (Table 4). The effect of variety was significant on dry root weight of cocoa. Crin-Tc 2 variety had significantly higher root dry weight compared to Crin-Tc 1 (Table 4).

The interaction of shade x irrigation volume x variety was not significant on dry weight of cocoa seedlings. Although not significant, cocoa seedlings raised under shade and received application of 600mls/plant/week had higher dry weight compared to those raised without shade (Table 5).

DISCUSSION

Optimal growth performance in the two cocoa varieties was obtained with shade. Opeke (2005) had earlier reported that provision of good shade enhances survival of cocoa seedlings during the dry season. He further reported that shade protect Cocoa plant from harmful effects of direct insolation and minimize the risk of leaf and branch scorch by establishing a more equitable eco-climate through the reduction of high intensity, temperature and air movement. This was in agreement with Olatunde *et al.* (2014) who attributed the better performance of the Cocoa seedlings grown under 50% shade on the high assimilation rate of the cocoa seedlings under this condition.

Adequate water provision in this study was found to be very critical for survival and growth of cocoa. Plant that received higher irrigation rate of water had better growth performance. Water deficit inhibits plant growth by reducing water uptake into the plant cells thus alters the rheological properties of the cell wall. Consequently, inhibition of growth by water deficit occurs prior to inhibition of photosynthesis or respiration (Hummel et al., 2010). This was in agreement with findings of Suzuki *et al*., (2014) who reported that among the abiotic stress, drought and heat stresses affects new cacao the most.

The interaction of shade and adequate water were critical for optimal growth of cocoa. Cocoa seedlings grown with shade and supplied with adequate moisture were superior to those grown under moisture and Heat stress. This indicated the complimentary role of shade in reduction of evapotranspiration rate from the leaf and soil of cocoa.

CONCLUSION

Apparently, from the results obtained from this study, shade is important for the growth of cocoa during the dry season period. Adequate moisture of 600mls/plant/week is necessary for optimal growth of cocoa and Crin Tc-1 as a better variety.

ABSTRACT
In Nigeria, there is increase in the demand for healthy and uniform micropropagated plantain plantlets especially during the start of the rainy seasons. Attempt has been made in this study to use different growth substrates to assist in the mass propagation and adequate supply of micropropagated plantain plantlets all year round. The growth substrates used were sawdust only, sawdust: top-soil (1:3), and sawdust: top-soil (3:1). At 21 days after treatment, the results showed that the percentage survival of the micropropagated plantlets was highest in sawdust only (100%) and highly significant when compared to the other substrates sawdust: top-soil (1:3) and sawdust: top-soil (3:1) both recorded 99% survival of the plantain plantlets. The average plant height was (124 mm) sawdust only> (105 mm) sawdust: top-soil (1:3)> (102 mm) sawdust: top-soil (3:1) while the average number of leaves was (8) sawdust: top-soil (1:3)> (7) sawdust only and (7) sawdust: top-soil (3:1). We therefore concluded that the use of sawdust only as a substrate for hardening of plantain plantlets will yield better results and produce well primary hardened plantain plantlets.

Key words: Plantain, plant tissue culture, sawdust, fruits, hardening chamber.

INTRODUCTION
Plantain (*Musa* sp. AAB cv. Agbagba) belongs to the family Musaceae. They are perennial monocotyledonous fruits grown in many tropical areas. The total world production of plantain and banana reached 70.8 metric tons in the year 2006 (FAO, 2007). The fruits are used both as staple food and dietary supplements (Assani *et al*., 2001). Generally, plantain cultivars are good sources of carbohydrates, proteins, vitamins and minerals. However, many pests and diseases are threatening the production plantain cultivars. In order to augment conventional breeding and to avoid constraints imposed by pests and pathogens, transgenic and *in* vitro approaches are being considered (Jain and Swennen, 2004). Plant tissue culture or micropropagation of plantain and banana has been extensively used for rapid production of high quality, disease-free and uniform planting material irrespective of the season and weather. However, a large scale application of this technology is hindered by high mortality experienced by micropropagated plantain plantlets when transferred into *ex vitro* conditions. During *in vitro* conditions, plantain plantlets grow under special conditions in relatively air-tight vessels i.e. air humidity is higher and irradiance is lower than in conventional culture (Uzaribara *et al*., 2014). High mortality is observed upon transfer of micro shoots to *ex vitro* conditions as the cultured plants have non-functional stomata, weak root system and poorly developed cuticle (Mathur *et al*., 2008). Primary and secondary hardening is an integral and vital activity of the whole process of tissue culture technology. Improper hardening leads to the failure of whole technology. Success in hardening is a must for the survival of micropropagated plantain plantlets to meet urgent demand for food security (Sukanya Parkhe *et al*., 2018, Radeshyam and Subramani, 2008). In this study, the role of formulated growth medium for acclimatization (primary hardening stage) of micropropagated plantain plantlets was investigated.

MATERIALS AND METHODS
Area of study and source of materials
This study was carried out at the Biotechnology Research Unit, National Horticultural Research Institute (NIHORT), Ibadan. The micropropagated plantain plantlets were collected from Biotechnology Unit of NIHORT, Ibadan.

Micropropagated plantain primary hardening experiment
The micropropagated plantain plantlets were subjected to primary hardening treatment using different formulated substrates i.e. sawdust only, sawdust + top-soil (1:3) ratio, and sawdust+top-soil (3:1) ratio. Eleven micropropagated plantain plantlets were used per treatments in a round tray placed in a humidity chamber with relative humidity of 75% and temperature of 35^{o}C for 21 days.

Data Analysis
The experiment was laid out in a completely randomized design in three replicates. Data were subjected to Analysis of Variance (ANOVA) and means were separated using SPSS version 23,

Duncan's Multiple Range Test at P < 0.05. The experiment was repeated twice.

RESULTS AND DISCUSSION

Effect of different growth substrates on the average plant height of micropropagated plantain seedlings after acclimatization experiment

The effect of different substrates on the survival and growth of the plantain plantlets were shown in Figure 1. The average height of the plantain plantlets in all the treatments used were initially 101 mm. After 21 days of treatment, the plantain plantlets with treatment of sawdust only had the highest average plant height of 124 mm as compared to the ones of sawdust +soil 1:3 which was 105 mm and sawdust +soil 3:1 which was 102 mm (Fig. 1). This agrees with the findings of Baiyeri *et al*., (2005) who concluded that banana plantlets at pre-nursery stage had the highest survival rate in mixture of sawdust only as compared to that of rice hull. However, Fornkwa *et al*., (2015) concluded that the treatment (substrate) biochar: soil: sand can be a better substrate for acclimatization of some plantain varieties in terms of leaf, stem and root development.

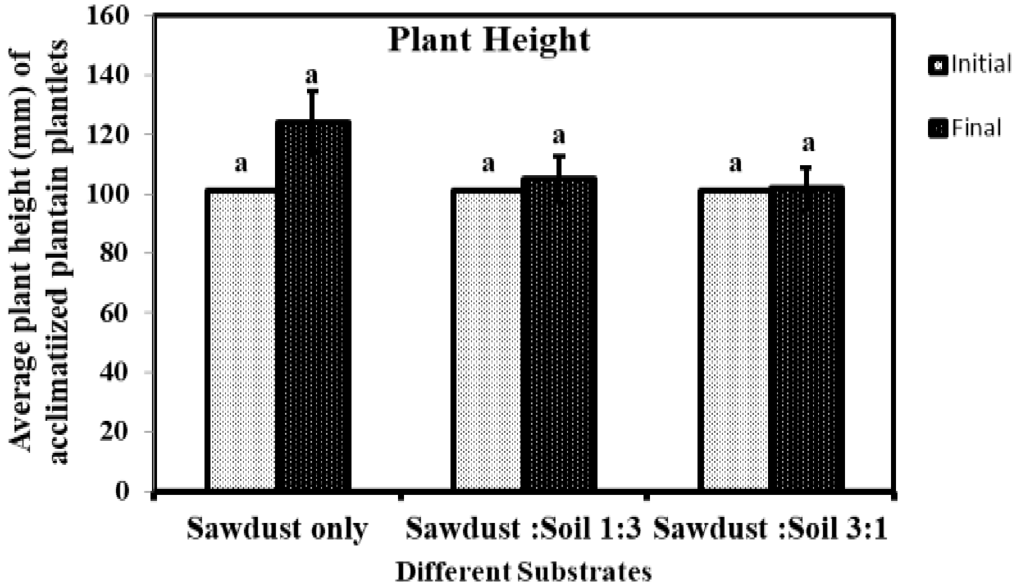

Figure 1: The effect of different growth substrates [sawdust only, soil+sawdust (1:3) soil+sawdust (3:1)] on average plant height (mm) of the acclimatized plantain plantlets showing the initial average plant length compared to final average plant length after 21 days of treatment.

Effect of different substrates on the number of leaves of tissue culture plantain seedlings after acclimatization experiment

In Fig 2, the plantain plantlets hardened on with sawdust: top- soil 1:3 had more average leaves of 8 when compared with the other substrates sawdust only was average of 7 leaves and sawdust+soil 3:1 was also average of 7 leaves. This is in line with the fimdings of Fornkwa *et al*., (2015) who concluded that sawdust alone as a substrate was not sufficient for the developments of more leaves on plantain seedlings during acclimatization.

Effect of different substrates on the percentage survival of tissue culture plantain seedling after acclimatization experiment

In Fig 3, the plantain plantlets hardened on both sawdust only and sawdust: top-soil (1:3) were having the percentage survival of plantlets after 21 days which was 99% as compared with those in sawdust only which had the highest percentage survival of plantlets of 100% after 21 days. Ubalua and Okorafor (2013) reported 100% survival rate of sweet potato plantlets grown on sterile substrates (river sand, saw dust, rice mill waste, river sand/rice mill waste, river sand/saw dust, saw dust/rice mill waste and jiffy peat) and 58% survival rate on unsterilized substrates. Sawdust is an ingredient that can keep the soil loose, which in turn enables the roots to spread out easily thus, giving it more breathing space and aeration. Consequently, better plant growth is achieved in sawdust growth medium. Kiran *et al*. (2018) as well as Ubalua and Nsofor (2017) also reported that acclimatization and growth of in vitro raised plantlets are highly correlated with the substrate porosity.

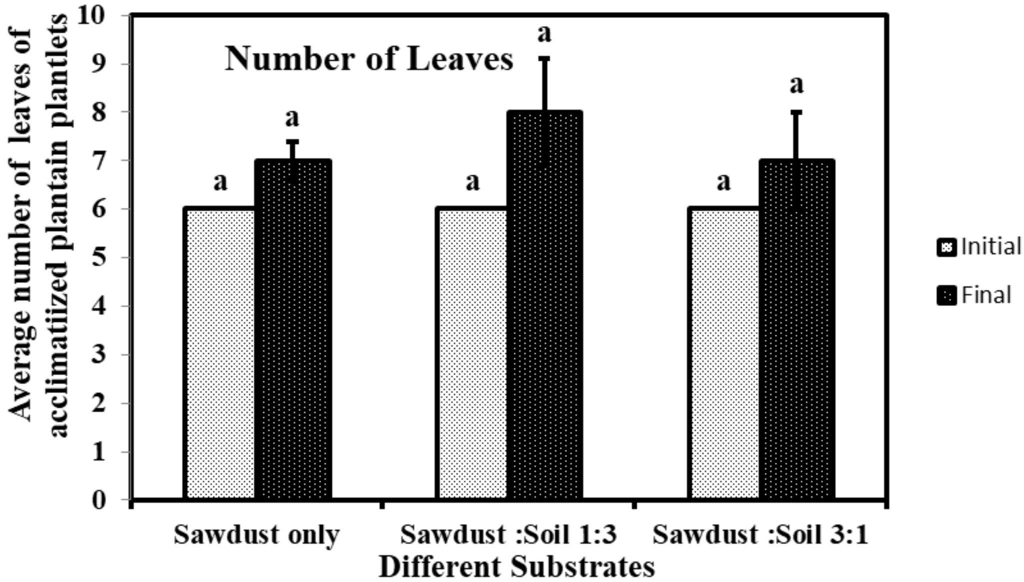

Figure 2: The effect of different growth substrates [sawdust only, soil+sawdust (1:3) soil+sawdust (3:1)] on average number of leaves of the acclimatized plantain plantlets showing the initial average plant length compared to final average plant length after 21 days of treatment.

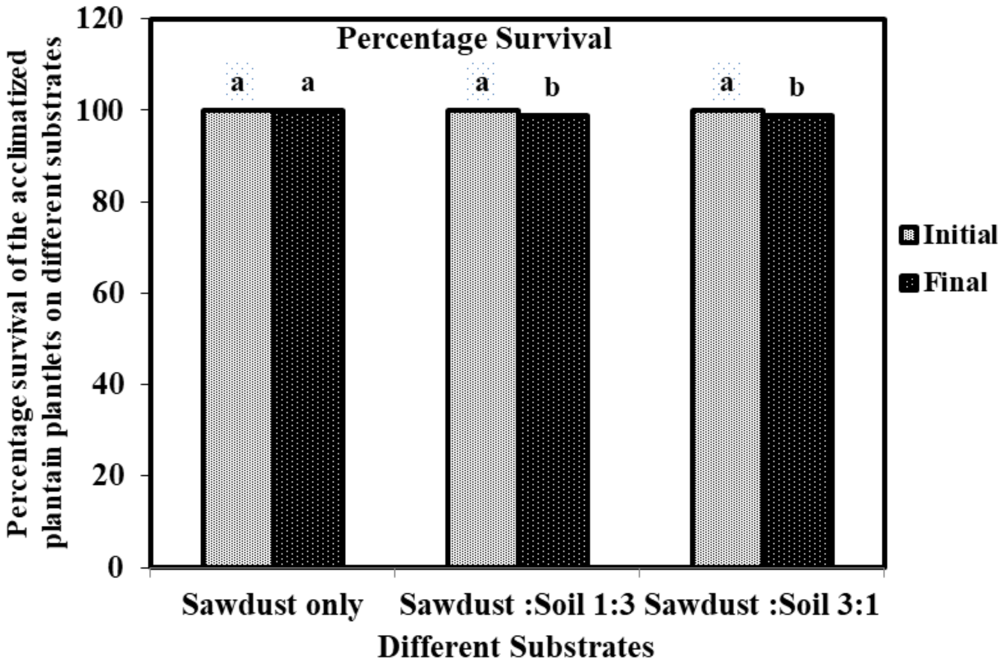

Figure 3: The effect of different growth substrates [sawdust only, soil+sawdust (1:3) soil+sawdust (3:1)] on percentage survival of the acclimatized plantain plantlets showing the initial average plant length compared to final average plant length after 21 days of treatment.

CONCLUSIONS

It is clear that the use of sawdust as substrates for primary hardening of micropropagated plantain plantlets enhanced and promoted better growth and survival of the plantlets because it had better air-permeability and also had appropriate retention. This substrate was suitable because the roots are not disturbed and it induces the growth of the leaves faster. The improved rooting and acclimatization achieved by this work could be used to optimize the secondary hardening of the plantain plantlets.

ACKNOWLEDGEMENTS

ABSTRACT

This research is aimed at optimizing the protocol for acclimatization of tissue cultured pineapple plantlets. Previously conventional substrates consisting of top soil mixtures have produced low yield and low survival rate of the tissue culture plantlets. Semi-Autotrophic Hydroponics (SAH) technique is being compared with Sawdust (SD) and Topsoil (TS) as a suitable method of acclimatization and further rooting of the plantlets. The experiment was conducted at the department of Biotechnology and Tissue Culture, National Horticultural Research Institute, Jericho-Idishin, Ibadan. Feb 2021 – April 2021. The crown of Ananas comosus (pineapple) was extracted and was cultivated in MS media. The plantlets were sub-cultured twice, after which they were taken into the hardening chamber. The plantlets were acclimatized in sterile substrate- Semi-Autotrophic Hydroponics substrate and other unsterile substrates – Topsoil (TS), Sawdust (SD), Sawdust and Topsoil (3:1) and Sawdust and Topsoil (1:3). 100% survival rate was observed for the plantlets grown SAH media as compared to the ones acclimatized on Topsoil and Sawdust combinations. The SAH media also enhanced further rooting of the plantlets, and there was significant increase in plant height. In conclusion, SAH media is a very effective media for the hardening and the acclimatization of micro-propagated plantlets.

Key words: Semi-Autotrophic Hydroponics, Acclimatization, Tissue Culture, Micro-propagation.

INTRODUCTION

Acclimatisation is an important step in the micro-propagation of plants. During in vitro culture, plantlets grow under special conditions in air tight vessels, thereby increasing humidity and controlling the temperature, unlike conventional culture (Yaya *et a*l., 2015). The aseptic environment in vitro reduces stress of pathogenic organisms. Quite a number of micropropagated plants do not survive the transition from in vitro environment to the field due to change in temperature, humidity and lightning (Hazarika, 2003). The ultimate success of tissue cultured plants on a commercial scale depends is the ability to transfer the clean plantlets from a controlled, aseptic environment to land successfully while maintaining a low cost and high survival rate. During the process of Tissue Culture, plantlets are handled with utmost care in a stable and well controlled atmosphere. The culture media serves as the nutrient source for the growing plantlet. The temperature, light and humidity of the laboratory are also controlled to suit the need of the plantlet. The transfer of tissue culture plantlets from the lab to soil usually leads to them being exposed to abiotic stresses, like altered temperature, light intensity, and humidity conditions, and biotic stresses, like soil microflora. The transfer of tissue culture plantlets from laboratory to soil needs to be slow and stepwise. This process is known as acclimatisation, which is the adaptation of organisms to a new environment.

Problem Statement

Various unsterilized substrates have been tried in the past for the acclimatization of micro propagated plantlets, leading to poor survival rate and poor yield. Ubalua and Okorafor (2013) reported 58% survival rate for sweet potato plantlets grown on unsterilized substrates. There is therefore need to develop a low cost easily accessible technology that would produce clean, virus free, sterile plantlets in large quantity within a short period of time, hence the introduction of the Semi-Autotrophic Hydroponics (SAH) Technology. This is a novel technology that is low-cost, licensed and rapid alternative method for the acclimatization of tissue culture cultivated plantlet and successful transfer to field. (Pelemo *et al*., 2019).

MATERIALS AND METHODS

The experiment was carried out at the tissue culture laboratory of National Horticultural Research Institute, Ibadan, Nigeria. Pineapple crowns were obtained from the research field of National Horticultural Research Institute. The crowns were sterilized with 50% Clorox (Sodium Hypochlorite 5.2%, (15mins)), 20% Clorox (10mins) and rinsed with sterile distilled water. Sterile crowns were cultured in the prepared medium which comprised of Murashige and Skoog (MS) (1962), supplemented with macro and micro elements, vitamins (Nitsch and Nitsch, 1965), 3% sucrose and 0.1 g/L myo-inositol. Cultures were incubated at 25

± 2°C for duration of four weeks for shooting and rooting induction.

Tissue Culture Media Composition

- Full MS (Murashige and Skoog) Media
- Vitamins
- 30% Sucrose
- 0.1g/L Myo-inositol
- 0.02g/L Cysteine
- Hormones

Hardening and Acclimatization in SAH Media

Clean, mature virus free plantlets were transferred into SAH (Semi-Autotrophic Hydroponics) Media for acclimatization to take place. SAH nutrient solution is added fortnightly to enhance growth. 15 micro-propagated plantlets were used per SAH container.

SAH Media Composition

SAH substrate consists of Nitrogen (N), Phosphorus (P) and Potassium (K) in the ratio 1:1:1

Nutrient Solution A: 35.4g of Solution Calcium Nitrate in 15L of distilled water

Nutrient Solution B:

- 14.7g of Magnesium Sulphate
- 4.08g of Potassium Monophosphate
- 15.5g of Potassium Nitrate
- 0.02g of Ferrous Sulphate

Make up to 15L with distilled water

Nutrient Solution C:

Mix 500ml of Solution A and 500ml of Solution B + 2litres of water to form Solution C

Note that Solution B must be kept in a black keg or container to prevent oxidation of iron compounds.

Hardening and Acclimatization in Saw Dust and Soil Mixtures

The micro-propagated plantain plantlets were subjected to primary hardening treatment using different formulated substrates i.e. Sawdust only, sawdust + top-soil (1:3) ratio, sawdust+top-soil (3:1) ratio and top soil only. Ten micro-propagated plantain plantlets were used per treatments in a round tray placed in a humidity chamber with relative humidity of 75% and Temperature of 35°C.

RESULTS AND DISCUSSION

There was a significant effect of substrate on root length, plantlet height and leaf number ($p<0.05$) for the acclimatization period (Table 1). Mean values for all substrate combinations were illustrated in figure 1. There was a significant increase in Plant Height for the substrate SAH, as against other substrates. The plantlets in SAH, SD and SD:TS 1:3 showed a significant increase in root length, with SAH having the highest value, followed by SD. The plantlets in SAH also had 100% survival rate as against SD:TD 3:1 which had 50% survival. It was demonstrated that pineapple acclimatization was the most efficient in Semi Autotropic Hydroponics media, because the growth yield increased significantly compared to the conventional method in sawdust and topsoil under the same environmental conditions (Fig. 2 and 3). These finding are in agreement with the findings of Ariadne *et al*. (2015) who agreed that the use of SAH with in vitro rooted plants increased efficiency in the 'transfer from culture' process, because it improved the survival percentage and facilitated management of them.

Table 1: Showing Least Squares Means for the plant growth parameters

SUBSTRATE	PLANT HEIGHT		NO OF LEAVES		ROOT LENGTH	
	Day 1	Day 15	Day 1	Day 15	Day 1	Day 15

ABSTRACT

The National Horticultural Research Institute (NIHORT) has the mandate to produce large scale plantain suckers, pineapple suckers, and other horticultural crops using Plant Tissue Culture technique (micropropagation) and Temporary Immersion Bioreactor System (TIBS). The conventional field split-corm technique and PIFF (macropropagation) method for low-cost plantain multiplication is also used to complement plantain production effort. Recently, a new technology called Semi-Autotrophic Hydroponics (SAH) was introduced to assist mass propagation of horticultural crops. An average of 1,024 plantain tissue culture planting materials and 40,000 pineapple tissue culture planting materials were realized at 28 weeks after culture. For plantain tissue culture, the average number of suckers regenerated using TIBS was thrice what was realized in conventional tissue culture at the same period. Consequently, the application of biotechnology for efficient mass production of disease-free horticultural crop planting materials for food security in Nigeria is essential.

Key words: Plantain and Banana, Murashige and Skoog medium (MS), suckers (planting materials), hormones, plant tissue culture

INTRODUCTION

There is urgent need to supply enormous numbers of healthy and uniform planting materials to local and commercial farmers. The traditional methods of horticultural crop propagation especially plantain, banana, and pineapple cannot meet this demand. Fortunately, the National Horticultural Research Institute (NIHORT) has the mandate for these crops. Hence, the Biotechnology Research Unit, NIHORT, Ibadan employs micropropagation or plant tissue culture methods widely known for large scale clonal propagation to meet some of the Institute's crop mandate which include varieties of fruits, citrus, vegetables, spices and ornamentals. Plant tissue culture is a process of *in vitro* aseptic culture of cells, tissues, organs or a whole plant under controlled environmental and nutritional conditions with the aim to produce clones of the parent or explants. It has made possible the mass production of desired traits with disease-free and uniform plantlets. The technique thus brings farmers the great benefits of high-quality planting materials all year round. Some of the achievements of using biotechnology applications for efficient mass production of plantain (*Musa* sp. AAB cv. 'Agbagba'), pineapple (*Ananas comosus* var. smooth cayenne), and *Telfairia occidentalis* for food security in Nigeria are hereby reported.

MATERIALS AND METHODS

Conventional plant tissue culturing

Plantain (*Musa* sp. cv. Agbagba) conventional plant tissue culturing

Plantain sword suckers are gotten from the Institute's germplasm field collections. They were thoroughly washed under running tap water for at least 1 hour. The explants were collected from the sword suckers and brought to the laboratory for further tissue culture preparatory work. The plantain explants were cultured aseptically following the methods of Akinyemi *et al.* (2018).

Pineapple (*Ananas comosus* var. smooth cayenne) conventional plant tissue culturing

Fresh pineapple crowns were collected from the Processing Unit, NIHORT. The explants were initiated, sub-cultured and multiplied following the methods of Akin-Idowu et al., 2014. The subculturing was done aseptically to avoid contamination and loss of the explants.

Ugu (*Telfairia occidentalis*) conventional plant tissue culturing

Embryo of *Telfairia occidentalis* were cultured on media in test tubes and allowed to develop shoots and roots. Sub-culturing was done at 21 days after the first culture. Nodal cuttings were taking from the regenerated plantlets and transferred into fresh media in other test tubes for proliferation steps following the methods of Akinyemi and Esuola (2012).

Temporary Immersion Bioreactor System (TIBS)

Plantain and pineapple in Temporary Immersion Bioreactor System (TIBS)

Regenerated tissue culture plantain and pineapple plantlets were placed in MS liquid medium containing appropriate hormones and vitamins in TIBS jars. The TIBS was set-up to run automatically.

RESULTS AND DISCUSSION

Plantain, pineapple, and Ugu conventional plant tissue culturing

An average of 1,024 plantain tissue culture plantlets and 40,000 pineapple tissue culture plantlets were realized at 28 weeks after culture (Fig. 1A-B). In addition, the biotechnology unit has developed successful protocols for mass multiplication of plantain, banana, pineapple, and ugu plantlets (Fig. 2A-J).

Plantain and pineapple in Temporary Immersion Bioreactor

The average number of plantain and pineapple suckers produced using the TIBS liquid medium set-up after 21 days were three-fold and ten-fold respectively, when compared to the conventional tissue culture placed on agar solidified MS media. This result is useful as it rapidly produces disease-free planting materials to meet the high demand by farmers in order to generate more income in the face of the current prevailing adverse climatic conditions (Fig. 2B). For plantain tissue culture using TIBS, the average number of suckers regenerated is thrice what is realized in conventional tissue culture at 28 weeks after culture.

Semi-Autotrophic Hydroponics (SAH)

The backbone of the micropropagation process lies in the successful rooting and hardening of the tissue culture-derived plantlets. Semi-Autotrophic Hydroponics has been successfully used in the acclimatization of rootless pineapple tissue culture-derived plantlets (Fig 2G).

Challenges in plant tissue culture laboratory

The major challenges faced are incessant power failure or irregular electricity power supply, lack of constant running tap water; need to maintain a sterile laboratory environment, and access to quality chemicals and consumables. For biotechnology applications to be successful, the provision of constant electricity is non-negotiable.

CONCLUSIONS

Biotechnology application is very important as it complements conventional plant production practices for sustainable Agriculture in Nigeria. The Plant Tissue Culture Laboratory, NIHORT is well equipped to handle production of plantain, pineapple, *Telfairia occidentalis* plantlets, and plantlets of other horticultural crops. This is very useful for meeting the needs for clean planting materials by farmers. We recommend for policy on the adoption and use of these healthy planting materials by local and commercial farmers for better livelihood and reduction in transfer of diseases.

ACKNOWLEDGEMENTS

The authors are very grateful to the Management and Staff of the National Horticultural Research Institute, Nigeria for their support. Ojo, Y.K. and Adeyemi, M.S. are acknowledged for field assistance.

ABSTRACT

Air layering is a method of macropropagation technique which still finds its relevance in the present day domestication and routine plant multiplication efforts of fruit trees, including Malay apple (Syzygium malaccense: Myrtaceae family). There is dearth of information concerning propagation of S. malaccense by air layering in Ishiagu derived savanna agroecological zone of southeast Nigeria. Therefore, field trial of season effect and 1-Naphthalene Acetic Acid (NAA) rooting hormone application on air layering of S. malaccense was conducted in Ishiagu field condition. The treatments comprised two seasons (dry and wet seasons weather) and five NAA concentrations (0.01, 0.02, 0.04, 0.08% and control – zero NAA) which were arranged in a factorial experiment in randomized complete block design and replicated three times. Number and length (mm) of adventitious roots formed were assessed at eight weeks after girdling. Data were analysed using descriptive statistics and ANOVA at $\alpha_{0.05}$*. The result indicated that branches of S. malaccense air layered during wet season produced longer and more adventitious roots (2.3±0.96 and 3.9±1.60, respectively) than the dry season air layered branches (1.6±0.67 and 1.9±0.48, respectively). The 0.02% NAA induced more number of roots (3.6±2.82) than the control (no NAA) (2.5±0.50), while the least (1.9±0.65) was produced by 0.08% NAA. Highest root length was however, produced by control (4.6±1.30), and followed by 0.02% NAA (3.2 ± 0.55). In Conclusion, 0.02% NAA proved to enhance root initiation in air layering of Syzygium malaccense in both dry and wet seasons.*

INTRODUCTION

Fruit trees constitute important biological resources in many agro-ecological systems and forest ecosystems all over the world. This is evident by the fact of these species long time economic and ecological impacts in nature (Altieri, 2000; Mithofer, 2005). Fruits are full of nature's rich in essential nutrients, antioxidants, dietary fibres and health benefits for ready use by humans and animals without alternation in most cases, unlike vegetables and other edible agriculture and horticulture produce that may require necessary pre-treatments, like heating, sometimes before consumption (FAO, 2017; Bioverity International, 2019). The tropics, more than any other region of the world is endowed with great diversity of fruit tree species that have provided humans with basic food and nourishment for ages since the domestication of beneficial wild plants (Kulnlein *et al*., 2009).

Syzygium malaccense is a species of tropical fruit tree belonging to the Myrtaceae family; native to Southeast Asia and the Oceania, including Australia and New Guinea. It has been introduced throughout other parts of the tropics (including Nigeria where it is known simply as "local apple"). The *S. malaccense* has a number of English common names. It is known as a Malay rose apple, or simply Malay apple, mountain apple, Otaheite apple, pink satin-ash (Whistler and Elevitch, 2006; Christenhusz *et al.,* 2018). The combination of tree, flowers and fruit has been praised as the most beautiful of the *Syzygium* genus. The fruit is oblong-shaped and dark red in color, although some species have white or pink skins. The flesh is white and surrounds a large seed. Its taste is bland but refreshing. Jam can be prepared from it by stewing the flesh with brown sugar and ginger (Keay, 1989; Orwa *et al.,* 2009).

Air-layering is a technique that has been widely used in domestication of indigenous fruit trees in west and central Africa in capturing the attributes of elite trees within genetically diverse wild populations, so avoiding the long, slow process of tree breeding. The natural tendency of some plants to strike roots when their branches come into contact with soil forms the basis of propagation by layering. However, there is little research work available on air layering of *Syzygium malaccense* in southeast Nigeria. The goal of this research work is to contribute to the promotion and domestication of local fruit production in the sub-region. Specific objectives therefore included: to determine amenability of *S. malaccense* to air layering propagation in the study location; to evaluate effect of growth hormone (NAA) application on adventitious root induction of air-layered *S.*

ISSN: 2814-0508

malaccense; to determine optimum growth hormone (NAA) concentration for best rooting ability in air layered *S. malaccense*.

MATERIALS AND METHODS

The experiment was conducted at Tree Crops Nursery of Federal College of Agriculture (FCA), Ishiagu Ebonyi State, in the derived savanna agroecological zone of southeast Nigeria. The College lies along 05˚55'N latitude, 007˚33'E longitude and elevation of 59 m above sea level with average annual rainfall of 1735.7 m and average annual temperature of 29.4 ˚C and mean relative humidity of 69% during dry season. The basic weather data of Ishiagu location is shown in Table 1. The treatments consisted of two seasons: dry (March) period and wet (July) period; and five 1-Naphthalene Acetic Acid (NAA) concentrations (0.01, 0.02, 0.04, 0.08% NAA and control – zero), which were arranged as factorial experiment in Randomized Complete Block Design ((RCBD) and replicated three times. There were three (3) tree stands representing the three blocks/replicates. Branches (1.0 ± 0.2 cm in diameter) were girdled by cutting a 5 cm wide ring of bark to expose the cambium at the proximal end. Moistened mixture of river sand and saw dust (1:1; w/w) was tied around the girdled part using polythene sheet. The growth medium held in the polythene sheet around the girdled portion was kept moist by injecting 100 ml of distilled water into it twice a week using hypodermic syringe. The experiment was monitored for eight weeks after girdle operation when the air layered part has developed noticeable adventitious roots. Measurements on percent adventitious root formation, root length (mm) and number of root per successful air layered branch were taken. Statistical analysis of data was performed by use of descriptive statistics and Analysis of Variance (ANOVA). Separation of treatment means for significant effect was done by the use of Least Significant Difference (LSD) at p≤0.05.

December	0.0	23	33

†Main flowering period of *Syzygium malaccense* is January – March and May.

RESULTS AND DISCUSSION

Effect of NAA rooting hormone application and season of propagation on root length of air layered Syzygium malaccense

The results in Table 2 indicated that the wet season produced longer roots than the dry season, while the various hormone concentrations used in the experiment indicated that 0.02% NAA was better than all the rooting hormone concentrations, with exemption of control (zero NAA). Even in dry season, the 0.02% concentration of the NAA growth hormone still produced more extended roots than other treatment concentrations. The zero NAA concentration however, produced significantly longer adventitious roots at p≤0.05 in both dry season and wet season trials than other concentration of the rooting hormone. This is in consonance with Ogbu *et al.* (2019) report in the domestication study of *Pentaclethra macrophylla* by marcotting across different dry and wet seasons. Dhillon and Mahajan (2000) reported that wet season was the best time for air layering in *S. malaccense* in respect of rooting success and survivability. Besides the favourable moisture availability during the wet season that tend to sustain adventitious root production, the physiology of tree growth phases shows (Table 1) that *S. malaccense* undergoes active vegetative growth cycle during this wet season period than dry season. The period between January and March coincides with the reproductive cycle of the Malay apple, with minor blooming on May (Keay, 1989). Thus, when tree undergoes period of reproductive cycle, anti-auxin substances are released that make active vegetative growth to be suspended and the buds appear to enter state of dormancy (Awodoyin and Olaniyan, 2000). Hence, shoots air layered or collected for stem cuttings at such reproductive phase may largely be unresponsive or slow to formation of adventitious roots due to inhibiting endogenous factors (Jaenicke and Beniest, 2002; Hartmann *et al.,* 2007; Chadha, 2009). This may offer additional reason for the relative poor adventitious root formation observed among stems air-layered during dry season (i.e. period of reproductive growth).

Table 2: Root length (mm) of air layered *Syzygium malaccense* treated with different NAA concentrations across two seasons in Ishiagu derived savanna zone of Southeast Nigeria

	Naphthalene acetic acid (NAA) concentrations (%)					
Season	Control (zero)	0.01	0.02	0.04	0.08	Mean
Dry (March)	3.3±5.70	1.6 ± 0.23	2.6 ± 0.62	0.7± 0.23	1.6± 0.47	1.6 ± 0.67
Wet (July)	5.9±10.00	2.3 ± 0.47	3.7 ± 0.47	2.0 ± 0.81	1.0± 0.40	2.3 ± 0.96
Mean	4.6±1.30	1.9 ± 0.35	3.2 ± 0.55	1.4 ± 0.65	1.8± 0.30	

Value = mean±SD; r=3, LSD (0.05) treatment combinations = 1.11; LSD (0.05) NAA concentrations = 0.78
LSD (0.05) Seasons = 0.52.

Effect of NAA rooting hormone application and season of propagation on number of roots of air layered Syzygium malaccense

The result on Table 3 indicated that wet season produced longer roots than the dry season. The various hormone treatments used in the experiment also indicated that 0.02% NAA rooting hormone was the best among the other treatment concentrations. Even in the dry season the 0.02% concentration of the NAA growth hormone still produced more number of roots than other concentrations. The wet season was more preferable for rooting of air layered shoots of *S. malaccense* because moisture availability is one of the essential conditions for successful air layering among other endogenous factors like the species phenology, as earlier explained (Hartmann et al. 2007, Ogbu *et al.,* 2019). Callus formation was observed in both seasons in all the treatment concentrations. However, root initiation was more in wet season due to relatively low temperature coupled with higher humidity compared to dry season. Moreover, the presence of inflorescences (when tree undergoes period of reproductive cycle during dry season), which exert anti-auxin retarding influence on vegetative growth activities (Awodoyin and Olaniyan, 2000; Ogbu and Okocha, 2018), might have contributed to the observed low adventitious root formation in the dry season than wet season.

Table 3: Number of roots of air layered *Syzygium malaccense* treated with different NAA concentration across two seasons in Ishiagu derived savanna zone Nigeria

	Naphthalene acetic acid (NAA) concentrations (%)					
Season	Control (0.00)	0.01	0.02	0.04	0.08	Mean
Dry (March)	2.0±3.50	2.0 ± 0.00	1.6 ± 0.47	1.3± 0.47	2.6± 0.47	1.9 ± 0.48
Wet (July)	3.0±4.70	4.3 ± 1.24	5.6 ± 1.24	4.6± 0.47	1.3± 0.47	3.9 ± 1.60
Mean	2.5±0.50	3.1 ±1.15	3.6 ± 2.82	2.9± 1.65	1.9± 0.65	

Value = mean±SD; r=3, LSD (0.05) treatment combinations = 1.51, LSD (0.05) NAA concentrations = 1.06,
LSD (0.05) Seasons = 1.73

CONCLUSION

The result of the study indicated that air layering method is a potential, viable and economical method of vegetative propagation of *Syzygium malaccense.* Air layering is relatively simple and very easily adopted by farmers due to high success rate and low mortality. From the results obtained by air layering of the fruit tree *S. malaccense,* it can be concluded that wet season enhanced air layering of the species more than dry season. The hormone treatments proved successful in inducing adventitious root as 0.02% NAA was more effective in promoting root formation in both seasons than other concentrations used in experiment.

THE EFFECTS OF ROOTING HORMONES ON CALLUS DEVELOPMENT AND PLANT SURVIVAL OF MARCOTTED AFRICAN STAR APPLE (*GAMBEYA ALBIDA*)

*Enudeme, N.M. and Ojeifo, I.M.

Delta State University, Abraka, Nigeria

*Corresponding author's e-mail: sundaymartins43@gmail.com

ABSTRACT

A field experiment was carried out in the Teaching and Research Farm of Delta State University, Asaba Campus to evaluate the effects of different rooting hormones on marcotted Gambeya albida. A Completely Randomized Design with three replicates was used to assess the impact of Honey, IBA 1000 ppm, IBA 500 ppm and Control on callus production and pant survival. Vegetative variables evaluated included number of survival of marcotted stem after severance from the tree, number of stems with callus, propagule survival and callus growth were assessed. The study showed that there were significant differences between the Rooting hormones. The result obtained for number of successful marcots showed that IBA 1000 ppm had the highest percentage of successful marcots with 4.30 (38%), while Control had 1.91 (18%) at 12 weeks after severance from the tree. This study has shown that callusing can be influenced by the use of rooting hormone. Since, an increase in success was obtained for IBA, higher concentrations should be exploited in further studies. The success achieved showed that it is possible to regenerate propagules of African cherry through the use of rooting hormones especially, Indole-3 Butyric acid.

Key words: Rooting hormones, Marcotting, African star apple.

INTRODUCTION

In Nigeria, *Gambeya albida* is classified among the endangered tree species (Ojeifo and Okonta, 2008), with a high possibility of going into extinction in the near future. The gestation period of *G. albida* seeds or propagated propagules is very long having a long phase of about 10-12 years before its first fruiting. Also, the plant apical demance (25 – 37m) discourages planting and makes harvesting difficult (Don and Boateng, 2014). Furthermore, the availability of seed is seasonal. The use of marcotting technique has been widely used in the domestication of indigenous fruit trees in west and central Africa, such as *Dacryodes edulis, Cola spp, Chrysophyllum spp*. (Anegbeh, Ladipo and Tchoundjeu, 2005). Marcotting provides the best opportunity to multiply valuable trees for cultivations (Simmons and Leakey, 2000). Application of growth regulators helps to accelerate callus development and rooting, especially with the use indole-3-butyric acid (Leakey, 2000). The objective of this study is to determine the effects of rooting hormones on marcotts of *G. albida* for the regeneration clonal propagules.

MATERIALS AND METHODS

The experiment was conducted in the Teaching and Research Farm of Delta State University, Asaba Campus, Asaba. Asaba is located in Oshimili South Local Government Area of Delta State. The study area is located at longitude 6^0 49" E and latitude 6^0 14" N. It's a region of moderate rainfall. Rainfall season is between April and October with a mean annual rainfall of 1000 -1800mm. Four treatments were replicated three times, and each plots consisted of 16 pots. Callused marcotted stems, after severance, were arranged in Completely Randomized Design and spaced 50cm by 50cm on the field. The experiment was carried out using four different treatments which were honey and IBA at 1000ppm, 500ppm and control (without hormone). Marcots were set on a matured *Gambeya albida* plant which has fruited over ten years. Marcotting involved the removal of a ring of bark 4cm wide from a selected branch. The treatments were applied to the wounded branches after the removal of the bark with a budding knife. Ball of earth weighing about 400-600g, which comprised topsoil, sawdust and organic manure was wrapped around the injured portions. Thereafter, the soil medium was wrapped with a polyethylene sheath. Both ends of the sheath were tied with a thread. Marcots were severed at 5cm from the point of marcot at 12 weeks after marcotting and potted into a polyethylene pots and filled with top soil. These were placed in the nursery and watered daily, to enable the development of the callus into roots. Vegetative variables were collected fortnightly from 6 to 12 weeks before and after planting which included number and percentage of survival of marcotted stems before and after severance of macottsfrom the tree, Number and percentage of stems with callus Callus rating (1-5, where 1 represents No Callus while 5 represents Very High Callusing). The data collected were subjected to Analysis of Variance and the treatment means were separated using Least Significant Difference at 5% level of probability.

RESULTS

The results obtained in this study showed that the number of survival of marcotted stems after severance from the tree was generally influenced by the different rooting hormones, with IBA having the highest value at week 12 when compared to other hormones. There was significant difference between the treatments. IBA at 1000ppm produced the highest values of survival. The lowest value was obtained for control (Fig. 1).

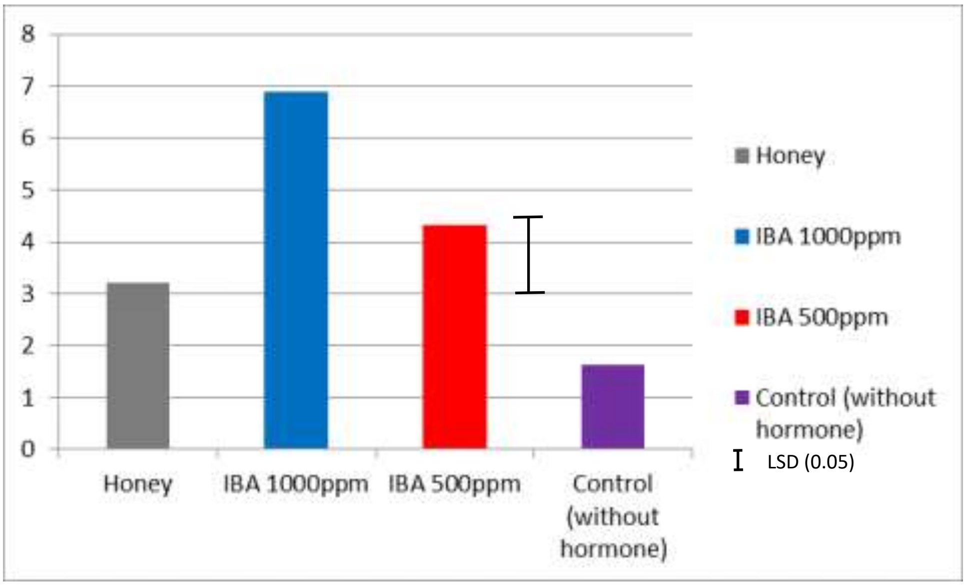

Figure 1: Effects of Rooting Hormones on the number of survival of marcotted stems after severance from the tree

Callusing was generally influenced by the different rooting hormones, the highest was 1BA at 1000 ppm attaining a maximum value of 4.30 (38%) at 12 weeks after marcotting when compared to other hormones. There was a general increase in the number of stems with callus with preceding weeks and with the different rooting hormones from 6-12 weeks after marcotting, except for honey which has a decreased value of 2.02 (18%) at week 12. The result showed that there was a significant difference between the treatments. IBA 1000 ppm had the highest values after marcotting, while the lowest values were obtained for control (Table 1).

Table 1: Effects of Rooting Hormones on number and percentage of Stems with Callus after Severance from the Tree

Rooting hormones	Weeks after Marcotting			
	6	8	10	12
Honey	1.63 (20)	1.79 (18)	2.50 (23)	2.02 (18)
IBA 1000ppm	2.90 (36)	3.32 (34)	3.50 (32)	4.30 (38)
IBA 500ppm	1.87 (24)	2.89 (29)	2.99 (28)	3.00 (26)
Control(without horrmone)	1.43 (20)	1.60 (19)	1.90 (17)	1.91 (18)
LSD (0.05)	0.20	0.18	0.60	0.91

The number of survival of marcotted stems after severance from the tree showed that the treatments were generally influenced by the different rooting hormones, with IBA1000 ppm and control having the highest and lowest values respectively throughout the study (Table 2). Callus size was generally influenced by the different rooting hormones, and was highest with 1BA 1000 ppm

ISSN: 2814-0508

attaining a maximum value of 3.70 (34%) at 12 weeks after marcotting. The untreated marcotted stem (control) consistently had lowest number of callus size than the other treatments throughout the period of study. The results indicated that there was significant difference between the treatments throughout the period of study (Table 3).

Table 2: Effects of Rooting hormones on the number and percentage of survival of marcotted stems after severance from the tree

Rooting hormones	Weeks after Marcotting			
	6	8	10	12
Honey	2.32 (23)	1.91 (21)	1.52 (19)	2.30 (21)
IBA 1000ppm	3.46 (34)	2.90 (32)	2.91 (35)	3.70 (34)
IBA 500ppm	2.93 (29)	2.63 (29)	1.58 (23)	3.42 (32)
Control (without hormone)	1.90 (14)	1.39 (18)	1.58 (23)	2.02 (13)
LSD (0.05)	0.32	0.83	0.91	1.41

Table 3: Effects of Rooting Hormones on the Callus Size (1-5) and percentage after Severance from the Tree

Rooting hormones	Weeks after Marcotting			
	6	8	10	12
Honey	1.62	0.99	1.25	1.33
IBA 1000 ppm	3.00	3.00	3.36	3.91
IBA 500 ppm	2.99	2.91	3.00	3.12
Control (without hormone)	1.01	2.13	2.21	2.30
LSD (0.05)	0.50	1.11	1.03	1.33

The results obtained from the study showed that an increase in the application of rooting hormones had effect on the number of stems with callus; callus size, number of survival of marcotted stems before severance from the mother plant and number of survival of marcotted stems after severance from the mother plant.

DISCUSSION

Some studies shown that callus formation follows the pathway of rooting, and newly formed callus cells have the possibility to be a group of fast-dividing root primordium-like cells (Che *et al*., 2007). Callus, a precursor of roots of marcotted stems of *Gambeya albida* was most successful with the application of rooting hormone Indole 3-butyric acid. At the point of severing the marcots which was 12 weeks after initiation of study, healing had taken place in most of the marcots and many had developed evident callus. These were the tools used as indicator of marcots survival. The results obtained from the study showed that an increase in the application of rooting hormones had effect on the number of stems with callus; callus size and number of survival of marcotted stems before and after severance from the mother plant.

It was observed from the study that cuttings callused relatively `well at all concentrations and in control plot, but very little in the use of Honey. The best results were obtained with IBA 1000 ppm and IBA 500 ppm with 3.91(38%) and 3.12 (30%) of successful marcots respectively. Though, honey had a stimulatory effect, and resulted in low callusing. According to the experiment conducted by Don and Boateng, (2014) claimed that the use of different IBA concentrations of 25, 50, 100, 200 and 300 ug/ml (which is equivalent to ppm) on marcotted *Gambeya albida* did not enhance rooting. This may be due to the low concentration of rooting hormone used. This study showed that *Gambeya albida* has potential for vegetative propagation by marcotting and better results can be obtained with the use of rooting hormone. The use of rooting hormones initiated early callusing and promotes early root growth and the earlier the root grows, Therefore, high concentrations of indole3-butyric acid should

ISSN: 2814-0508

be evaluated for the vegetative propagation of *G. albida*.

ABSTRACT

The experiment was carried out at the Horticultural Nursery of Crop Production Department of Federal University of Technology, Minna. Single red and yellow ixora (*Ixora coccinea*) were used in this study. Ixora cuttings were obtained from matured parent plants at School of and Agricultural Technology (SAAT) Complex of Federal University of Technology, Minna. cuttings were dipped in natural hormone concentration (coconut water) and then planted into polythene pots filled with top soil. The study lasted for thirteen weeks. Beginning from March 2015, routine weeding was carried out manually, by hand picking and insects were controlled using Laraforce all through the experiment. Data were collected on the following morphological parameters viz: sprout count and leaf count from 4 to 13 WAP, at weekly intervals. At 13WAP, the experiment was terminated by collecting leaf samples for dry matter determination. All data collected were subjected to analysis of variance engaging SAS software package 2008 and the means were separated using Duncan Multiple Range Test (DMRT) at 5% level of Probability. The analytical result showed that there was a significant difference between the hormone treatments. Hardwood cuttings dipped in natural hormone (coconut water) and planted immediately (0hrs) produced significantly higher effect on parameters viz: number of leaf and sprout count with red ixora having a significantly higher effect than yellow ixora. It is therefore recommended that for mass propagation of Ixora (*Ixora coccinea*) cuttings in the guinea savanna agro-ecology of Nigeria, hardwood of red ixora dipped for zero hour in natural hormone (coconut water) should be used.

INTRODUCTION

Ixora which is a native of tropical Asia and Africa is now common in all Eastern pantries, both in its wild state and as a cultivated garden shrub. It flowers almost throughout the rainy season. A revolution, according to McGregor and Stice (2008), is occurring in the export of horticultural products from developing countries since overall, high value products including horticulture, livestock, fish, and organic products) now make up 66% of all developing countries of agricultural product export. It is common to find people associating the purchase of flowers with luxury. With increased prosperity in Nigeria, the amount of cut flowers purchased per household increase (Koshioka and Amano., 1998).

Globally, horticulture has become a leading sector for poverty reduction in developing countries. The value of world production of floriculture products is estimated at approximately €100 billion and around 10% of this production enters international trade. Trade in floriculture products will increase by 3.5% annually to 2012 (Leonhardt, 2006). About half of the existing nurseries in Nigeria were set up in the recent past (Ellis *et al.,* 2003), an indication that the industry is growing more in recent times. Ornamental plants such as ixora is in high demand for landscaping, bouquet making and wreath as well as cut flowers in Nigeria, Ghana, Italy, Germany and other parts of the world. Yet, these economically important ornamental plants have a low genetic and physiological capacity for adventitious root formation and, therefore, limit their commercial production. Such ornamental plants have been popularly termed as "difficult-to-root". Economically, the demand for these ornamentals necessitate that the difficult-to-root phenomenon be solved. Since the growth medium relates to every cultural practice in the production of nursery crops in containers, the selection and preparation of the medium is extremely important and could pay great dividends in terms of plant growth and quality (Hall, 3003). There is no universal or ideal rooting mixture for cuttings. An appropriate propagation medium depends on the species, cutting type and propagation system (McDonald *et al.,* 2002).

Ixora *coccinea* is an evergreen shrub that blooms in rainy seasons spectacularly in the landscapes of the Guinea Savanna Region of Nigeria. Due to the rise in temperature with reduced relative humidity during dry season, it makes the successful propagation of *ixora 000000atnacinea* almost impossible to be raised; due to insufficient water. However, this leads to poor vegetative sprouting from the cuttings (Hartmann *et al.,* 2002). This thus, necessitates provision of micro-climate by shedding. In the quest of achieving a successful propagation of *Ixora coccinea*, it becomes imperative to utilize adequate materials and methodologies that would ensure successful rooting and growth of *Ixora coccinea* stem cutting.

Global warming affects the growth of most ornamental crops today. Growing conditions such as sunlight, water, temperature, soil and fertilizer have deviated from the past trends (Blazich, 2006). Agricultural production under this situation has increasingly threatened human and animal health. It becomes very important to provide possible solution's in curtailing this drastic climatic change. It has been scientifically proven that plants utilize carbon-iv-oxide (CO_2) to carry out photosynthetic activities, and in this process, oxygen (0_2) that is required by man and animals, is been released as its bye product (Iganberdiev and Lea, 2002). Ixora is a shrubby evergreen plant that is well adapted to different agro-ecological zones, particularly, the semi-arid and arid zones. This makes it useful in the landscaping thereby serving as a huge CO^2 sink. In order to achieve a successful propagation of Ixora (*Ixora coccinea*), it becomes imperative to provide available materials and techniques that could ensure successful rooting of this plant when propagating it vegetatively.

In the context of above, this experiment is designed to: 1) Assess and compare the performance of red and yellow Ixora (*Ixora coccinea*) under varying treatments of coconut water as a natural hormone and 2) Determine the ixora specie that performs best under natural hormone treatments

MATERIALS AND METHODS

Study Location: The experiment was carried out in the beginning of March 2015, in the horticultural nursery of crop production department, school of agriculture and agricultural technology of Federal University of Technology Minna, Niger State of Nigeria. The geographical location is latitude 6^0 30'E and longitude $9^0$40'N, which lies at the Southern Guinea Savanna zone of Nigeria.

Materials

The following materials were used for the implementation of this research work are:

Ixora cuttings, Coconut water, Beaker, Secateurs, Shading material (Sac), Wooden pole for shading, Measuring tape and rule, Polythene container, Top soil, Rope for security

Types of Ixora Cuttings and Mixtures

Hardwood and softwood of red and yellow ixora was used for experimental work. The cuttings were collected from a 3 years old parent plants. The planting material and hormone mixtures are as follows:

Red hardwood control (RHC), Read softwood control (RSC), Red hardwood + 12 hours coconut water (RH12), Red softwood + 12 hours coconut water (RH12), Red hardwood + 24 hours coconut water (RH24), Red softwood + 24 hours coconut water (RH24), Red hardwood +fresh hours coconut water (RH0), Red softwood + 0 hours coconut water (RS0), Yellow hardwood control (YHC), Yellow softwood control (YSC), Yellow hardwood + 12 hours coconut water (YH12), Yellow softwood + 12 hours coconut water (YS12), Yellow hardwood + 24 hours coconut water (YH24), Yellow softwood + 24 hours coconut water (YS24), Yellow hardwood + fresh hours coconut water (YH0), Yellow softwood + 0 hours coconut water (YS0).

Source of Planting Material

The cuttings of red and yellow ixora (*Ixora coccinea*) for the experiment were collected from established parent plant within School of Agriculture and Agricultural Technology (S.A.A.T.) in Gidan Kwanu Campus of Federal University of Technology, Minna.The natural hormone (coconut water) was derived from a matured coconut fruit purchased from kure ultra-modern market.

Propagation

The red and yellow ixora (*Ixora coccinea*) cuttings were obtained from school of Agriculture Complex of Federal University of Technology, Minna. The length was 15 centimetres. Secateurs was used in cutting the Ixora and the leaves were removed gently to avoid injuries, thereby inhibiting its exposure to pests and insects attack. The two types of cuttings were softwood and hardwood. The cuttings were planted by inserting each single Ixora plant-tip into polythene container. Planting was done immediately the cuttings were obtained and dipped in coconut water. The planting process was also done by gently inserting the moist cuttings into the media therein.

Experimental Design

The experiment was 2x2x4 factorial design arranged in a Completely Randomized esign (DRD) and replicated three times.

Data Collection

Data was recorded at weekly interval as from four weeks after Ixora cuttings were planted. The data was collected on the following growth parameters viz:

ISSN: 2814-0508

Leaf number: The number of leaves were counted and recorded from the oldest leaf at the base of the shoot to the youngest at the top of the plant.

Number of Sprouts: The sprouts were counted and recorded from the base of the plant to the top.

Leaf dry Matter: Leaf samples of red and yellow ixora (*Ixora coccinea)* were collected from each treatment on the field and were taken to the laboratory. The fresh weight of ixora leaf sample were determined using electric weighing balance. After then, the leaf samples of red and yellow ixora were packed, labelled and kept at 70^{0}C for 72 hours in the oven. The oven dried ixora leaf samples were unpacked and leaf dry weight was determined using electric weighing balance after 72 hours of oven drying. According to Okalebo *et al.,* 2002, dry matter was calculated mathematically, thus: Dry Matter (%) $(\%) = \frac{Dry\ weight}{fresh\ weight}\ x\ 100$

Statistical Analysis

The data collected on growth parameters were statistically analyzed using the analysis of variance (ANNOVA) for the complete randomized design while means were separated by Duncan's Multiple Range Test (DMRT) at 5% level of probability. The analysis was perfected with SAS software package.

RESULTS AND DISCUSSION

The results in table 1 shows the effect of varying hormone treatments of coconut water on leaf count of ixora. The varying hormone treatments have significant effect on leaf count of both red and yellow ixora at 6,8,9,10 and 11 WAP, where red ixora produced significantly the highest number of leaves while yellow ixora significantly produced the least number of leaves respectively. The varying hormone treatments had significant effect on the leaf count at 6,7,10,11 and 12WAP. Where ixora cuttings dipped in coconut water and planted immediately produced significantly the highest number of leaves although statistically similar to control and ixora cuttings dipped in hormone for a period of 12hours while ixora dipped in hormone for a period of 24hours significantly produced the least number of leaves. With regards to wood of ixora, there was no significant difference on the leaf count at 4-5WAP but that was not the case at 6-13WAP, where significant difference was observed on the leaf count. Hardwood significantly produced the highest number of leaves while softwood significantly produced the lowest number of leaves at 6-13WAP respectively.

Furthermore, the results in table 2 shows the effect of varying hormone treatments of coconut water on sprout count of ixora. The varying hormone treatments had significant effect on sprout count of both red and yellow ixora at 7,8,9,10 and 13WAP. With regards to ixora species, red ixora significantly produced the highest number of sprout while yellow ixora significantly produced the lowest number of sprout at 7,8,9,10 and 13WAP respectively. The varying hormone treatments had a significant effect on sprout count at 5 and 9WAP only, where ixora dipped inhormone and planted immediately (0hrs) significantly produced the highest sprouts though statistically similar with ixora cuttings dipped in hormone for a period of twelve hours (12hrs) and ixora cutting dipped in hormone for a period of twenty-four hours (24hrs). control produced significantly, the lowest sprout. With regards to wood of ixora, there was no significant difference in number of sprout at 4WAP only, but that was not the case at 5-13WAP where significant differences were observed. Hardwood significantly produced the highest number of sprouts while softwood significantly produced the lowest number of sprout at 5-13WAP, respectively.

CONCLUSION /RECOMMENDATION

The practical approach to enhance successful multiplication f ornamental plants is through the use of growth hormones (Greensil, 1975). The study showed that there was a significant difference between the hormone treatments. Hardwood cuttings dipped for zero hour in coconut were (natural hormone) produced significantly higher effect on parameters viz: leaf dry matter, number of leaf and sprout count with red ixora having a significantly higher effect than yellow ixora. It is, therefore, recommended that for mass propagation of ixora (*Ixora coccinea*) cuttings in the guinea savanna agro-ecology of Nigeria, hardwood of red ixora dipped for zero hour in natural hormone concertation (coconut water) should be used. Also, further study should be carried out during the dry season so as to compare the effect of coconut water on the same varieties of ixora cuttings as this research work was carried out in the rainy season.

ABSTRACT

In vitro micropropagation is recognised and has been employed in the mass production of healthy and homogenous planting materials. Pineapple (*Ananas comosus*) is one of the economically important fruit crops of the tropics. Poor survival rates during hardening and acclimatization have been identified as one of the problems affecting the micropropagation technique. This work therefore, evaluated the synergetic effects of rooting hormones Naphthalene acetic acid (NAA) and Idole-3-butyric acid (IBA) with Adenine sulphate (AdS) on the rooting attributes of tissue culture derived pineapple. Rooting was induced by subculture of established plantlets into ½ strength of MS medium (Murashige and Skoog) supplemented with NAA (1.0, 2.0 mg/l), IBA (1.0, 2.0 mg/l) and AdS (50, 100 mg/l). The control was treated with neither any hormones nor the AdS but subculture on ½ MS only. Five plantlets were used per treatment with three replicates. Root emergence was first observed with medium combination of ½ MS supplemented with 2.0mg/l NAA and 50mg/l AdS at 14days. Medium combination of MS supplemented with 2.0mg/l NAA with 50mg/l and 100mg/l AdS showed a highly established root system with mean root length and root number (15.2cm, 7.68cm and 11.8cm, 7.3cm) respectively. Thus, NAA perform better than IBA and addition of AdS enhanced proliferation and rooting growth parameters of pineapple plantlets.

Key words: Tissue culture, Pineapple, Adenine sulphate, Naphthalene acetic acid, Indole butyric acid.

INTRODUCTION

Tissue culture micropropagation is recognised and has been employed in the mass production of healthy and homogenous planting materials**.** Micropropagation of pineapple plants has many advantages over conventional methods of vegetative propagation. For example, this technique could allow for an efficient and rapid increase of selected varieties. The conventional way of producing healthy and high-quality pineapple is time-consuming. Conventional methods of obtaining materials from the sucker, crown, and slips of the pineapple take up to and/or more than 18 months after the fruit is harvested. Furthermore, imported plant material is very costly. In addition to that, the multiplication rate of pineapple is slow when using conventional propagation method, this causes inability to meet the high demand for pineapple planting materials. Nevertheless, these constraints can be overcome through plant tissue culture technique where the mass quantity of *in vitro* clonal pineapple can be produced within a short period. Tissue cultured pineapples have similar physical and chemical properties when compared to conventionally grown plants (Jackson *et al*., 2016).

Adenine sulphate (AdS) has been used in other plant species like *Musa paradisiaca*-plantain (Akin-Idowu *et al.,* 2020), *Trifolium repens* L. (Gabriela Vicaş, 2011), *Stevia rebaudiana* Bertoni (Kamram *et al.,* 2014), *Jatropha curcas* L. (Medza *et al.,* 2010) with a beneficial effects on multiplication particularly when in combination with cytokinins. However, little to nothing is known about auxins in synergy with AdS for optimum root formation. Formation of adventitious root is a complex process that is influenced by multiple endogenous factors such as phytohormones and as well as environment (Xuan *et al*., 2008). Survival rates during hardening and acclimatization have been identified as one of the problems affecting the pineapple micropropagation technique. This study was therefore carried out to access the potential synergistic influence of Auxins (NAA and IBA) with AdS combination for optimum adventitious root formation of tissue culture derived pineapple.

MATERIALS AND METHODS

Plant Materials

Pineapple crowns (Smooth Cayenne) were used as explants source. The experiment was conducted at the Biotechnology unit of the National Horticultural Research Institute (NIHORT) Headquarters, Ibadan. Surface sterilization process was carried out according to the method of (Akin-Idowu et al., 2014) with slight modifications. The explants were regenerated and subsequently multiplied on proliferation media according to the established protocol of the Laboratory. Root was induced by subculture of established proliferated plantlets into ½ strength of MS medium (Murashige and Skoog) supplemented with NAA, IBA and AdS as shown in the Table 1 with each treatment consisted of five plantlets in three replicates. Root data taken include root number (RN), root Length (RL-cm) and root Thickness (RT-mm with the aid a digital Vernier Calliper).

Table 1. Composition of treatment groups with other media components is as follows; Ascorbic Acid 5ml, Sucrose 30g, Myinositol 0.125g, Agar 8.0g/L, at pH 5.8.

Treatment	Group
T1	No hormone, No AdS
T2	1.0ml IBA+50mg/L AdS
T3	2.0ml IBA+100mg/L AdS
T4	1.0ml NAA+ 50mg/L AdS
T5	2.0ml NAA+100mg/L AdS

RESULTS AND DISCUSSION

Root Induction/Emergence

Plant growth regulators are vital in plant tissue culture since they play an imperative part in stem elongation, apical dominance and root emergence. The success rate of plant tissue culture depends on the choice of the nutrient medium. Saad and Elshahed, 2012 affirmed that the cells of most plant cells can be grown in cultured media. The ratio of the auxin to the cytokinin determines the type of culture established or regenerated, while Auxins on one hand promote both cell division and cell growth cytokinin on the other hand promote cell division. A high auxin to cytokinin ratio generally favours root formation, whereas a high cytokinin to auxin ratio favours shoot formation. An intermediate ratio favours callus production. The influence of AdS is known in tissue cultures as many plant species and types of vegetative tissues show superior effect when combined with different levels of cytokinin and auxin (Zapartan, 2001). In this study, the effects of AdS were well observed in treatment T4 (Table 2) the highest roots mean number and root length with well established root system (Figure 1). Abdel *et al.,* 2013 reported contrary results in which different auxin types and concentrations and different media strength were evaluated on the induction and proliferation of adventitious root on two cultivars of pineapple. According to these authors, IBA performed better than NAA at equal concentrations, except 1.0 mg/L, both of the cultivars (Smooth Cayenne and Morris) produced longer roots on IBA than NAA. But percentage rooting was approximately the same for IBA and NAA. Although the authors only compared different concentrations of auxins and cytokinins on Smooth Cayanne and Morris on root induction, but did not include AdS in their study. In this present study, 1.0mg\L NAA +50mg\L AdS would be recommended for Smooth Cayanne based on root number and root length and days of root emergence (Figure 1). This was in tandem with Abdel *et al*. (2013) as suggested based on the root length results they got for Smooth Cayanne.

Table 2. Mean root induction and elongation rate. RN-Root numbers, RL- Root Length, RT-Root thickness

Treatment	RN	RL(cm)	RT(mm)

ABSTRACT

To improve the stability and productivity of coffee plants, many strategies for Robust coffee propagation could be applied. The goal of this study was to compare alternative propagation procedures for establishing coffee plantation. The stability and production capacity of cutting propagation procedures was investigated in this study. For optimum cutting development, vertical orthotropic branch stem cuttings were collected and dipped in rooting media, inserted into the well-prepared bed, and covered with nylon. For data collection, the rooted cuttings were transferred into the field, laid in Complete Randomized Block Design with three replicates. Variation in morphological characteristics was determined using analysis of variance and multivariate analysis. On the basis of morphological characters, differences between genotypes were detected. Plant height, number of leaves, stem girth, and number of plagiotropic branches were the key characters that contributed considerably to the variances, according to the findings. Plant height and the number of leaves were positive association. Plant height and number of leaves were identified as important variables in this study that might be used in genotype selection in a breeding program.

Key words: Coffee genotypes, vegetative, seeds and techniques of propagation

INTRODUCTION

The establishment of coffee plantation is crucial, and this necessitates the use of healthy and vigorous seedlings. Because Robusta coffee is self-incompatible, it must be cross-pollinated (Hetzel, 2015; Moraeset al., 2018). Seeds from cross-pollinated species have a wide range of genetic diversity and are genetically distinct from parent trees. However, farmers and coffee breeders all over the world have been propagating coffee through seeds for a longer time (Van der Vossen, 2001) including germplasms (Koo *et al*., 2004). Through vegetative propagation techniques, an effort has been made to establish coffee plantation. Angelo *et al*. (2018) advocate shoot grafting or cutting as the optimum technique of vegetative proliferation in Robusta coffee. Cutting/grafting is a method of plant propagation that employs the vegetative section of the plant to produce new plants that are identical to the parent plant. Cuttings ensured maximum homogeneity, decreased the time required for conventional breeding, and produced genotypes with vigour and desired features (Partelli *et al*., 2014). Cuttings also provided a distinct maturation and duration period (Martins et al., 2019; Partelli *et al*., 2019, 2020). Stem cuttings in Robusta coffee plants could serve two purposes either as rootstock for grafting or for establishment of coffee plantation/research purposes. According to Syafaruddin*et al*. (2014), Robusta coffee developed through grafting techniques were found to be stable and high yield when compared to those propagated by seeds. The advantage of grafting over cuttings is the vigour given to the scion by the rootstock. Grafting provide strong root system that could serve as a drought tolerant and disease resistant to scion (Bittenbender*et al.,* 2001).

The age of the mother tree, stem juvenility, plant regulator concentration, seasonality, and environmental variables during rooting growth all influence adventitious root formation (De Oliveira *et al*., 2015; Stuepp *et al*., 2017). As a result, callus must be generated and developed into adventitious roots in order for stem cuttings to grow successfully. Cutting should be collected from young branches that are in good condition and free of disease (Wendling *et al*., 2014). De Oliveira et al. (2015) discovered that soft wood cutting with a node outperformed woody cutting with a node in *C. canephora*. Few studies have been conducted on propagation procedures that will improve the establishment and performance of coffee plants. As a result, this research was conducted to determine the vegetative propagation technique that could be used in Robusta coffee genotypes and offer a foundation for good growth and production increase.

MATERIALS AND METHODS

Stem cutting were collected from orthotropic branches that were vertical, softwood stem cutting was taken at about 7-10 cm long, with a pair of leaves cut into two. The cuttings were planted in growing medium. The stem cuttings were planted vertically in a mixture of sawdust and top soil at a ratio of 1:1. The cuttings of each genotype were planted on well prepared bed, covered with white nylon to create a semi microclimate for cutting development. Shaded nursery is the best for cutting production.

Data were collected on plant height, stem girth, number of leaves, number of plagiotropic branches, leaf length and leaf width.

Data Analysis

Data were subjected to analysis of variance (ANOVA) to determine the significant variation that exits among the characters in respect to the genotypes while multivariate analyses were computed with the use of SAS statistical software version 9.1.3 (2008), to evaluate the relative contribution of each character to the phenotypic variation and the level of their associations.

RESULTS AND DISCUSSION

Table 1 summarizes the results of the RCBD experiments in terms of characters studied. Analysis of variance revealed significant variations among the genotype ($p<0.001$). For Number of plagiotropic branch (NPB) and Leaf Length (LL), the block genotype connection exhibited significant variation ($P< 0.001$). Plant height, number of leaves, number of plagiotropic branches, and leaf length were all significantly different between genotypes. Other parameters were also not different significantly.

Table 1: Analysis of variance of eight genotypes of coffee

Source	DF	PH	SG	NL	NPB	LL	LW

Where Plant height = (PH), Stem girth = (SG), Number of plagiotropic branch = (NPB), Number of lea = (NL), Leaf length = (LL) and Leaf width

Result of the principal components in Table 2 showed characters with eigenvalues greater than 1 contributed variation observed among the 8 genotypes of coffee. The first principal component accounted for (29 %) of the total variation. Leaf length, leaf width, plant height and leaf number among others characters contributed to the variation in the first PC. Similarly, number of leaves, number of plagiotropic branches, plant height and stem girth contributed significantly to variation observed in the second PC which amount to (22 %). In the third PC stem girth, leaf length1, leaf width 1, and leaf length 2 were the most characters that contributed to the variation indicated. The three PCs contributed (64 %) of the total variation observed among the genotypes. Plant height, number of leaves, stem girth, and number of plagiotropic branches were the most significant characters that contributed to the variations observed in PCs, based on significant contributions of each character to the variations observed in PCs. As a result, because these characters contribute significantly to variance, they could be used to select genotypes. The findings of this investigation corroborated Kitilaet's (2011) report on coffee arabica.

Table 2: Eigenvectors, eigenvalues, proportion %, and cumulative variance % of the characters studied

	Prin1	Prin2	Prin3
PH	0.38	0.43	-0.34
SG	0.07	0.28	0.84
NB	0.11	0.49	0.04
NL	0.25	0.53	-0.06

LW	0.47	-0.29	-0.01
Eigenvalue	2.31	1.79	1.03
Proportion %	0.29	0.22	0.13
Cumulative variance %	29	51	64

Where Plant height = (PH), Stem girth = (SG), Number of plagiotropic branch = (NPB), Number of leaf = (NL), Leaf length1 = (LL) and Leaf width = (LW)

ISSN: 2814-0508

The correlation study in Table 3 indicated positive relationship between plant height and leaf number, implying that an increase in leaf number contributed to an increase in plant height. This could be due to a higher number of leaves exposed to photosynthetic activities, implying an increase in carbohydrate production by plants. Similarly leave width was positively correlated with leaf length, implying that increase in leaf width could lead to increase in leaf length.

Table 3: Linear correlation coefficient of the characters studied on coffee

	PH	SG	NB	NL	LL	LW2

LW2						1.00

Where Plant height = (PH), Stem girth = (SG), Number of plagiotropic branch = (NPB), Number of leaf = (NL), Leaf length = (LL) and Leaf width = (LW)

CONCLUSION

The necessity of stem cutting in the establishment of coffee plantations for early seedling growth and stability was revealed by this study. Leaf number was found to contribute to plant vigour, which resulted in early plant stability at the juvenile stage. As a result, it is recommended to establishing coffee by cuttings for rapid growth and yield.

ABSTRACT

Effect of plant growth substances on the growth and development of red C. nitida seedlings was investigated in Cocoa Research Institute of Nigeria (CRIN) Headquarters. Two (200) hundred nuts were collected from CRIN Headquarters scarified and pre-germinated before transplanting into polythene pots. The study was carried out using randomized complete block design. Hormonal treatments of 50mg/L,100mg/L and 200mg/L of different concentrations of gibberellic acid, indo-3- acetic acid, kinetic acid and 20% coconut water were applied to C. nitida seedlings at 4 weeks after planting and subsequently at 2 weeks' interval for 96 weeks. The control seedlings were sprayed with distilled water. Each treatment was replicated thrice. Morphological parameters, fresh and dry weight of root, shoot leaves and whole plant were determined. Root/shoot ratio, shoot water/shoot dry matter, shoot dry matter content and leaf area ratio were carried out. The data collected was subjected to analyses of variance (ANOVA) separation of means using Duncan Multiple Range Test (DMRT). 50mg/L GA_3 induced plant height (117.38 cm), stem girth (1.81cm), number of branches (21.83) and leaf area (167.71cm) except for number of leaves where 50mg/L kinetin had the highest (132.83), respectively. Similar result was obtained for fresh weight of root, shoot, leaves, root length and fresh weight of whole plant with 50mg/L GA_3 having the highest value (77.10 g, 125.93 g, 84.87 g,52.67cm and 281.23 g) and the result not significant at 5% level of probability except for fresh weight of leaves. 100mg/L GA_3 had the height in dry weight of root, shoot and dry weight of whole plant. The highest root/shoot ratio and shoot water/shoot dry matter was enhanced by 100mg/L GA_3 while shoot dry matter and leaf area ratio was produced by 50mg/L GA_3 respectively. Plant growth hormones of low concentration 50mg/L GA_3 elicited the highest growth in C. nitida seedlings when compared to the control.

Key words: Plant hormones, Red *C. nitida* seedlings, Morphological parameters.

INTRODUCTION

Kola nut (*Cola nitida)* also known as gbanja or goro) is the seed kernel of a large African tree grown commercially around the world. It originates from the Congo and throughout West Africa, but today, it is cultivated in Jamaica, Indonesia and South America. In Nigeria, Kola is the second most important indigenous cash crop. It is estimated that the country currently produces 70% of world's kola nuts with an annual production of 250,000 metric tons of fresh nuts mostly from south-west (Oludemokun, 1983). Kola nut serves as stimulant for the consumers and also for industrial uses as beverage and cough syrup made from its juice. Kola nut and kola by-products are noted for many industrial and domestic uses thereby contributing immensely to local and foreign exchange earning of the country. The nuts are nutritious, containing nearly 1% protein, 1.35% fats and 45% starch. (Quarcoo, 1973). Kola nut is being used as an alternative natural medicine in Europe and America. It also has industrial usage for the production of drugs, soft drinks, wines, candies, beverages, animal feed formulation, liquid soap and dyes (Beattie 1970; Daramola, 1978).

Despite the economic importance of kola stated above, the rate of uniformity in germination and its slow growth rate is a major challenge. Therefore, this study is aimed at boosting its growth and development as well as unifying the kola seedlings using plant growth regulators. Plant growth regulators in low concentration regulates growth, differentiation and development, either by promotion or inhibition (Naeem *et al*. 2004), and allows physiological processes to occur at their normal rate (Gulluoglu 2004). Among PGRs, auxin and gibberellin play vital role in regulating developmental processes within plant bodies (Gou *et al*. 2010). Auxin promotes cell elongation, especially of shoots, and induces apical dominance and rooting, while gibberellin helps in cell growth of stem, leaves and other aerial parts by causing cell elongation, and increase in internodal length. A higher concentration of gibberellins increases plant growth (Bora and Sarma 2006) while higher concentration of auxin inhibits it (Hussain *et al.* 2010). Thus, only low doses of auxin are effective in growth promotion (Vwioko and Longe 2009). The different concentrations of GA had significant effect on growth in mustard (Akter *et al.* 2007). Baydar (2000) reported that oil synthesis increases with increasing dose of GA in safflower. Like gibberellins, auxins are effective in increasing oil yield. Farooqui et al. (2005) reported that indole acetic acid (IAA) application increases oil yield enormously in *Cymbopogon martinii* and *Cymbopogon winterianus.* Faizanullah et al. (2010) reported that judicious application of growth hormone increases seed yield in linseed. However, seeing the potential effects of plant growth hormones on *C. nitida* plant, there are possibilities to investigate the influence of these PGRs on different growth parameters. The present study was aimed with the objectives of i) evaluating the effect of plant growth regulators on seedlings growth and development and ii) determining the yield components of *C. nitida* nut.

MATERIALS AND METHODS

Raising nuts for seedlings

The experiment was carried out Cocoa Research Institute of Nigeria (CRIN) Headquarters, Ibadan, Oyo State. A total of two hundred red *C. nitida* nuts were obtained from mature fresh pods from Cocoa Research Institute of Nigeria Headquarters. Nuts extraction was achieved by splitting matured pods with a sharp knife, the nuts were soak and washed in water to remove the testa on them. Five seed boxes of (90x60x30cm) size each was filled with a mixture weathered sawdust and topsoil (ratio 50:50). A shade was erected for the pre-nursery to prevent the seeds from desiccation and cultural practices such as weeding, watering and spraying of pyrinex 0.5L/1L of water against termite infestation was carried out. The bulk soil taken from the site (0-15cm depth) was sieved to remove stones and plant debris and 2.5kg of the sieved soil was placed into a polythene bag (25cmx13cm). The nuts were first pre-germinated in the nursery before transferring into the polythene pot.

Pre- soil analysis

Soil samples was randomly collected from 0-15cm depth on the site, mix thoroughly and the bulked sample was taken to the laboratory, air dried and sieved to pass through a 2mm screen for chemical analysis. The soil pH (1:1 soil/water) was determined using pH meter. Organic matter was determined by the wet oxidation method (Walkley and Black, 1934). Soil phosphorus (P) was extracted by the BrayP1 and measured by the Murphy blue coloration and determined by Spectronic 20 at 882um (Murphy and Riley, 1962). Soil potassium (K), calcium (Ca), and magnesium (Mg) was determined with flame photometer, Mg was determined with an Atomic Absorption Spectrophotometer. The total Nitrogen (N) was determined by the microjedah method (AOAC, 1990).

Nursery Establishment

Kola seedlings were transplanted into polythene bag, one per pot arranged in a randomized completely block design (RCBD) replicated three times. The parameters such as plant height, number of leaves, leaf area, stem girth and number of branches was recorded from four weeks after germination. The treated plants were spray every 2 weeks with 50ppm, 100ppm and 200ppm of IAA, Kinetin, GA_3 and 20% coconut water while the control was watered with distilled water. Growth parameters were measured every four weeks for 96 weeks (2years) after planting. Weeding was done at three months after planting and repeated at 6, 9, 12, 15 and 18 months. At 96 weeks after planting, the seedlings were carefully removed from the polythene bags for the measurement of the fresh shoot, root and leaves. Furthermore, dry matter yield was taken after oven dried in an oven at 60^{O}c for 2h.

Total fresh and dry weights determinations

Total fresh weight per plant was estimated as the sum of the leaf, stem and root. Fresh weight was determined at the expiration of the nursery stage. The organ was weigh with a H72 mettler balance. After weighing, they were put in an envelopes and oven-dry for the determination of the dry weights. The plant organ was oven dried at 60^{o}c for 24 h to constant weight. Leaves stem and root dry weights were summed up to give the total dry matter production per plant.

Shoot and Root ratio:

The treated and the control plants obtained were divided into shoot and roots after which they were dried separately in the oven at 60^{0}C for 24h and their different weights were measure using a weighing balance. The shoot and root ratio was calculated using the formula below.

$$\textbf{Shoot–Root Ratio} = \frac{\text{Dry weight of Root}}{\text{Dry weight of Shoot}}$$

Leaf Area Ratio:

Leaves of treated and control plant were measured using a meter rule. Bigger and smaller leaves were measured multiply by the correction factor, 0.67 before taking the mean. The leaf area ratios were calculated using the formula shown below:

ISSN: 2814-0508

$$\text{Leaf Area Ratio} = \frac{\text{Leaf Area total}}{\text{Dry weight of whole plant}}$$

Shoot water and Shoot dry matter contents:

The fresh weights of shoots from the harvested treated and control seedlings was recorded, replicated three (3) times after which the shoot was dried in an oven for 24h at 60°C and their dry weight be calculated using the following formula:

$$WC = \frac{Wf - Wd}{Wf}$$

Where:

Wc = Shoot water content

Wf = Shoot fresh weight.

Wd = Shoot dry weight.

The percentage shoot dry matter content was obtained using the formula below:

$$DC = \frac{\text{Shoot dry weight}}{\text{Shoot fresh weight}} \times 100$$

Statistical analysis

The average data obtain for the physiological and growth parameters and soil chemical composition of kola seedlings for the two experiments were analyzed using ANOVA. The treatment means were compared using a Duncan Multiple Range Test at the 5% probability level (Gomez and Gomez, 1984).

RESULTS AND DISCUSSION

Soil analysis before planting

The initial physical and chemical properties of the soils are presented in Table 1. Based on the established critical levels for the soil in South-Western Nigeria, the soil was acidic (5.70). The soil organic matter and organic carbon were 17.83 and 30.74 while that of sawdust were 12.12 and 20.90 respectively. The soil nitrogen and sawdust values were 1.011 and 0.017 while the available P was 9.07 mg/kg for soil and 5.36mg/kg for sawdust. The exchangeable K value for soil and sawdust were 0.66cmol/kg and 0.34cmol/kg. The values for Ca, Na, Mg and Mn for soil are 0.37cmol/kg, 0.46cmol/kg, 0.18 cmol/kg, and 0.05cmol/kg, while that of sawdust were; 0.34cmol/kg, 0.16 cmol/kg, 0.12 cmol/kg, and 0.04cmol/kg, respectively. The soil is sandy loam in texture, belonging to Onigambari series: an Alfisol.

Table 1: Physicochemical characteristics of the soil before planting

Soil properties	value	Sawdust physical value

There were increases in plant height of seedlings of *C. nitida* subjected to hormonal treatment and the controls as the number of months after planting increased. (Table 2). The highest value of the plant height of 137.7cm was obtained at 24 MAP in seedlings treated with gibberellic acid at 50mg/L, followed by seedlings treated with 50mg/L kinetin (111.32cm) and the least mean value was obtained for the control (61.09cm). There were no significant differences at 24MAP between plant heights of the treated seedlings and control. Increased in stem girth were observed at different concentrations of plant hormones and the control as the number of months after planting increased. The highest mean value of stem girth was recorded in 50mg/L gibberellic acid (1.88) at 24MAP. This was followed by 100mg/L gibberellic acid (1.83) and the least was obtained for the control (1.26). However, no significant differences were observed among the treated and the control. The positive results of GA_3 treatments are similar to that obtained by Islam *et al.* 2010 who found that at 70 days after sowing, 1.0mg/L GA_3 gave more plant height (44.29cm) which was statistically different from those of 2.0mg/L GA_3 and 0.50mg/L which gave plant height of Black gram (42.26cm and 42.06cm), respectively. Islam *et al.* 2004 observed that 0.664mg/L GA_3 enhanced plant height significantly in Lentil. These results also conform to those of Geekiyanage *et al.* 2006 and Sasaki, (1989). Similar results of plant height stimulation were observed by Currah & Thomas (1979) upon application of 100mg/L GA_3 on carrot plant. Spraying of kinetin on Datura innoxia plant at 1mg/L, 5mg/L and 10mg/L was found to cause increased vegetative growth (Abdel-Rahman & Abdel- Aziz, 1983). Similarly, GA_3 spraying was found to stimulate production of flowers in lettuce (Metzger, 1988). Biddington & Dearman (1987) also observed that GA_3 application increased the growth of bean and leaf length of lettuce (Olympios, 1976). An increase in stem girth was observed by Kadiri (1991) in his studies with *Abelmoschus esculentus* and *Lycopersicon esculentus* treated with various concentrations of GA_3 and 2, 4-D. The role of GA_3 has been highlighted in both somatic embryogenesis and organogenesis resulting in cell division and elongation (Al-khayri *et al.,* 1992; Komai et al., 1996; Molvig and rose, 1994 and Geekiyanage *et al.,* 2006). Ebofin *et al.* (2004) similarly recorded enhancement in leaf number and plant height in *Prosopis africana* and *Albizia lebbeck*. This might explain why GA_3 increased plant height and stem girth.

Table 2: Mean plant height (cm) and stem girth of red *C. nitida* seedlings treated with different concentrations of plant growth substances ranged between 4MAP to 24MAP

Means followed by the same letters on the same columns are not significantly different at 5% probability level using Duncan Multiple Range Test. IAA- Indole-3-acetic acid, GA_3 Gibberellic acid, KT- Kinetin, C.W- Coconut water, MAP- months after planting

Increase in number of leaves of the treated and control of *C. nitida* seedlings were observed as the number of months after planting (MAP) increased. Significant differences were obtained for 8, 12, 20 and 24 MAP except for 4 and 16MAP. The highest number of leaves at 24MAP was recorded for seedling treatments with 50mg/L gibberellic acid (142.67), followed by 100mg/L gibberellic acid (111.44) and 50mg/L IAA (111.44) respectively the least was obtained in control (41.89). Increased in number of branches were obtained in all the treated and control *C. nitida* seedlings as the number of months increased. Significant differences were observed in all the hormone treatments when compared to the control. With respect to the hormone treatments at 24MAP, the highest number of branches was obtained for seedling treatment of 50mg/L gibberellic acid (13.89). This was followed by 100mg/L gibberellic acid (12.67) and the least was recorded for control (7.33). The highest leaf area at 24MAP was recorded for seedlings treatment of 50mg/L gibberellic acid (163.44), followed by 50mg/L kinetin (158.53) and the least was obtained for control (72.80). This result obtained was not significant when compared to the control (Table4). Similar results were obtained by

ISSN: 2814-0508

Alamu and Mc David (1979), in their studies with tannin (*Xanthosoma sagittifolium*) where they observed that application of GA_3, auxin and cytokinins increased the number of leaves of the plant by promoting the development of auxillary leaf systems. The observation of Usman *et al.* (2005) in explants of *halimii* whereby the highest number of leaves was observed at 75mg/L NAA treatment results shows that low concentration of 50mg/L GA_3 gave the highest number of leaves which was significantly different from that of control in *C. nitida* seedlings.

Table 5 shows the fresh weight of root, shoot, leaves, fresh root length and fresh weight of whole plant of the treated seedlings of *C. nitida* and controls. Significant differences were obtained among the treated *C. nitida* seedlings from those of the controls except for fresh weight of leaves and root length (Table 5). The highest fresh weight of shoot at 24MAP was observed in seedlings treated with 50mg/L gibberellic acid (153.37), followed by 100mg/L gibberellic acid (144.83) and the least mean value was observed for control with value (32.03) respectively. Root fresh weight shows that seedlings treated with 50mg/L gibberellic acid had the highest (67.57), followed by 100mg/L gibberellic acid (61.70) and the least was obtained for the control (15.33) respectively and result highly significant. (Table 5). However, 50mg/L gibberellic acid had the highest (282.10) in fresh weight of whole plant root, this was followed by 100mg/L gibberellic acid (267.50) and the least was observed in controls (60.77) respectively. (Table5). This result is contrary with Heijari *et al.* (2005) who reported seedling diameter, shoot fresh weight, root fresh weight and root length were hampered by low MJ concentration in Scots pine. Similar observations were reported by Zhang *et al.* (2002). However, morphological characters were strongly inhibited by increasing MJ concentration. Results similar reported by Koda, (1999) Salicylic Acid (SA) is a growth regulator which participates in the regulation of physiological processes in plants. It stimulates flowering in a range of plants, increases flower life, controls ion uptake by roots and stomatal conductivity Bhupinder *et al.* (2003). Application of SA also significantly increased dry weights of root and top part of barley and soybeans. The mechanism of salicylic acid was reported by Oata (1975) and Pieterse and Muller (1977) who concluded that salicylic acid induced flowering by acting as a chelating agent. This view was supported by Raskin *et al.* (1987) who confirmed that salicylic acid functioned as endogenous growth regulators of flowering and florigenic effects.

Control	7.53^{c}	11.61^{c}	6.36^{c}	28.80^{c}

Means followed by the same letters on the same columns are not significantly different at 5% probability level using Test Duncan Multiple Range. IAA- Indole-3-acetic acid, GA_3 Gibberellic acid, KT- Kinetin, C.W- Coconut water, MAP- months after planting.

Table 6 shows the dry weight of root, shoot, leaves and fresh weight of whole plant of the treated seedlings of *C. nitida* and controls. Significant differences were obtained among the treated *C. nitida* seedlings from those of the controls. The highest dry weight of root, shoot, leaves and dry weight of whole plant for seedlings given hormone treatments at 24MAP was observed in seedlings treated with 100mg/L gibberellic acid, simply followed by 50mg/L gibberellic acid and the least was observed for control. (Table6). Quaderi *et al.* (2006) reported that IAA increases dry matter by increasing photosynthesis activity in mungbean. Ibrahim *et al.* (2007) reported that the application of bioregulators (GA_3, IAA, benzyl adenine, ancymidol) significantly increased the total dry weight of shoot system in fababean.

Table 7 shows the root- shoot ratio, shoot water and shoot dry matter and leaf area ratio of the treated seedlings of *C. nitida* and controls. Significant differences were obtained in all the parameters tested among the treated *C. nitida* seedlings from those of the controls. The highest shoot- shoot content and leaf area ratio given hormone treatments at 24MAP was observed in seedlings treated with 200mg/L kinetic acid with mean value of 0.78 and 12.19. 100mg/L GA_3 had the highest in shoot water and shoot dry matter with value 60.90, followed by 20% coconut water and the least was observed in control with value 48.36. (Table 7). Mukhtar, (1993) obtained a similar result of increased shoot- root ratio and leaf relative water content for seedlings of *Abelmoschus esculentus* treated with single 100ppm GA_3 treatment and a combination of 100ppm GA_3 + 15% coconut milk at 9 weeks after sowing. Currah and Thomas, (1979) obtained a similar finding of increased shoot-root ratio of carrot plant (*Daucus carota* L.) treated with 100ppm GA_3. Stuart and Cathay (1961) and Akhtar *et al.* (2008) explained that increases in shoot-root ratio by hormones treatments are due to the fact that they enhance the stem elongation plants. In addition, cytokinins such as those contained in coconut water, 6-benzylaminopurine (BAP) also facilitate cell division and sprouting. (Pan, 2001). Quaderi *et al.* (2006) reported that IAA increases dry matter by increasing photosynthesis activity in mungbean. Ibrahim *et al.* (2007) reported that the application of bioregulators (GA_3, IAA, benzyl adenine, ancymidol) significantly increased the total dry weight of shoot system in fababean.

Table 7: Mean root/shoot ratio, shoot water and shoot dry matter, shoot dry matter content and leaf area ratio of red *C. nitida* seedlings given hormonal treatment of different concentrations at 24MAP

IAA- Indole-3-acetic acid, GA_3 Gibberellic acid, KT- Kinetin, C.W- Coconut water, MAP- months after planting.

The present study clearly showed that among various plant growth substances applied, gibberellin, 50mg/L at low concentration had most pronounced stimulatory effect on growth components, which might be due to their effect on physiology of plant (Naeem *et al.* 2004). Gibberellin promotes growth by stimulating cells for quick division, as well as elongation, by increasing mechanical extensibility and plasticity of cell wall, which is followed by hydrolysis of starch to sugar, resulting in reduced water potential and allowing water to enter inside the cell.

ABSTRACT

Potted experiments was conducted at National Horticultural Research Institute Mbato Okigwe South eastern Nigeria during fruiting season of 2019 and 2020 to evaluate the effect of different nursery media on the seed germination and seedling development of two bush Mango (Irvingia gabonensis) species. In doing this, from the Bush mango conservation area in Mbato, freely felled fruits from the two species of Irvingia trees were picked separately, depulped to expose the nuts containing the seeds and shade dried for 3 days. Top soil (Ts), Saw dust (Sd), Poultry manure (Pm), Woodcharcoal(Wc) and Irvingia peel (Ip) and their 50% portion mixture namely; Ts x Sd, Ts x Wc, Ts x Pm, Ts x Ip, Sd x Wc, Sd x Pm, Sd x Ip, Wc x Pm, Wc x Ip, and Pm x Ip. A total of 5 sole nursery growth media and 10 of their mixtures giving 15 treatments per specie of the Bush mango constitutes the experiment. For each of the treatment 30 poly bags (25cm x I8cm) were filled, I5 each for the two variety (V_I & V_2) and placed under a tree shade. The I5 polybags were arranged 5 per roll replicated 3 times in a Completely Randomized Design (CRD). Each of the polybags were planted to a depth of 5cm with one seed of the respective variety and watered once in three (3) days using watering can. Germination and Cotyledon emergence started to strive from the third week and with eye observations, Log Books bi-weekly records were taken on percentage emergence, shoot heights, number of shoot/leaves leaf lengths, breadths and stem girths. Data generated were subjected to ANOVA and pertinent means were separated using fishers LSD at 5% level. There was no seed emergence on treatments Ip x Wcv_2, Ip x Pmv_1 and Ip x Pmv_2 throughout (2-14WAS) the trial period. Treatments Tsv_1; Tsv_2; Sdv_1; Sdv_2; Ts x Wcv_1; Ts x Pmv_1; Ts x Pmv_2; Ts x Sdv_1; Ts x Sdv_2; Pm x Sdv_1 and Pm x Sdv_2 were earliest at 4WAS for seed emergence records of 3,3; 3,6; 3; 4,3 ;4,5 and 4,6 out of 45 samples, respectively. At 14WAS Treatment Ts x Pm with record of 44 out of 45 samples giving 97.7% seed emergence was the highest. It was followed by Ts x Sd at 95.5% and 93.3% by Sd and the least 2 out of 45 samples at 4.4% for treatments Ip; Wc; Pm; Ts x Ip, Ip x Wc and Ip x Sd respectively. Treatment Ip x Sdv_2 as an unsuitable nursery media, had delayed seed emergence till 12WAS and at 14WAS the seedling wildered and diminished. Shoot height was highest at 39cm on Tsv_1 on the 14WAS and least at 5.8cm on treatment Wc x Pmv_1. Number of leaves was highest at 9.2 on Ts x Pmv_2 and least at 1.0 on Ts x Pmv_1. At 14WAS lengths and breadths of leaves were highest at 16.7cm on Tsv_1 and 6.1cm on Ts x Pmv_2 and least at 2.7cm on Ipv_2. Shoot stem girth was highest at 0.53cm on Ts x Pmv_2 and least at 0.21cm on treatment Wc x Pmv_2. The implication of this trial result is that for a tremendous earliest day at 8WAS to seed germination, nursery media Sawdust should be used. Then for a sustained pot-bound seedling production with good number of leaves and sizable girths Topsoil mixture with poultry manure (Ts x Pmv_2) is advised. Any media mixture involving Irvingia peels waste gave delayed and little results and in some cases wildered just at the end of the trial.

Key words: Bush mango, media, germination, *Irvinga*, seedlings, seeds

INTRODUCTION

Irvingia is one of the three genera in the family Irvingiaceae (Okafor,1975, Rundel, 2016). With 2n-28 chromosomes profiling, Irvingia comprises 7 species; 6 in tropical Africa and 1 in South east Asia (PROTA,2007). Bush mango, Dika nut tree, Sauvage, Chocolatier and Ogbono is the various names of *Irvingia*. (Harris, 1996). Currently, it is called African Wild Apple. The origin of species is traceable to wild humid low-land rainforest of central African and West Africa characterized with Ultisols (Van Dyke,1997). It is popularly found in the Tropical Rainforest of Garbon and in the Derived Savannah belts of Southern Nigeria (Okafor,1983, Nzekwe,1995). Okigwe, Imo State in South-eastern Nigeria soil is classified as Ultisols (Mbagwu,1992; Okpara *et al.*, 2012; Okpara *et al.*, 2017; Okpara *et al*,2018; Okpara *et al*, 2020). In this part of Southern Nigeria, *Irvingia* has two distinct forms namely, *Irvingia gabonensis* var gabonensis with sweet edible pulp and *Irvingia gabonensis* var excels (wombolu) with bitter inedible pulp (Okafor,1975; Vihotogbe, 2012). The two types have trees and seedling that looks identical but their fruits mesocarp or pulp taste clearly and steadily different from the other(Vihotogbe, 2016). Their DNA analysis suggests that these two (2) taxa are clearly and genetically distinct and that their genome do not hybridize even when planted in close isolation distances (PROTA,2007). They two species flowers separately. The inedible bitter, *I. wombolu,* fruits during dry season months of December to March while the sweet and edible type fruits during raining season from April to August. These days, may be for climate change, their fruiting months' over-laps into the other. Both species are called African Bush Mango Tree (Vihotogbe, 2016). They are large, long-lived, evergreen tropical tree of 10 to 50 meters high with gestation period of 10 – 15 years (Okafor,1975; Harris,1996; Vihotogbe, 2016). NIHORT Mbato Okigwe has over two (2) hectares of land area of conservation of these species. The fruit falls freely from the tree top upon maturity. The fruit in the wild is classified as one of the major Non-Timber Forest Products(NTFPs) are usually picked from tree base by farmers and rural locals as important component of rural livelihood (FOA, 2015; Rundel, 2016). *Irvingia* fruit has been described as ellipsoid, to cylindrical drupe, occasionally near spherical 4-6.5cm x 4-6.5cm x 3.5 – 6cm smooth, green when ripe ,pulp bright orange, soft, juicy with few fibres ,stone woody,1 seeded with epigeal germination (PROTA,2007).The most valued part of the *Irvingia* species which is also traded internationally across Europe is the fruit seed n called kernel that is popularly used as a thickener for soup and stew making (Ejiofor,*et al.,* 1987; PROTA, 2007; Vihotogbe, 2012; Rundel, 2016). Other uses of *Irvingia* is the tree as a hard timber, the bark used as anti poison, anti dysentery and the fruit pulp for dye making (PROTA, 2007). The increasing local and international market demand of the kernels causes on over exploitation of trees in natural habitat and their result in poor regeneration in their postulated genetic diversity in Nigeria, Cameroun and Garbon (Vihotogbe, 2012). Before now the common source of new seedling stock of *Irvingia* is the forest (Tchoundeu *et al.*,1997). Today with new innovative from trials over time, growth media such as soils, saw mill waste, animal waste, kitchen waste, plant residue/waste and their mixtures can be harnessed and tapped to regenerate through seedling nursery of tree plant to create, replenish, expand and sustain plantations. Different nursery media affects sprouting and germination as well as seedlings differently. Raising planting materials on growth media is another method of ex-situ conservation of genetic materials (Hunter and Heywood, 2011). This involves collecting and placing growth media in empty cans, trays, pots, polybags, and other sizeable receptacles. Agricultural productivity increase is only possible with use of yield-enhancing technology (CCIA, 2019). Top soil is commonly used in germination of seeds but when used alone are very poor growth media (Baiyeri & Aba 2012). The use of Organic materials mix soils provides better root-substrate relation than conventional Topsoil (Baiyeri & Aba,2012). One of the most important criteria for successful rooting is a reliable rooting medium (Akintoye, *et al.,* 2012). To evaluate from the arrays of Topsoil, Poultry manure, Sawdust, Wood charcoal, Irvingia peel waste and their mix with a view of coming up with recommendation is what informed this trial.

MATERIAL AND METHODS

Potted experiments were conducted at National Horticultural Research Institute Mbato Okigwe South eastern Nigeria during fruiting season of 2019 and 2020 to evaluate the Effect of Different Nursery Media on the Seed germination and Seedling Development of two Bush Mango (*Irvingia gabonensis*) Species. The station lies on latitude 05^0 33^1N and longitude 07^0 23^1E and altitude of 130 meters above sea level. Okigwe is characterized by undulating dissected plains and soils derived from shale and sandstone, classified as ultisol. NIHORT Mbato Okigwe has over two (2) hectares land area of conservation of these two species namely *Irvingia gabonensis* var *gabonensis* and *Irvingia gabonensis* var wombolu also known as I*rvingia wombolu*. They two species flowers separately. The inedible bitter *I. wombolu* fruits during dry season months of December to March while the sweet and edible type fruits during raining season from April to August. These days, their fruiting over-laps into the other. From the conservation area some tree stands were selected and tagged according to species for fruit pickings. Freely felled fruits from the two species of Irvingia trees were picked separately, depulped to expose the nuts containing the seeds and shade dried for 3 days. Top soil (Ts), Saw dust (Sd), Poultry manure(Pm), Wood charcoal (Wc) and *Irvingia* peel(Ip) and their 50% portion mixture namely; Ts x Sd, Ts x Wc, Ts x Pm, Ts x Ip, Sd x Wc, Sd x Pm, Sd x Ip, Wc x Pm, Wc x Ip, and Pm x Ip. A total of 5 sole nursery growth media and 10 of their mixtures giving 15 treatments per specie of the Bush mango constitutes the experiment. For each of the treatment 30 poly bags (25cm x I8cm) were filled, I5 each for the two variety (V_I & V_2) and placed under a tree shade. The I5 polybags were arranged 5 per roll replicated 3 times in a Completely Randomized Design (CRD). Each of the

ISSN: 2814-0508

polybags were planted to a depth of 5cm with one seed of the respective variety and watered once in three (3) days using watering can. Germination and Cotyledon emergence started to strive from the third week and with eye observations and Log Books Bi-weekly records were taken on percentage emergence, shoot heights, number of shoot/leaves leaf lengths, breadths and stem girths. Data generated were subjected to ANOVA and pertinent means were separated using fishers LSD at 5% level.

RESULTS AND DISCUSSIONS

Tables 1 shows the Bi-weekly (till the 14wks) data collections on shoot emergence and percentage of the 45 samples each for the 15 treatments for two varieties investigated. Also taken was bi-weekly data for heights, number of leaves, leaf lengths and breadths and stem girths of the samples. There was zero seed emergence at 2WAS across all the treatments and varieties investigated. At 4WAS there was significant (P< 0.05) difference on treatments with records for earliest weeks to seed emergence. That seed emergence was observed beyond 2WAS sowing agrees with Okafor (1997) findings. Treatments Tsv_1; Tsv_2; Sdv_1; Sdv_2; Ts x Wcv_1; Ts x Pmv_1; Ts x Pmv_2; Ts x Sdv_1; Ts x Sdv_2; Pm x Sdv_1 and Pm x Sdv_2 were earliest to seed emergence records of 3,3; 3,6; 3; 4,3 ;4,5 and 4,6 out of 45 samples respectively. Of all the earliest to seed emergence records, treatments Sdv_2; Ts x Sdv_2 and Pm x Sdv_2 with records of 6; 5 and 6 seed emergence were significantly (p<0.05) higher than others. These other treatments not mentioned at 4WAS were observed with zero seed emergence.

At 6WAS, treatments Ts x Wcv_1 at 16 sample seed emergence was significantly (p<0.05) higher than other treatments. It was closely followed by treatments Sdv_2 and Ts x Sdv_2 each at 15 sample emergences and the least (3) each for treatments Wcv_1; Pmv_2 and Wc x Pmv_1 respectively. It is worthy of note that treatments Ipv_1; Ipv_2; Wcv_2; Pmv_1; Ts x Ipv_1, Ts x Ipv_2 ;Ip x Wcv_1; Ip x Wcv_2;Ip x Pmv_1;Ip x Pmv_2;Ip x Sdv_1; Ip x Sdv_2 and Wc x Pmv_2 all recorded zero seed emergence at the 6WAS.

At8WAS. Treatment Sdv_2 (Sawdust v_2) with 33 out of 45 for seed emergence was significantly (P<0.05) higher than 27 recorded for treatment Pm x Sdv_2 and 18 also recorded for treatment Tsv_1(Topsoil). The least was 2 seed emergence recorded for treatments Wc x Sdv_1 and Pmv_2. At this time or interval for expectant seed emergences, an average observer will label treatment Saw dust(Sdv_2) as the earliest with highest number for seed emergence. This may be true with NIHORT reports of 1997,2000,2005 and 2018 that acclaimed sawdust as the best for Irvingia spp germinations.

At 10 WAS the following treatments maintained zero seed emergence :-Ipv_1, Ipv_2; Wcv_2; Ts x Ipv_1, Ts x Ipv_2; Ip x Wcv_1, Ip x Wcv_2; Ip x Pmv_1, Ip x Pmv_2; Ip x Sdv_1, Ip x Sdv_2 and Wc x Pmv_2. Poultry treatment (Pmv_1) at 10 WAS recorded its ever seed emergence of 3 samples out of 45. Treatment Wc x Pmv_1 with 3 seed emergence at 6WAS recorded zero emergence and zero shoot at 10WAS.This wildering and diminishing of seedling after emergence recorded for treatment Wc x Pmv_1 suggests that the nursery media mixture was poor in giving the seedling the physical support the soil gives(Ekpo and Sita,2010).Still on 10 WAS, treatment Sawdust(Sdv_1) with 36 samples though not significantly(P<0.05) different was lower than treatments ,Ts x Pmv_1(39) which was significantly higher than other samples with seed emergences. The least (2) was recorded for treatment Wc x Sdv_1.

At 12 WAS, treatments IpV_I, Ipv_2; Wcv_2; Ip x Wcv_I, Ip x Wcv_2; Ip x Pmv_I, IIp x Pmv_2 and Ip x Sdv_2 maintained zero seed emergence even at I2 WAS in this trial. Some other treatments were observed at I2WAS with their first ever seed emergence and it includes treatments, Ts x Ipv_I, Ts x Ipv_2; Ip x Wcv_I; Ip x Sdv_1; Wc x Pmv_1, Wc x Pmv_2 with sample records of 4, 3; 2; 4; and 3,4 respectively. This trends of poor and delayed seed emergence could be attributed to poor aeration, nutrient and water balance that is inherent with these soil, sawdust, wood charcoal, *Irvingia* peel and poultry manure mixtures thus making these features as Akintoye *et al.* (2012) put it as unreliable nursery media. It is worthy of note here that at 8WAS Sawdust(Sdv_I) with 33 out of 45 samples was with superior significant(p<0.05) for earlier and numerical seed emergence higher than other treatments. Sawdust use here can be likened to a yield-enhancing technology which CCIA, afdb.org/affm (2019) affirmed as the surest ways to increasing agricultural productivity. This lead (33) by treatment sawdust at 8WAS increase at decreasing trend (36) at I0 WAS, was at this same interval running neck-to-neck with treatment Topsoil and poultry manure (Ts x Pmv_1;)at 39 without significant(P,0.05) difference even to the I4WAS.

At I4WAS this trend of seed emergence numerical margin without significant (P<0.05) difference even with percentage (%)comparison, continued from the I2WAS into the I4WAS with 39(86.6%) samples each for treatments Tsv_I; Tsv_2; and Pm x Sdv_I.

Fourthy -42(93.3%) out of 45 samples each was recorded for Sdv_1, Sdv_2, Ts x Wcv_1, Ts x Sdv_l, 43 (95.5%) for Ts x Sdv_2 only and lastly ,44(97.7%) samples out of 45 each for Ts x Pmv_1 and Ts x Pmv_2.The least of 2(4.4%) samples each was recorded for treatments Ipv_2, Wcv_l, Pmv_l, Ts x Ipv_2, Ip x Wcv_l, and Ip x Sdv_l. It is also at I4WAS that treatments Ipv_2 and Ip x Sdv_l recorded 2 (4.4%) samples as their first ever seed emergence. It is also worthy of note that treatment Ip x Sdv_2 with 4(8.8%) samples emergence at I2WAS lost it all (0%)to wildering at I4WAS probably to what Ingram *et al*. (2009) described as unsustainable nursery media.

Table 1 also shows data on shoot / seedlings heights from 2 – I4WAS following seed emergence of the two variety of Bush mango; *Irvingia gabonensis* and Irvingia *wombolu*. At 2WAS there was no seed emergence across all treatment which agrees with Okafor (1997).

At 4WAS, treatments that recorded seed emergence were significantly(P<0.05) earliest to shoot/height expression compared to others at later weeks after sowing(WAS). This includes treatments; Tsv_l; Tsv_2; Sdv_1, Sdv_2; Ts x Wcv_1; Ts x Pmv_1; Ts x Pmv_2; Ts x Sdv_1, Ts x Sdv_2; Pm x Sdv_1 and Pm x Sdv_2 with emerged seed shoots/seedlings height records of 3.8cm,3.0cm; 2.9cm,2.5cm; 2.6cm; 2.4cm,2.5cm; 2.2cm,2.1cm; 2.6cm and 2.9cm, respectively. There was no significant (P<0.05) difference for these recorded values.

At 6WAS,Shoots/seedlings heights was significantly(P<0.05) high at 6.1cm and 5.9cm on treatments Ts x Pmv_1 and Ts x Pmv_2 and least at 2.1cm for treatment Wc x Pmv_1..This trend continued till the 14WAS wherein treatments Tsv_l;Tsv_2 significantly(P<0.05) recorded highest heights of 39cm and 37cm and was followed with records of 29.1cm,29.0cm, 28cm,and 27cm for treatments Sdv_1; Ts x Sdv_2; Ts x Pmv_2; Sdv_1; and Ts x Sdv_1..That the top soil at 14WAS here gave highest seedling heights also confirms soil as universal best anchor for seedlings and crops (FOA,1981; Mbah,1996). The top soil as a nursery growth media stand the best with respect to 'pot – bound' or prolonged stay of seedlings in the nursery. The least for shoot/seedling heights was 5.8cm for treatment Wc x Pmv_1.Treatments that recorded Zero seed emergence also recorded zero shoot/seedling heights.

Table 1 also shows the number of shoot /seedling leaves from 2 – I4WAS following seed emergence of the two variety of Bush mango; *Irvingia gabonensis* and Irvingia *wombolu*. At 2WAS there was no seed emergence across all treatment which agrees with Okafor (1997).

At 4WAS. treatments that recorded seed emergence were significantly (P<0.05) earliest to shoot/seedling leaves expression compared to others at later weeks after sowing(WAS). This includes treatments; Tsv_l; Tsv_2; Sdv_1, Sdv_2; Ts x Wcv_1; Ts x Pmv_1; Ts x Pmv_2; Ts x Sdv_1, Ts x Sdv_2; Pm x Sdv_1 and Pm x Sdv_2 with emerged shoot/seedling number of leaves records of 1.1, 1.2; 1.3, 1.1; 1.5; 1.6,1.7; 1.3 ,1.4; 1.9 and 2.0, respectively. There was no significant (P<0.05) difference for these recorded values.

At 6WAS, shoot/seedling number of leaves were significantly (P<0.05) high at 3.2,3.0;3.0; and 3.0 for treatments Ts x Wcv_1, Ts x Wcv_2;Tsv_1 and Tsv_2 and least at 1.9 on treatment Wc x Pmv_1.This trend also continued till the 14WAS wherein significant(P<0.05) highest number of leaves of 9.2 and 8.1 was recorded for treatment Ts x $Pmv_1$and Ts x Pmv_2.This was followed without any significant(P<0.05) difference by treatments, Tsv_1 ;Tsv_2; Ts x Wcv_1 and Ts x Wcv_2 at 6.4;6.6;6.0; and 5.8 number of leaves. That treatment Topsoil poultry manure mix gave numerical lead in the number of leaves agrees the fact that poultry manure is rich in Nitrogen that readily enhances vegetative growth (Yagodin,1982; Munoz *et al.,* 2004; Baiyeri *et al*., 2012.). The least number of leaves per seedlings was observed at I.0 and 2.0 leaves for treatments Pmv_1 and Ipv_2.

Table 2 shows three (3) measured seedlings growth parameters that included leaf lengths, leaf breadths and stem girths only. At 2WAS there was no seed emergence across all treatment which agrees with Okafor (1997). At 4WAS treatments with earliest weeks to seed emergence recorded earliest to shoot emergence for expression of leaves for data collections that did not significantly (P< 0.05) vary among one another. The leaf lengths sequence of 3.3cm; 3.I cm; 2.2cm, 3.5cm; 3.9cm; 3.5cm,4.0cm; 3.9cm,4.0cm;.3.7cm and 3.9cm for treatments Tsv_l; C; Sdv_1, Sdv_2; Ts x Wcv_1; Ts x Pmv_1; Ts x Pmv_2; Ts x Sdv_1, Ts x Sdv_2; Pm x Sdv_1 and Pm x Sdv_2 respectively.

At 6WAS shoot/seedling leaf lengths were significantly(P<0.05) high at 8.1cm, 7.3cm; 6.9cm and 6.7cm for treatments Pm x Sdv_2; Ts x Pmv_2; Ts x Wcv_1 and Ts x Sdv_1 and least at 2.9cm for treatment Wcv_1.PROTA(2007) reported a range of 4.5 -8cm lengths of leave blades. The trend generally continued till the 14WAS that significant(P<0.05) high leaf lengths of 16.7cm, I5.6cm; I5.5cm; 15.0cm and I3.4cm were recorded for treatments Tsv_1; Ts x Sdv_1; Ts x Wcv_1; Ts x Pmv_2 and Pm x Sdv_2 and the least(2.7cm) for treatment Ipv_2 that coincidentally emerged seed for the first time at same interval of 14WAS.This suggest that Ipv_2 as a treatment is not a sustainable nursery media (Akintoye *et al*., 20I2).

Table 2 also shows that at 2WAS there were data to take across all the treatments but there was for leaf breadths at 4WAS and at 6WAS. Just like as it was in its complimentary leaf lengths records, leaf breadths were at 6WAS significantly (P<0.05) high at 4.8cm, 4.7cm; 4.0cm; 3.4cm and 3.3cm for Pm x Sdv_2; Ts x Wcv_1; Ts x Sdv_2; Ts x Pmv_l and Sdv_1.The least value was 1.8cm on treatment Wcv_1.The generally continued through to the I4WAS with significant(P<0.05) high records of 6.1cm; 5.9cm and 5.Icm for Ts x Pmv_1 ; Ts x Sdv_1 and Tsv_2 and the least(I.9cm) each for Ipv_2 and Pmv_1. PROTA (2007) reported a range of 2 -4 cm breadths of leave blades.

Table 2 also shows data on stem girths with the indication that at 2WAS, there were no to take across all the treatments but there at 4WAS through to the I4WAS. At 4WAS although there were significant (P<0.05) difference, treatments with earliest days to seed emergence recorded earliest stem girths data collections. Thus, at 4WAS, treatments Tsv_l;Tsv_2; Sdv_1, Sdv_2; Ts x Wcv_1; Ts x Pmv_1; Ts x Pmv_2; Ts x Sdv_1, Ts x Sdv_2; Pm x Sdv_1 and Pm x Sdv_2 recorded 0.25cm, 0.26cm, 0.3cm,0.3cm,0.25cm,0.25cm,0.3cm,0.3cm,0.25cm. 0.27cm and 0.28cm respectively. The trend generally continued from the 6WAS to the 14WAS wherein significant(P<0.05) high stem girths of 0.53cm, 0.51cm, 0.48cm,0.47cm and 0.46cm for treatments Ts x Pmv_1, Tsv_l; Ts x Sdv_2, Sdv_1 and Ts x $Wcv_1$and least (0.22cm) was recorded each for treatments Ipv_2 and Wc x Pmv_2 respectively.

CONCLUSIONS/RECOMMENDATIONS

The uptake of this trial result is that for a tremendous earliest day at 8WAS to seed germination, nursery media Sawdust should be used. Then for a sustained pot-bound seedling production with good number of leaves and sizable girths, Topsoil mixture with poultry manure (Ts x Pmv_2) is hereby recommended. Any media mixture involving *Irvingia* peels (waste) gave delayed and little results and in some cases, an already emerged seedling wilders and diminishes just at or near the end of the trial. Finally, these days, the fruiting seasons of the two *Irvingia* species over laps into the other. This appears to suggest a climate change effect which also opens doors for hybridization and other comparative trials involving the two species.

ABSTRACT

A study was carried out to determine the effect of pre-germination treatments on growth of Pipper guineense at Savanna Forestry Research Station Samaru, Zaria. The treatments include seeds with removed pericarps sown in river sand, seeds with removed pericarps sown in top soil, seeds with unremoved pericarps sown in river sand and seeds with unremoved pericarps sown in top soil. The experiment was laid out in a completely randomized design with five replications. The results of germination test show significantly ($P \leq 0.05$) higher germination percentage among all treatments combinations. Seeds with removed pericarps sown in top soil recorded the highest (95%) germination followed by seeds with unremoved pericarps sown in top soil (52.9%), seeds with removed pericarps sown in river sand (39.6%) while seeds with unremoved pericarps sown in river sand (19.6 %) had the lowest germination. Similar trends were observed with seedling heights and number of leaves with seeds having removed pericarps sown in top soil (4.08cm and 3.30) recording highest seedling height and number of leaves and this was followed by seeds with unremoved pericarps sown in top soil (3.64cm and 2.56), seeds with removed pericarps sown in river sand (3.44cm and 1.46) while seeds with unremoved pericarps sown in river sand (2.64cm and 1.32) had the lowest seedling height and number of leaves respectively. The above findings have shown the potential of all the pre-germination treatments especially seed with removed pericarps sown in top soil as most effective mechanism to break the dormancy of the seed in order to initiate germination and growth for efficient plantation establishment and conservation.

INTRODUCTION

Forests provide products for different uses at households and industrial levels (Appiah 2009). These products are grouped into timber and non-timber products (NTFPs). Although timber products are highly valued worldwide, the NTFPs which play an important role in sustaining livelihoods of communities living around forest areas, but have been given minimum attention. The contribution of non-timber Forest resources to the rural economy is known to be substantial but this cannot be quantified because of reliable data that are lacking. Lack of knowledge about the resources themselves and the demand for and value of these products make sound knowledge on the management planning extremely difficult. Precise information on the abundance, distribution, variation ecology, reproductive biology, traditional and new method of propagation of these non-wood forest resources are grossly inadequate (Gbile and Soladoye, 1995).

It is true that many of the major crops of the world are produced in areas outside their place of origin and Nigeria with the rest of Africa are not exceptions in this respect. It is equally true however, that at least 2,000 indigenous, food plants exist in various parts of the continent, many have been used for thousands of years but are now little appreciated. Most have not been assessed for their potential and they receive very scanty attention of Researchers and bodies that promote research in Nigeria, spice crops such as *Piper guineense, Ocimum graticimum* and so on are crops that receive very poor attention, (Adedipe, 1993).

Another factor affecting our indigenous species like *Piper guineense* is the issue of inadequate policy guidelines and lack of practicable conservation measures regarding the research, development and its initialization. Thus, at present, greater attention is paid to the development of exotic crops to the neglect of the indigenous ones. This has then led to the under-utilization of the potential species.

Today, *Piper guineense* constitutes part of the Nigerian crops that are fast disappearing from our natural vegetation and it should be noted that this crop has an important role to play in the food and chemical extractive security of our people. Food security can be defined as the access by all people at all times to enough food for an active, healthy life and it depends on both the availability of food and the ability to acquire it. Increasing food security involved increasing food supplies in addition to increasing income of the rural poor. There is a great potential for this disappearing crop i.e. *Piper guineense* and all other disappearing crops in general in the mixed crop farming system. If food and fibre production on continuous basis must be ensured in Nigeria, there is the need to conserve and re-cultivate some of these disappearing crops urgently. The value of some of these plants is better appreciated in their role in alternative medicine. There is then the need to prevent the loss of bio diversity (Okojie, 1993).

Piper guineense or African black pepper, a climbing perennial plant of the family Piperaceae, is used as spice, food preservative, insecticide, herbal medicine, and as fragrance in the cosmetic industry (Nwozo *et al.,* 2011). It is used for the treatment of cough, bronchitis, intestinal diseases, and rheumatism (Sarah *et al*., 2011). *Piper guineense* stimulates the digestive enzymes, lowers lipid peroxidation, prevents oxidative damage, and inflammation (Ogunniran, 2009). *Piper guineense* is a spice plant from the family Piperaceae and from genus piper. It is a West African spice plant commonly called Ashanti pepper. It is known as Uziza in Igbo and Iyere in Yoruba. Other common names are Benin pepper, Guinea pepper and false cubeb. Spices generally are parts of various plants cultivated for their aromatic pungent or otherwise desirable substances. They consist of rhizomes, bulbs, flower bud, fruit, seed, and leaves. They usually are categorized into tiny wild fruits, nuts, herbs, and leafy vegetables. *Piper guineense*, a spice plant from the class Magnoliopsida, order Piperales and family Piperaceae, is an important plant that has culinary, medicinal, cosmetic and insecticidal uses (Juliani *et al*. 2013, Besong *et al.* 2016). The plant is found in tropical regions of central and West Africa, where it is semi-cultivated in countries like Nigeria, especially in the southern parts (PURSEGLOVE et al. 1981). It is known in Nigeria as 'Uziza' (Igbo), 'Iyere' (Yoruba) and 'Masooro' (Hausa). Other common names are Ashanti pepper, Guinea pepper, Benin pepper and false cubeb. *Piper guineense* is an important source of various nutrients and phytochemicals such as proteins, carbohydrates, vitamins, minerals, fat, alkaloids, steroids, lignins, glycosides, saponins, flavonoids, tannins and phenolic compounds. It is also known to have antibacterial, antioxidant, anti-inflammatory, hepatoprotective, fertility, aphrodisiac, anticonvulsant and larvicidal properties (ECHO *et al*., 2012, Okoye and Ebeledike 2013, Nwankwo *et al*., 2014, Besong *et al*., 2016, Ukpai *et al*., 2017).

Germination is key to the successful regeneration and propagation of plants. The condition where an intact, viable seed fails to germinate under favourable conditions is known as dormancy (Bewley, 1997). The intensity of dormancy could be influenced by the species, genome and the type of dormancy (Zoghi *et al.,* 2011). Common methods that have been suggested to break physical dormancy in seeds include scarification by nicking, hot water and acid treatments, stratification (Vandenbeldt, 1992). However, very little effort has been directed towards using this indigenous tree in afforestation programs. The main problem encountered in propagating seedlings of most indigenous trees for afforestation programs in arid and semiarid areas is as a results of dormant seeds (Bewley, 1997). Seeds of such species need to be subjected to some chemical or physical treatment to break dormancy and obtain uniform germination (Hossain *et al.,* 2005).

Extinction is an irreversible process and so, we must not allow this native species to become extinct. This crop and many others can become extinct in a few decades if no proper attention is paid to the problem and so, desired attention should be given to these crops by the appropriate authorities. Therefore, this study investigates the seed germination of *Piper guineense* in different soils: top soil and river soil.

MATERIALS AND METHODS

Study Area

The study was carried out at Savanna Forestry Research Station Nursery, Samaru (11^0 11" N, 07^0 38" E and 686m above sea level) Zaria.

Treatments and Experimental Design

The treatments consisted of four pre-germination methods (removed pericarp/River Sand, removed pericarp/topsoil, not-removed pericarp/River Sand and not-removed pericarp/topsoil) which were replicated five times in a completely randomized design with 40 seeds per replicate which resulted in a total of 200 seeds per treatment. A total of 800 seeds were used for the whole experiment.

Sowing of seed

Fresh seeds of *Piper guineense* used for this study were purchased from Ojoo market (Ibadan, Nigeria) and were identified and authenticated at the Forest Herbarium Ibadan (FHI), Forestry Research Institute of Nigeria. Sieved top soil collected from Teak plantation and thoroughly washed river sand were filled into 10 germination boxes each, measuring 90cm x 45cm x 30cm. Forty (40) seeds each were sown in germination boxes according to the treatments combination resulting in a total of 20 germination boxes used for the experiment. Each treatment replicate was thoroughly watered every other day and kept for a period of two weeks, and the number of seeds that germinated per treatment were recorded. After germination, 15 randomly selected seedlings were transported into each polythene pots filled with top soil and river sand according to the treatments. The growth of seedlings was observed for four weeks, and constantly watered to avoid dryness.

Data collection and analysis

Data collected includes number of germinated seeds from each treatment, and cumulative average recorded after two weeks, while data on seedling height and number of leaves were obtained from five randomly selected plants and their cumulative average recorded after four weeks. Germination percentage was computed using the formula below.

$$\text{Germination \%} = \frac{\text{Number of germinated seeds}}{\text{Total number of seeds sown}} \times 100$$

All data collected were subjected to analysis of variance (ANOVA) using SAS software package. Mean differences among treatments were separated using Least Significant Difference (LSD) at *P*=0.05

RESULTS AND DISCUSSION

The results of effect of different pre-germination treatments on germination and growth of *Pipper guineense* seeds and seedlings are discussed below.

Effect of Pre-germination treatments on seed germination of *Pipper guineense*

There were significant ($P \leq 0.01$) differences in germination of *P. guineense* seeds subjected to different pre-germination treatments 2weeks after sowing (Table 1). Seeds with removed pericarp (67.3%) recorded significantly ($P \leq 0.05$) higher germination than seeds with unremoved pericarp (36.3%). Similarly, seeds planted in top soil (73.9%) had significantly ($P \leq 0.05$) higher germination than seeds planted in river sand (29.6%) respectively.

Interaction between seed pericarp and soil type on germination of *Pipper guineense* seeds

The interaction between seed pericarp and soil type on germination of *P. guineense* 2WAS is presented in table 2. There was significant interaction of the two seed pericarp with the two soil type on the germination of *P. guineense* 2weeks after sowing. Seeds with removed pericarp sown in top soil (95.0%) recorded significantly ($P \leq 0.05$) higher germination than other three treatments. This was followed by seeds with unremoved pericarp sown in top soil (52.9%) which also recorded significantly ($P \leq 0.05$) higher germination than seed sown in river sand with removed pericarp (39.6%) and seed sown in river sand with unremoved pericarp (19.6%). The germination recorded from seed sown in river sand with removed pericarp was also significantly ($P \leq 0.05$) higher than seed sown in river sand with unremoved pericarp.

sowing (table 3). Seeds with removed pericarp (4.8) recorded significantly ($P \leq 0.05$) higher seedling height than seeds with unremoved pericarp (3.8). Similarly, seeds planted in top soil (3.7) had significantly ($P \leq 0.05$) higher seedling height than seeds planted in river sand (3.9) respectively. There was no significant ($P \geq 0.05$) difference in seedling height resulting from the four different treatment combinations.

Effect of Pre-germination treatments on number of leaves of *Pipper guineense*

Significantly ($P \leq 0.05$) higher number of leaves were observed on *P. guineense* seedling subjected to different pre-germination treatments 4weeks after sowing (table 4 and figure 3). Seeds with removed pericarp (3.0) recorded significantly ($P \leq 0.05$) higher number of leaves than seed with unremoved pericarp (2.4). Also, seeds planted in top soil (3.7) had significantly ($P \leq 0.05$) higher number of leaves than seeds planted in river sand (1.7) respectively. There was no significant ($P \geq 0.05$) difference in number of leaves resulting from the four different treatment combinations.

Table 4: Effect of pre-germination treatments on number of leaves of *Pipper guineeense* seedling

Treatment	Number of Leaves
Seed Pericarp	
Removed	3.0a
Not Removed	2.4b
SED±	0.193

River sand	1.7
Top soil	3.7
SED±	0.193
Interaction	
Seed Pericarp*Soil Type	NS

Means followed by same letter(s) in the same column are not different statistically at *P=0.05* using LSD NS = Not significant

CONCLUSION

The results of this study shows that seeds of *Piper guineense* germinate better in top soil than river sand because of variations in seedlings heights and number of leaves produced. Also, the removal and non-removal of pericarps influences the growth rate, height and leaf production of the plant. It was found that *P. guineense* seeds with removed pericarps have higher rates of germination and quicker growth rates than seeds with unremoved pericarps. The combined effect of the two factors on germination and growth of *P. guineense* seeds shows that seeds with removed pericarps that were sown in top soil perform significantly better than other treatments combination. Hence, can be adopted to break its dormancy for better seedling establishment.

ABSTRACT

Seed nuts play a vital role as planting material in the production of rootstocks and seedlings for cashew plantations establishment. One of the major challenges faced by cashew nursery operators and farmers is low seed germination and this always contributes to the losses encountered in nursery management. This study was focused at investigating the effects of seed viability test on the germination of three cashew biotypes using three sowing media. The experiment was carried out at the nursery unit of the Cocoa Research Institute of Nigeria, Ibadan. Two hundred nuts Jumbo, Medium and Small cashew biotypes were used for floatation test in water. The same nuts were used for seed germination assessment in pre-germination chamber by sawdust, in polythene bags filled with top soil and in-situ using completely randomized experimental design. Jumbo biotype recorded the highest percentage cashew nut floatation in water (62.33%) while the least floated nuts (19%) were observed in Small biotype. Mean days to germination of the floated and sank nuts sown In-pot medium across all the three biotypes (with a range of 14.7 – 17.4) were lower than those sown in Pre-germination chamber and In-situ. The percentage of floated nuts that germinated was very high in Jumbo (53% - 58%) and least in Small biotype (37% - 40%). This study concludes that cashew nut sown in pot medium tends to germinate faster than the nuts sown in pre-germination chamber and in-situ. In addition, nut floatation in water is not an appropriate test for cashew viability determination because good percentage (37% - 58%) among the floated nuts will germinate.

Key words: Cashew germination, Nut floatation test, Seed viability, Pre-germination

INTRODUCTION

Cashew (*Anacardium occidentale* L.), an important edible nut crop, is cultivated in the tropical region of Africa, India, and Brazil, (Wickramasinghe, 2002). The nut is a basic input and is vital to the propagation of cashew; in the production of rootstocks and seedlings for plantations establishment. To grow plants from seed, some knowledge of the quality and germination requirements of the seed is required. Not all fruits will produce seed and not all seed produced will be viable. There are a number of quick tests that can be conducted on seed to determine whether or not the seed is potentially viable. Insect damaged seed and shriveled seed is unlikely to germinate. Fruits with no seed within will also not germinate (Seed notes, 2000). There are several ways for testing seeds viability; these include scarification, cutting test, excised embryo technique, biochemical and chemical method such as acid pre-treatment (Agbogidi *et al*., 2007), colour method, transparency, and germination method as well as floatation technique (Singh *et al*., 2011). However, floatation method is the fastest way of testing seeds viability, which is based on the observation that empty or nonviable seeds float while viable seeds sink or settle down to the bottom of the container (Bello and Gada, 2015; Pamela, 2012). Adeyemi and Hammed (2001) conducted a preliminary study on the effects of floatation test on the germination of two Iwo cashew selections and reported that the germination of floaters was as good as sinkers. Their study was limited to the varieties that were available as at the time the experiment was conducted (Iwo Selection) and only one sowing method (in-situ). Therefore, this is study was aimed at investigating the effects of seed floatation viability test and three sowing media on the germination of three cashew biotypes that are currently cultivated by farmers in Nigeria.

MATERIALS AND METHODS

The study was carried out between May and August, 2020 at the nursery unit of Cocoa Research Institute of Nigeria (CRIN) (latitude 4°- 14°N and longitude 3° - 14°E), Oyo State, South Western Nigeria. The three cashew biotypes; Jumbo, Medium and Small nut sizes produced in the current season with no sign of damage, insect pest attack or disease symptoms were collected from the cashew germplasm of the Institute. Two hundred nuts randomly selected from each biotype were introduced into a bucket fill with ordinary water at room temperature to separate and count those that sink in water from the floating ones and for data taken. The nuts that sank in water and those that floated were separately used for germination evaluation by using three different sowing media / environment; Pre-germination chamber using sawdust in a chamber, In-pot (polythene bag filled with top soil) and In-situ (on the farm land). Data were collected from each of the treatment categories on number of seeds germinated and days to germination after sowing. Data collected on cashew nut floatation test and germination were analyzed using descriptive statistics, while days to germination data were analyzed by variance (ANOVA) technique using SAS.

RESULTS AND DISCUSSION

The percentage cashew nut floatation in water varied widely across the biotypes (Fig. 1) with highest floatation (62.33%) recorded in Jumbo the while the least floatation (19%) was observed in Small biotype. Reverse was the case for the nuts (seeds) that sank in water. Small boitype recorded the highest sinkers percentage (81%) followed by Medium (65.33%), while least sinkers (37.67%) were observed in Jumbo. From this trend, it appears that there is simple relationship between cashew nut sizes and their floatation in water. Large cashew nuts tend to float more in water than smaller nut sizes and vice versa for cashew nuts sinking in water.

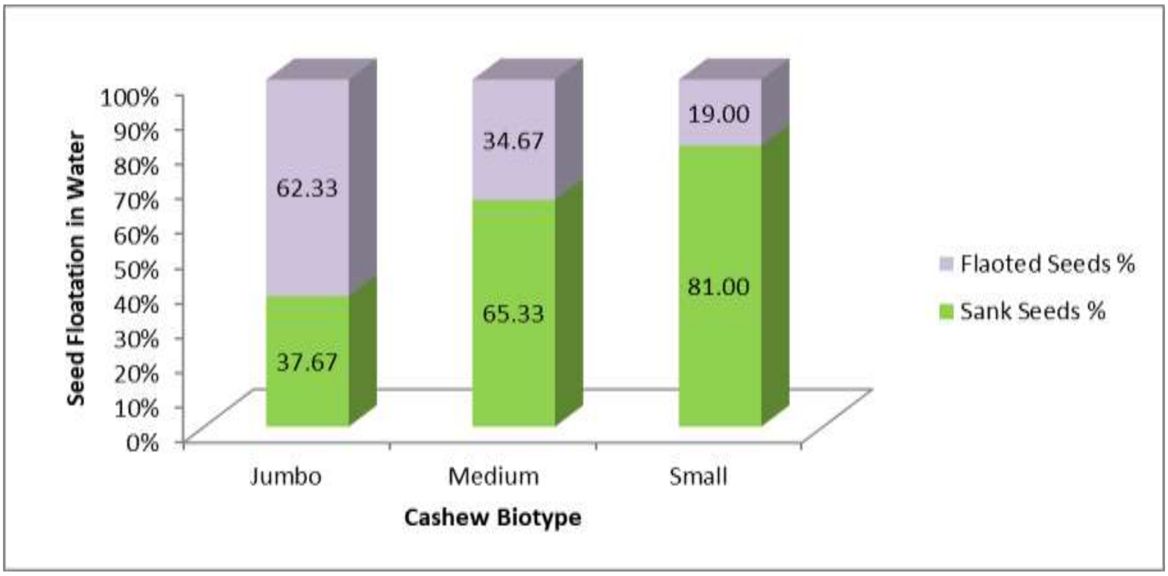

Figure1. Percentage of cashew nuts floated and sank during viability test of three cashew biotype

The summary statistics of the ANOVA for days to germination of the three cashew biotypes sown in three media is presented in table 1. The effect of germination medium as a main effect was highly significant (P≤0.001) on the days to germination. Interaction between nut floatation in water and germination medium was significant (P≤0.05) while biotype by germination medium interaction was highly significant (P≤0.001). From table 2, variation was observed in the days to germination of floated / sank nuts with respect to sowing medium with the highest Coefficient of Variation (27.19%) observed in Medium nuts that sank in water, while lest CV (11.72%) was observed in Medium nuts that floated in water. This indicates that Medium cashew nuts that sank in water are most sensitive to the sowing medium, while the floated nuts of the same biotype are least sensitive to sowing medium. The mean days to germination of the floated and sank nuts sown In-pot medium across all the three biotypes (with a range of 14.7 – 17.4) were lower than those sown in Pre-germination chamber (10.30 – 23.55) and In-situ (17.65 – 22.0). This implies that cashew nuts sown In-pot medium (polythene bags filled with top soil) tends to germinate faster than the nuts sown in Pre-germination chamber and In-situ for both sinks and floated nuts as compare to other sowing medium.

The results of cashew seed germination with respect to those that sank and floated in water as well as the three media for seed sowing across the treatments is presented in figure 2. First, there appears to be no significant difference in the germination percentage of cashew nuts sown In-pot, Pre-germinated in chamber using sawdust and In-situ across all the treatments. Furthermore, germination of cashew nuts that sank in water were very high in all the biotypes (77% - 90%) with no significant variations observed across the sowing media. It is noteworthy to report that the percentage of floated nuts that germinated was highest in Jumbo (53% - 58%) and least in Small biotype (37% - 40%). Adeyemi and Hammed (2001) made similar observation in their reports.

ABSTRACT

Drying operation is a critical step in the post-harvest processing of black nightshade seeds. This study was carried out to investigate the influence of drying methods on seed germination of this vegetable. Fruits of one accession of black nightshade were harvested at physiological maturity and extracted immediately after harvest and dried using three drying methods thereafter subjected to germination test. Traits assessed were germination percentage and emergence index. The results of analysis of variance revealed that the effect of drying method was highly significant (P<0.01) on germination percentage and emergence index of black nightshade seeds. Germination percentage of sample dried under shade using electric fan was significantly outstanding (65.06%). The germination value (46.7%) for sample dried with seed dryer was significantly higher than the value (31.7%) of sample dried with sun. Moreover, <70% germination percentage observed suggest that black nightshade seeds need treatment to break the dormancy before planting. These results support conclusion that shade drying of black nightshade seeds would enhance germination and speedy emergence.

Key words: Emergence index, germination, vegetable, traits

INTRODUCTION

Black Nightshade (*Solanum nigrum* L.) is one of African indigenous vegetables belonging to Solanaceae family. However, production of this mainly constrained by lack of quality seeds occasioned by methods of seed harvesting, processing and storage. Adebooye and Opabode (2005) reported that non-availability of improved seeds constitutes a major constraint to the cultivation and productivity of indigenous leaf vegetables (ILVs) of Africa. Drying operation is a critical step in the post-harvest processing of black nightshade seeds however; seed quality can be reduced during drying due to injury caused by unfavorable drying conditions. Black nightshade fruits harvested at physiological maturity usually contain high moisture of 60 to 70% hence the sooner the seed is extracted; cleaned and dried the better will be the quality. Germination and vigor are crucial aspects of seed quality therefore germination tests are used worldwide to determine the maximum germination potential of a seed batch under optimum conditions while speed of emergence of seedlings is one of the oldest seed vigour concepts. The objective of this study therefore was to compare three drying methods with a view to identify the best method suitable for a successful and cost effective production of biologically viable black nightshade seeds.

MATERIALS AND METHODS

Seed Production and processing

Fruits of one accession of black nightshade were harvested at physiological maturity stage during the growing season of 2015 and extracted immediately after harvesting. The extraction was done by hand to minimize mechanical damage. The extracted seeds were spread on absorbent cloth for six hours and thereafter partitioned into three equal parts (100g) and the samples were packed inside cloth bags.

Conduct of the experiment

The experiment was conducted at the Seed Testing laboratory (STL) of NACGRAB in July 2015 in a completely randomized design with five replications, in 3 x 3 factorial design. The factors were (i) Drying methods: shade-drying with an electric fan at room temperature, mechanical seed dryer at 30^{o}C and sun-drying (ii) Drying time: 3days, 6 days and 9 days.

One hundred seeds from each sample were drawn and evaluated for standard germination test according to ISTA rules (ISTA, 2003) in five replicates. Germination Index (GI) was calculated by taking the germination counts at 5, 7 and 9 days after planting using the following formula:

$$GI = \frac{\text{No of germinated seed}}{\text{Days of first count}} + \ldots + \frac{\text{No of germinated seed}}{\text{Days of final count}}$$

Statistical Analysis

Data on germination percentage were subjected to analysis of variance (ANOVA) using Statistical Analysis Software, SAS Version 9.1 (SAS, 1990). Pertinent means were separated by the use of the least significant difference (LSD) at 0.05 level of probability.

RESULTS AND DISCUSSION

The results of analysis of variance revealed that the effect of drying methods was highly significant ($P<0.01$) on germination percentage and emergence index of black nightshade seeds (Table 1). Somado, *et al*., (2006) also observed variation in germination performance of rice varieties due to drying methods when compared with the efficiency of sun-, shade-, silica gel- and conventional room drying on seed quality of rice.

Table 1. Mean squares from analysis of variance for standard germination test (STG) and germination index (GI) of black nightshade seeds evaluated using three drying methods

Source of variation	Degree of freedom	Standard germination (%)	Emergence index (days)
Replication	4	39.1ns	0.2ns
Drying method (DM)	2	4321.1**	1.5**
Drying time (DT)	2	5186.4**	1.4**
DM*DT	4	826.3**	0.8**
Error	32	84.1	0.1
Total	44	572	0.3
R^2		0.9	0.8
CV		19.1	4.1
Mean		48	7.5

*, **, Significant at probability level of 0.05 and 0.01, respectively; ns = Not Significant

Effect of drying methods on germination and emergence index of black nightshade seeds

Shade drying at room temperature using electric fan gave the best germination (65.1%) and lowest emergence index (7.3 days) among the three methods (Table 2). Drying using seed dryer at 30°C also showed tendency to enhance early germination (7.4 days) however, the germination performance was significantly lower (46.7%) when compared to shade drying method (Table 2). Sun drying gave the lowest germination (31.7%) and highest (7.9 days) germination index indicating that this method is not suitable for drying black nightshade seeds (Table 2). Moreover, in all the three methods used, the germination counts were below 65% which could be attributed to an innate dormancy in black nightshade seeds.

Table 2. Germination and Emergence index of black nightshade seeds as affected by drying methods and time.

Source of variation	Standard germination (%)	Emergence index (days)
DRYING METHOD		
Sun drying	31.7c	7.9a
Seed dryer	46.7b	7.4b
Shade drying	65.1a	7.3b
LSD	**6.8**	**0.2**
DRYING TIME		
Three Days	27.6c	7.5b
Six Days	64.0a	7.8a
Nine days	52.4b	7.2c
LSD	**6.8**	**0.2**

Means with the same letter are not significantly different at P= 0.05

In conclusion, the study identified shade drying method as the most effective method in enhancing germination of black nightshade seeds.

ABSTRACT

This study was carried out at NIHORT Ibadan as preliminary studies towards enhancing availability of improved mango seedlings for orchard establishment. Hence the evaluation of early germination in the pre-nursery, multiple seedlings incidence and early growth and development of seedling in poly-pots was carried out. Ripe Mango fruits were collected and depulped, air dried and cut open to remove the seed from the stone. The seeds were planted in cured sawdust and irrigated in alternate days. Treatments used were V_1 (Ogbomosho), V_2 (Otutu) and V_3 (land race) cultivars Twenty seeds (20) were planted per plot and replicated three times. The seedlings were transplanted into poly-pots at (8WAS) after the pinkish young levels had turned green. Data collected were (1.) Early germination percentage (2) polyembryo incidence (3) seedlings performance. Ogbomoso and Land race gave highest early germination (100%) and multiple seedlings incidence (5), while land race had the tallest (46.20 cm) and branch (1) in the nursery to enhance multiple grafting of different rootstocks on the same seedling. Each of the rootstock studied had good agronomic performance and are therefore recorded for production of mango rootstock.

Key words: *Mango, germination, polyembyo and cultivar*

INTRODUCTION

Mango (*Mangifera indica* L.) belongs to the family *Anacardiaceae*,(Minja *et al*., 2017). It is a popular fruit in the world; common in tropical and subtropical part of the world, (Shah *et al*., 2010), ranking 15 among other fruits(Francoise, 1986). India is the world leading producer while Nigeria is the highest producer in Africa (Mitra, 2016). Good planting materials are required for orchard expansion. In Nigeria, different varieties are grown, these include Otutu, Opioro, Ogbomoso, land race or cherry etc. Among these varieties, some are characterised with higher tolerance to pest, disease, and drought, waterlogged and other environmentally oriented stress factors. Mango has good tap roots systems which helps it to withstand high wind speed, drought. With these, carriage of heavy fruit production is ensured. According to Baita *et al*. (2010), graft wood results in vigorous trees, high fruit yield or small trunk. Restricted growth and poor fruit yield are all functions of poor rootstock types compatibility with graft wood from a desired mother tree, (Baita *et al*, 2010). Mango is a highly cross-pollinated and allopolyploid in nature. Therefore, it is necessary to keep desirable cultivars available. Vegetative propogation can play a significant role especially through grafted seedling production. This requires selection of "mango rootstocks that are fast growing and with high graftwood seedlings compatibility. This enhances effective grafting and availability of quality seedlings for field establishment.

MATERIALS AND METHODS

This study was carried out at NIHORT Ibadan Ripe Mango fruits were collected and depulped, air dried and cut open to remove the seed. The seeds were planted in cured sawdust and irrigated in alternate days. Varieties planted were V_1 (Ogbomosho), V_2 (Otutu) and V_3 (land race), Twenty (20) seeds each were planted per pot using CBD replicated three times. The seedlings were transplanted into poly-pots at 8WAS Data collected were early germination percentage, polyembryo incidence and growth of seedlings in the poly-pot.

RESULTS AND DISCUSSION

The result of the germination showed that, V_1 (Ogbomosho) had the least early percentage germination (25%) while V3 (Landrace) had the highest percentage early germination. as shown in Table 1. Ali and Elozeiri (2017) stated that moisture content and rehydration can affect germination of mango seeds because, seeds having inherent more moisture content attain saturation upon rehydration hence triggers germination earlier than other seeds with low inherent moisture content. The overall result of the germination showed that, V_1 (Oghomosho) and V_3 (Landrace) gave the highest percentage germination (100%) respectively, while V_2 (Otutu) gave the lowest percentage germination (55%). This may be as a result of variation in seed deterioration time among the varieties. early deteriorating time Mahasin & Mustafa, (2015) observed that mango seeds deteriorate 4 weeks after sowing, but this period of deterioration may differ from one cultivar to the other.

Table 1: Early Germination Percentage of Mango Rootstocks Seeds at 15 days after sowing (DAS) and at 36 DAS

Varieties	2WAS	4WAS
V_1Ogbomosho	25%	100%
V_2- Otutu	30%	55%
V_3- Landrace	60%	100%

V_1- Ogbomosho, V_2- Otutu, V_3- Landrace, DAS- Days after sowing.

The results on polyembryo incidence on mango rootstocks under evaluation revealed that V_1 and V_3 have higher number of polyembryo incidence than V_2. (Table 2). These implies that, a farmer can use a small area, same number of seeds, labour and cultural practices to produce more number of seedlings for market in V_1 and V_3 than V_2, that is why farmers focus on enterprises with more economic returns. From our observation, during germination of seedlings, only one or two seedlings emerged simultaneously, there after other seedlings continue to emerge at different intervals sometimes about 2, 3 and 4 after the emergence of the first emerged seedlings.

Table 2: Range of poly embryo incidence across three varieties of mango rootstocks

Varieties	Range of polyembryo per seed (multiple seedlings)
V_1 – Ogbomosho	1-5
V_2- Otutu	1-4
V_3- Landrace	1-5

The result of influence of mango rootstock varieties on the early growth of seedlings in the poly-pot (Table 3) revealed that, V_3 gave the highest (46.20 cm) plant height followed by V_2 (29.80 cm) while V_1 gave the least plant height (24.50 cm). This can be attributed to the cultivar having early growth vigour than some other cultivars, (Getulio *et al*., 2003) stated that one of the most important features in selecting mango rootstock seedlings is vigour, early root establishment/spared, early thickening of the stem and other desired traits.

Table 3: The influence of mango varieties on the early growth and development of seedlings in poly-pots nursery at 12 weeks after transplanting

Varieties	Plant Height (cm)	Stem Girth (mm)	No. of leaf	No. of Branch
V_1 - Ogbomosho	24.50	5.05	9.60	0.00
V_2- Otutu	29.80	7.09	8.66	0.00
V_3- Landrace	46.20	6.39	13.20	1.00

V_2 had the thickest stem girth (7.09 mm) followed by V_3 (6.39 mm) and V_1 (5.05 mm). Considering the importance of stem girth in attaining "graft-ability" and its eventual implication on number of seedlings produced, V_3 and V_2 are highly recommended due to the early attainment of graft-able girth. Stem girth is a useful indicator of seedling vigour, (Getulio *et al*., 2003).

Number of leaves is a pointer to the level of leaf production by cultivars. Factors affecting high production of leaves in seedlings include plant vigour, soil fertility status, proper irrigation and pest/disease management. The highest number of leaves was recorded in V_3 (13) followed by V_1 (9) whereas the least number of leaves was gotten from (V_2 with (8) number of leaves. Branching was observed in V_3 (land race) only. Photosynthesis helps growth of crops and improves assimilation of photosynthates which leads to drymatter accumulation, (Seyyed and Reza, 2012). More branching can increase ground cover and reduce weed density by shading the weed seed in the seed bank and dominating the emerged ones, (Aluko and Tee, 2015).

CONCLUSION

Ogbomoso and Land race gave highest early germination and multiple seedlings incidence, while land race had the thickest stem girth and tendencies of branching in the nursery to enhance multiple grafting of different rootstocks on the same seedling. Each cultivar of mango rootstocks under study has their desire traits, from germination to multiple seedling incidence and early performance in the nursery, therefore, with good agronomic practices, the cultivars can be used for this purpose at this level.

ABSTRACT

An experiment was carried out to evaluate the performance of five cultivars of mango on Ogbomosho rootstocks at the National Horticultural Research Institute, Ibadan. The test cultivars were Ogbomosho, Tommy Atkins, Edward, Kent and Saigon evaluated over five years. The experiment was a randomized complete block design with five replications. Data collected were plant height, number of leaves, stem girth, primary branches, secondary branches, canopy cover, number of fruits and fruit yield. Data collected were subjected to analysis of variance (ANOVA) and significant means were separated using LSD at 5% probability level. Results from this study showed that significant varietal differences existed among the varieties of mango evaluated in terms of plant height, number of leaves, stem girth, number of fruit and fruit yield. Kent was observed to be significantly taller than other varieties right from the first year (2016) to the last year of observation (2021). Ogbomosho, Tommy Atkins and Edward produced the highest number of leaves. Kent and Edward did not produce fruit in the first three years of transplanting, fruits were observed in the fourth year of transplanting. Meanwhile, Ogbomosho, Tommy Atkins and Saigon produced comparable number of fruit at early stage of transplanting but later Saigon produced significantly higher number of fruit. In 2020 and 2021, Saigon and Ogbomosho produced 23 and 15 fruits respectively while Kent and Edward produced 6 and 5 respectively. At the last year of observation, Ogbomosho mango variety produced significantly higher fruit yield (4.5 kg) while no significant difference existed in fruit yield of other mango varieties. It can then be concluded that Ogbomosho, Tommy Atkins and Saigon are early fruiting varieties but Kent produced bigger fruits at first fruiting.

Key words: Mango cultivars, Tommy Atkins, Edward, Kent, Saigon, rootstocks.

INTRODUCTION

Mango *(Mangifera indica)* belongs to the family Anacardiaceae. It is indigenous to Asia, India in particular. Mango is widely cultivated in many tropical and subtropical regions. It is the most extensively exploited fruit for food, juice, flavour fragrance, and colour. It is also an outstanding source of vitamin A and C apart from normal minerals and other vitamins (Sadhu, 1999). Mangos are delicious, sweet, juicy and refreshing. They are a great fruit to use when cooking in the kitchen, especially because they can be used equally for savoury and sweet dishes. According to the National Horticulture Board, there are about 1500 varieties of mango across the subcontinent of India (www.finedinninglovers.com). Number of mango varieties varies from one country to another. There are over 400 varieties of mango in Florida (toptropicals.com.> articles > fruit. Mango fruits vary in characters or quality such size, colour, taste, shape, juice content, fibre content among others. Ten best mango cultivars are Alphonso, Kesar, Langra, Chaunsa, Badam, Safeda, Totapuri, Neelam, Dasheri and Himsagar. Many cultivars of mango are available across Nigeria. There exist about 15 cultivars of mango in NIHORT. These include Ogbomosho, Tommy Atkins, Kent, Edward (Haden × Carabao), Saigon (Vietnanese tropical mango variety, most highly consumed fruit in the world with sweet flavor and succulent) alohatropical.com., Palmer, Julie, Lippen, Governor, Johnbull, Peach and Haden. Among the local cultivars of mango in Nigeria, Ogbomosho is the most popular due it sweetness, juicy content and low fibre. It is also adopted as rootstock material for it adaptability to our soils and poly-embryonic nature suitable for rapid multiplication. Ogbomosho, Tommy Atkins, Kent, Edward and Saigon are desirable cultivars that attract high demand from mango growers. It is then pertinent to evaluate their performance, most especially yields for accurate prediction for potential growers. Mangos are also classified as early-season (Bombay Yellow, Malda, Pairi and Saflar), early to mid-season (Langra, and Rajapuri) and mid-season (Alampur, Alphonso, Bangalora and Dusehri) types (www.producebook.com). Mangos are also classified as sweetest (Carabao), largest (Keitt) and smallest (Anwar Ratol). The genus Mangifera contains several species that bear edible fruits. Most of the fruits belong to the species *Mangifera indica.* The other edible Mangifera species generally have lower quality fruits and are commonly referred to as wild mangos (Bally, 2006).

MATERIALS AND METHODS

The experiment was carried out at National Horticultural Research Institute, Ibadan located in the forest savanna transition zone of Nigeria ($7^{0}40^{1}$ N, $3^{0}84^{1}$ E and 194m above sea level) between 2016 and 2021. The test cultivars were Ogbomosho, Tommy Atkins, Edward, Kent and Saigon which were all grafted on Ogbomosho rootstocks. The rootstock seedlings were raised from carefully selected stones of test rootstock cultivars (Ogbomosho) in the year 2015. The seedlings were grafted in 2016 and transplanted to the permanent field of plot size 10 m x 10 m. The experiment was laid out in a randomized complete block design (RCBD) with five replications. Major cultural activities carried out were weeding and pruning of rootstock outgrowths at regular intervals. Data collected were plant height, number of leaves, stem girth, primary branches, secondary branches, number of fruits, fruit weight and canopy cover. Data collected were subjected to statistics analysis using analysis of variance (ANOVA) and significant means were separated with LSD at 5% probability level.

RESULTS AND DISCUSSION

Results of the analysis of variance (ANOVA) showed that significant differences existed among the varieties of mango evaluated in terms of plant height through the period of observation (Table 1). Kent grafted on Ogbomosho was observed to be significantly taller (89.64 cm, 176.00cm, 190.60cm, 304.00cm and 391.40cm) than other varieties right from the first year (2016) to the last year of observation (2021), except that Tommy Atkins was taller than Kent in the year 2019, but it was not significantly different from Kent. Ogbomosho grafted on Ogbomosho was the shortest among the five varieties of mango grafted on Ogbomosho (Table 1). Significant varietal difference also existed in the number of leaves produces by the mango varieties evaluated. During the period of observation for number of leaves produced by theses varieties (i.e. 2017 and 2019), Ogbomosho, Tommy Atkins and Edward produced the highest number of leaves while Kent and Saigon had the lowest number of leaves (Table 2). Unlike number of leaves, Kent had the widest stem girth of 24.43cm, 48.94cm and 56.71cm in 2017, 2018 and 2019 respectively. Saigon had the lowest stem girth (17.48cm) in 2017, in 2018 Ogbomosho, Edward and Saigon had the lowest stem girth while no significant difference existed in stem girth of all the varieties of mango evaluated except Kent that has significantly higher stem girth than others (Table 2). Like stem girth, Kent had significantly higher canopy cover (364.40 cm) than other varieties of mango grafted on Ogbomosho rootstock (Table 2).

Table 1: Plant height of five mango varieties grafted on Ogbomosho rootstocks

Variety	Plant height (cm)				
	2017	2018	2019	2020	2021
Ogbomosho	39.78c	92.42c	158.20c	199.00c	248.00c
Tommy Atkins	61.42b	104.10b	210.00a	245.00b	0.00d

$LSD_{0.05}$	24.16	Ns	33.83	3.68	6.35	6.63	61.79

Kent and Edward did not produce fruit in the first three years of transplanting, fruits were observed in the fourth year of transplanting (i.e. 2020). Meanwhile, Ogbomosho, Tommy Atkins and Saigon started fruiting from first year after transplanting, but in 2017 no significant variation

ISSN: 2814-0508

existed in the number of fruits they produced (3, 4 and 4 respectively). In 2018 and 2019, Saigon produced significantly higher number of fruit (7 and 12 respectively) than both Ogbomosho and Tommy Atkins that produced 4 fruits each in 2018 then 8 and 7, respectively in 2019 (Figure 1). In 2020 and 2021, Saigon and Ogbomosho produced significantly higher number of fruit (23 and 15 respectively) which were comparable to each other while Kent and Edward produced the least number of fruit (6 and 5 respectively) which were also not significantly different form each other. The same trend observed in the number of fruit produced by the mango varieties in 2020 was also observed in 2021 (Figure 1).

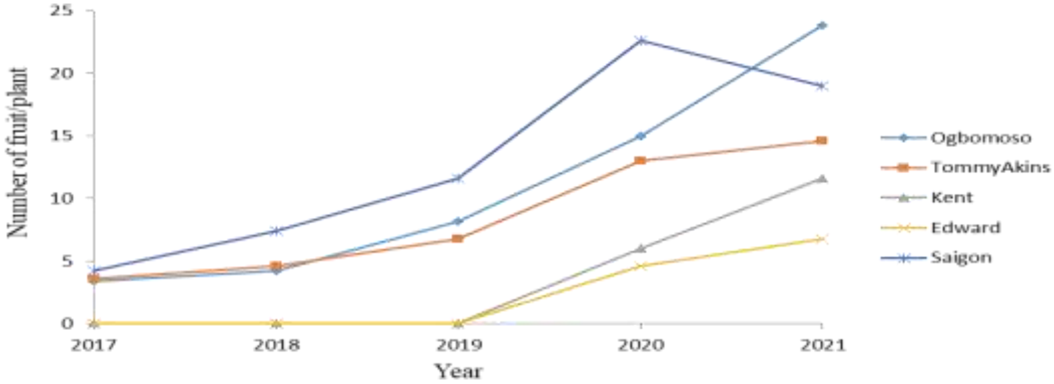

Figure 1: Number of fruit produced by five mango varieties grafted on Ogbomosho rootstock

In 2017 and 2018, Tommy Atkins and Saigon mango varieties produced comparable fruit yield of 0.78 kg 0.71 kg respectively while Kent and Edward produced no fruit. In 2019 Saigon variety produced significantly higher fruit yield of 2.2 kg followed by Ogbomosho and Tommy Atkins which produced comparable fruit yield of 1.6 kg and 1.5 kg respectively while Kent and Edward are yet to produce fruit at this time (Figure 2). In 2020, Kent mango variety grafted on Ogbomosho root stock produced significantly higher fruit yield (7.7 kg) than all other varieties of mango grafted on Ogbomosho root stock, meanwhile no significant difference existed in fruit yield of other mango varieties grafted on Ogbomosho root stock. Unlike in 2020, Ogbomosho mango variety grafted on Ogbomosho root stock produced significantly higher fruit yield (4.5 kg) in 2021 while no significant difference existed in fruit yield produced by other mango varieties grafted on Ogbomosho rootstock (Figure 2).

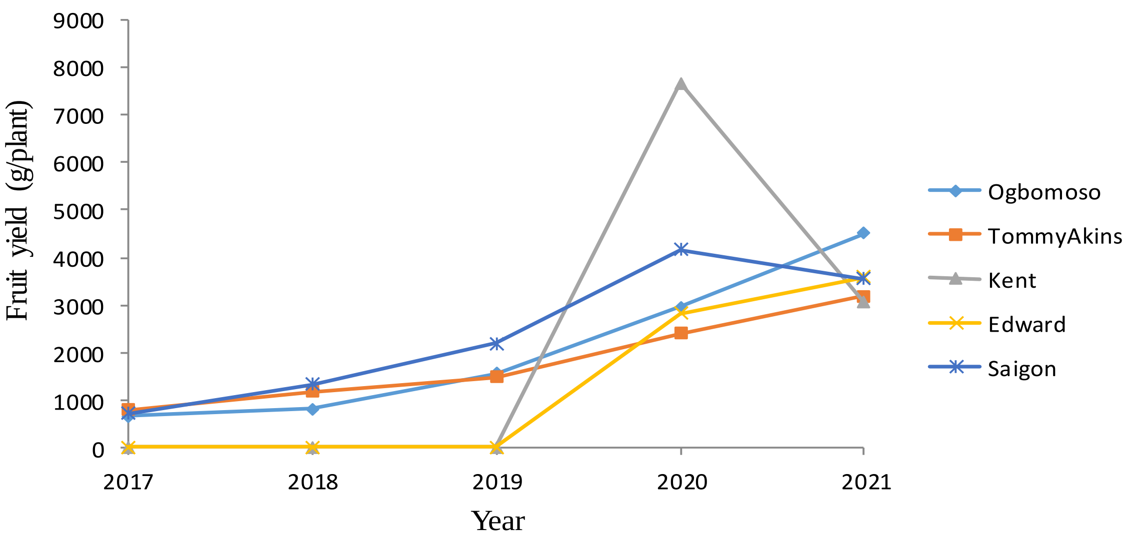

Figure 2: Fruit weight of five mango varieties grafted on Ogbomosho rootstock

The variation observed in growth and yield of these varieties of mango may be attributed to the genetic variation among the varieties responding to the climatic conditions. The findings of this study are supported by the idea that yield is highly variable factor depending upon the cultivars and age of plants, climatic conditions, incidence of pests and diseases. Majority of the workers had the idea that yield potential was a varietal character. The increase in yield in terms of weight might be either due to the large sized fruits or due to more number of fruits per plant. Similar results were obtained by Kumar and Singh (2005), Sinha *et al*., (2007) and Kundu *et al*. (2009).

CONCLUSION

It can then be concluded that Ogbomosho, Tommy Atkins and Saigon are early fruiting varieties but Kent was taller with broader canopy cover and produced bigger fruits at first fruiting. These varieties can be selected depending on the traits of interest for breeding and production purposes.

ABSTRACT

The cultivation of Cola nitida nuts has decreased worldwide over time due to its pronounced dormancy and uneven germination among several other factors. A study was therefore initiated to look at the ways of breaking the dormancy in order to improve the seed germination. The experiment was conducted in the screen house to determine the effects of biotype-colour, method and intensity of scarification of Cola nitida seed on germination and morphological growth of the resultant plantlets. It was a 3 x 2 x 3 factorial experiment in completely randomized design with three replicates. It involved seed biotype-colour at 3 levels (white, pink and red), scarification-method at 2 levels (epicarp-scraping and epicarp line-cutting), scarification intensity at 3 levels (single, double and triple epicarp scarification) and the controls (untreated white, pink and red seeds) totaling 21 treatments combinations. Sowing carried out after treatment application. Data collected on percentage germination, morphological growth performance and dry matter content were subjected to analysis of variance and means separated using Duncan's Multiple Range Test ($p \leq 0.05$). Germination of between 3.33% and 6.66% was observed early at 2 Weeks After Sowing (WAS) in the white kola seeds scraped once as well as pink and red kola seeds cut twice. At 20 WAS, white, pink and red kola seeds scraped once gave germination of between 96.6 and 100% while the untreated nuts of white, pink and red recorded low germination of between 40 and 60%. Seedlings raised from white kola seeds scraped thrice had the highest plant height value (37.6 cm) followed by those from red kola nuts scraped once with height value (35.1 cm) while seedlings raised from untreated white and red seeds had lowest height values of 12.6 cm and 19.9 cm, respectively. In conclusion, epicarp of white seeds of C. nitida, should be treated to single, double and triple line-cutting or scraping, pink seeds should be treated to single scraping while epicarp of red nuts should be treated to single, double and triple scraping before sowing for improved germination and early seedling growth.

Key words: Scarification method, Scarification intensity, Epicarp scraping, Epicarp line cutting, Seed-biotype colour, Seed dormancy, Seed germination

INTRODUCTION

Kola (*Cola nitida)* is one of the several tropical tree crops in the genus *Cola* and family *Sterculiaceae* (Oladokun, 1985). The genus kola comprises about 125 species (Onomo *et al*., 2006). However, the two most common and useful fruit producing species within the genus are *Cola nitida* (Vent.) Schott and Endl. and *Cola acuminata* (P. Beauv.) Schott and Endl. The former being of much more economic importance than the latter (Russell, 1955; Eijnatten, 1973). Its cultivation has been well established in countries like Carribean Island, Mauritius, Sri Lanka and Malaysia (Ashiru, 1973). In Nigeria the cultivation is ecologically limited to the rain forest zones of Southwest and riverine areas of Southern region as well as areas historically co-habited by the Yorubas or people from Yoruba extraction, for example some parts of Niger state of Nigeria (Ndagi *et al*., 2012). For several years, kola nuts served as an important article of internal trade in Nigeria and some other parts of Africa, mainly in the South Eastern and Western region where it serves as the main livelihood of many farmers and traders (Sundstrom, 1966). Kola nuts from both wild and cultivated trees of *C. nitida* are marketed fresh or cured (Burkill 1961). Kola nut is perhaps second only to oil palm in importance in the list of indigenous cash crops in Nigeria. According to FAOSTAT (2019), Nigeria produces 161,135 M/ton (52.59%) followed by Cote D'Ivoire 60,066 M/ton (19.6%), Cameroon 50,518 M/ton (16.49%), Ghana 25,303 M/ton (8.26%) and Sierra Leone 8,773 M/ton (2.86%) of the total world production. The use of kola nut, like coffee, tea and cocoa, is of immense benefits in local and industrial application. In spite of the immense benefits of kola, some debilitating factors have been limiting its production in Nigeria. Among these constraints are delayed germination, poor field establishment, poor agronomic practices and ageing kola farms (Adebiyi *et al*., 2011), which led to discouragement in its cultivation by farmers. Therefore, investigating the effects of seed biotype-colour, method and intensity of scarification on germination and growth performance of kola plantlets will elucidate information on appropriate method of improving germination and growth performance of the crop.

MATERIALS AND METHODS

Fresh kola seeds of same mother plant (*Cola nitida*) were sourced from a local market in Olugbo Odeda, Ogun State, South Western Nigeria. Seeds smaller than 15g or infested / infected with insects / diseases were discarded. Seeds of 15g and above, in weight were used for this study. The seeds were separated into three biotypic colours – red, pink and white. The experiment was conducted in the screen house of the College of Plant Science and Crop Production, Federal University of Agriculture, Abeokuta, Ogun State Nigeria (Latitude 7^0 15'N Longitude 3^0 25'E). The experiment was a 3 x 2 x 3 factorial laid out in a completely randomized design with three replicates.

Factor-1 includes kola seed biotype-colour at 3 levels (white, pink & red). Factor- 2 includes method of scarification at 2 levels: (Epicarp-line-scrapping, Epicarp-line-cutting). Factor-3 includes intensity of scarification at 3 levels: (Single-epicarp-mark, Double-epicarp-mark & Triple-epicarp-mark). Fresh sawdust was collected and filled into 50cl containers which had earlier been perforated underneath to allow for excess water drainage. After preparing the seeds in accordance with the treatments, they were sown inside the plastic cups at seeding rate of one seed per cup, horizontally on their sides at a sowing depth of about 4-5 cm. The saw dust was watered to wet for two weeks before planting to allow for partial weathering and moisture percolation in to the medium. Ten seeds were sown per treatment giving 180 seeds per replicate which amounted to 540 treated nuts plus 90 untreated nuts giving a total of 630 nuts for the whole experiment. Watering was carried out daily, early in the morning and evening to prevent the plant from water stress. Data were collected on weekly Germination percentage, Plant height (cm), Stem diameter (mm), Number of leaves, Leaf area (cm^2) and dry matter yield (g/plant) were subjected to Analysis of Variance procedures and treatment mean comparisons were carried out with Duncan multiple range test ($p \leq 0.05$) using CoStat (CoStat, 1996).

RESULTS

Germination

Germination was observed as early as 2 WAS on pink and red seeds cut twice with 6.66% each, white seeds scraped once, white seeds cut once and twice, pink and red seeds cut once with 3.33% each. All other treatments recorded no germination. At 8 WAS, white, pink and red biotype kola seeds scraped once and white and pink biotype seeds cut once attained more than 50% germination, all other treatments had between 10.0% and 46.6% germination and the differences were significant at $P < 0.05$. At 20 WAS, (beyond which no germination was observed) pink seeds scraped once had 100% germination followed by white and red seeds scraped once with 96.6% each, white, pink and red seeds cut twice had germination of 93.3% each, pink seeds cut once and red seeds scraped twice each had 90.0% germination. while untreated white, pink and red kola seeds had germination percentage of 60.0%, 40.0% and 40.0%, respectively. The differences were significant at $p \leq 0.05$ (Table 1).

Plant Height (cm)

At 16 WAS, red kola seeds scraped once gave seedlings of highest height value of 33.1cm followed by seedlings raised from white and red seeds scraped thrice with 29.1cm and 28.1cm, respectively. All other treated seeds gave seedlings of between 11.0cm and 25.7cm. Compared to the seedlings raised from red seeds scraped once with tallest seedlings, the seedlings raised from untreated white, pink and red seeds had 44.1%, 83.3% and 65.8% reduced plant height values and the differences were significant at $p \leq 0.05$. At 20 WAS, seedlings raised from white kola seeds scraped thrice had highest height value of 35.9cm followed by those of red seeds scraped once with 34.8cm, red seeds scraped thrice with 32.5cm, pink seeds scraped once and pink seeds scraped thrice with 31.0cm and 30.3cm, respectively. The plant height of seedlings raised from all other treated seeds was between 20.7cm and 28.8cm. Seedlings raised from white seeds scraped thrice had height advantages of 45.6%, 68.5% and 65.7% compared to seedlings raised from untreated white, pink and red seeds of *C. nitida*, respectively, in the pre-nursery (Table 2).

DISCUSSION

Germination of *C. nitida* usually takes long time, sometimes up to one year to reach a reasonable percentage. Mechanical hindrance has been implicated for delay in germination of C. nitida (ibikunle and Mackenzie, 1975). Breaking this mechanical barrier allows better respiration with concomitant physiological activities. Removal of testa, scarifying of the cotyledons or breaking the adhesive force that held the two cotyledons together will remove the mechanical barrier and enhance germination (Ibikunle and Mackenzie, 1974). This breaking of the nitida effect by way of scarification of the cotyledons which form the basis of this research work was a success. It was observed that germination occurred at 2 weeks after sowing for treated white, pink and red biotype nuts, where pink and red kola seeds cut twice recorded the highest percentage germination, but, not significantly different from other treated seeds. While the untreated white, pink and red coloured nut were yet to germinate. This is in contrast with the report of oladokun (1998), that white seeds germinated earlier, followed by pink and red nuts in that order. This was verified in this study whereby no germination was observed for the untreated white pink and red kolanuts at 2weeks after sowing, whereas treated white, pink and red kolanut had 3.33%, 6.66% and 6.66% mean germination respectively. A combined effect of colour, method and intensity of scarification was influential on plant height at the pre-nursery. Seedlings derived from white kola seeds scraped thrice had the tallest plant height and significantly different from others, however, seedlings derived from white kola seeds cut thrice had more number of leaves, but statistically not significant, seedlings derived from pink kola seeds scraped once had the widest stem girth but statistically not significant.

CONCLUSION

Under similar conditions, white kola seeds scraped once and pink kola seeds scraped once would germinate faster than red kola seeds scraped once. Pink kola seeds scraped once can attain 100% germination. Seedlings derived from white kola seeds scraped thrice would grow more vegetative at the pre-nursery. Kola nut colour, scarification method and intensity of scarification interacted to induce germination to the tune of 96.6% - 100%. White kola seeds scraped once and thrice and pink kola seeds scraped once and thrice should therefore be recommended for early germination of kola seeds and growth performance. Regardless of nut colour, kola nuts should therefore be scraped once or singly for improved germination and subsequent seedling growth.

ABSTRACT

Huge loss of tomato yield is being experienced in recent years due to erratic rainfall and desertification in environments prone to drought as a result of climatic changes. Tomato varieties are required to increased production in ecologies prone to drought. It is vital to screen, identify and select drought tolerant genotype(s) useful for breeding of drought tolerant tomato varieties. Screen house experiment was conducted in completely randomized design with three repetitions under water stress during dry season. Thirteen traits were measured on five plants for plant height, number of branches, number of leaves, leaf length, leaf width, leaf area, number of flowers, number of marketable fruits, number of non-marketable fruits, total number of fruits per plant, average fruit weight, Biomass and fruit yield. The results showed that, Tom 6, Tom 25 and Tom 28 genotypes performed better under moisture stress for biomass, number of fruits per plant, number of marketable fruits and fruit yield per plant. Based on the rank summation index, Tom 6, Tom 28, Tom 21, Tom 61 and Tom 64 stand out to be superior genotypes under moisture stress condition which can be selected for breeding and higher fruit yield under moisture stressed environment.

Key words: Drought, moisture, stress, tomato, dry season

INTRODUCTION

Tomato (*Lycopersicon lycopersicum* MILL.) is one of the most cultivated and consumed vegetable throughout the world and second after potato (*Ipomia batatas* L.) (FOASTAT, 2005). Tomato is very rich in minerals, vitamins, essential amino acids and high level of lycopene anti-oxidants. In Nigeria, the major production areas of tomato lie between latitudes 7. 5^{o}11' and 13.0^{o} N longitude in the Sahel-Sudan Savannah. Despite its wide cultivation and importance for improved health and as source of income generation, drought stress is one of the major causes of fruit yield reduction in the Sahel and Sudan agroecologies due to short seasoned erratic rainfall and increment of temperature from climate change. Jurekova *et al*. (2019) observed that declined soil water contents tend to reduce leaf area in tomato genotypes. Significant reduction of plant height was observed for plants under water stress (Jasmina *et al.,* 2013). Fruit length, fruit diameter and average fruit weight were affected by soil moisture stress at 40% field capacity (Nahar and Ullah 2012). Significant differences for number of fruits per plant, plant height, number of leaves and average fruit weight were observed under water stress (Oliveira *et al*. 2021). The available varieties in the country are very intolerance to drought. Screening is a pre-requisite for selection of tomato under moisture stress. Hence sourcing and screening of tomato germplasm for the identification of genotypes tolerant to drought is required for increased production and productivity of the crop. Such materials will be useful for predetermined breeding programme to develop tomato genotypes that can produce economic fruit yield in a drought prone environment. The study was conducted to screen tomato genotypes under moisture stress so that drought tolerant genotype(s) would be identified and use as starting materials in the tomato drought tolerance breeding program.

MATERIALS AND METHODS

Sixty-five tomato genotypes were evaluated using a completely randomized design in three repetitions in the screen house at the National Horticultural Research Institute, Bagauda research farm (11°33´N latitude and 8°23´E longitude of the equator) in the Sudan savanna during the 2012 dry season. The climate of the region is characterized by mean of annual rainfall of 830mm with mean daily temperature ranged from 18.4^{o}C to 45^{o}C. Seedlings were raised in nursery and transplanted into pots about 30 days after sowing. Non-stress plants were irrigated with 900mm of water a week, while stressed plants were irrigated with 300mm of water a week. The treatments were imposed two weeks after transplanting. Data were measured on three plants for plant height, number of branches, number of leaves, leaf length, leaf width, leaf area, number of flowers, number of marketable fruits, number of non-marketable fruits, total number of fruits per plant, average fruit weight, Biomass and fruit yield. Data obtained were analyzed using JMP Pro 14. For the purpose of selection, Rank Summation Index (RSI) according to Malumba and Mock (1978) was generated from each trait. The index was formed by ranking each trait in descending order. Finally, the values assigned to each trait was added, thereby obtaining the sum of the ranks, which indicates the classification of the genotypes (Cruz and Carneiro, 2003). Rank Summation Index as computed by Malumba and Mock (1978) will be estimated as follows:

$$RSI = \sum_{i=1}^{n} R_i \, s$$

Where,

RSI = Aggregate performance of a genotypes using the ranking of each of the desired traits

R_i = Rank of the mean of each of the desired traits

RESULTS AND DISCUSSION

Mean Performance

The mean performance revealed highly significant (P≤0. 01) differences among the genotypes for plant height, number of branches, number of leaves, number of fruits per plant and number of marketable fruits while significant (P≤0. 05) variation was observed for leaf length, leaf width and leaf area (Table 1); indicating the presence of considerable genetic variability in the studied genotypes which is prerequisite for any crop improvement. Akhoundnejad (2020) reported significant differences among three genotypes for fruit length, diameter and average fruit weight under drought stress while Oliveira *et al*. (2021) observed significant differences for number of fruits per plant, plant height, number of leaves and average fruit weight. Non-significant differences were recorded for number of flowers per plant, biomass, number of non-marketable fruits average fruit weight and fruit yield per plant. Phenotypic differences were observed across the sixty-five tomato genotypes under moisture stress for studied traits. Tom 18 was taller (38.67cm) and Tom 42 was shorter plant (5.42cm) among the genotypes (Table 1). It was observed that, Tom 18 produced highest number of branches (7.17) followed by Tom 11 while minimum number of branches (0.67) were noticed in Tom 30. Similar results were published by Amalia Tetrani Sakya *et al*., 2020. Maximum number of leaves per plant was recorded for Tom 11 (11.83) while minimum was observed in Tom 35 (2.33). Tom 59 showed longer leaf (6.65cm) and wider leaf (4.05cm). Shorter and narrow leaves were noticed in Tom 42 and Tom 35 (Table 1) with values of 1.63cm and 0.88cm, respectively. Results revealed that, there was strong correlation between leaf length and leaf width; the longer the leaf the wider the leaf (Table 1) among the genotypes. Tom 59 also revealed maximum leaf area (4.20cm^2), because of its longer and wider leaves compared to other genotypes. Whereas minimum leaf area was recorded in Tom 37 (0.63cm^2). The results corroborated with findings of Mohammad *et al*. 2012 and Oliveira *et al*. 2021. Tom 25 recorded heavy (81.67g) biomass per plant, followed by Tom 15 (71.67g); whereas, Tom 37 showed minimum biomass per plant (3.33g). The result showed that, Tom 25 recorded high number of fruits per plant (60.33) followed by Tom 3 and Tom 1 with values of 34.33 and 29.33, respectively. Tom 25 also recorded high number of marketable fruits per plant (59.00) whereas minimum number of marketable fruits per plant was noticed in Tom 35 (0.67). Highest number of non-marketable fruits per plant (1.67) were observed in Tom 28, Tom 31 and Tom 28. Thirty-one genotypes revealed no single non-marketable fruit per plant, indicating that imposed drought stress does not affect their fruit quality among the genotypes. Similar results were reported by Oliveira *et al*. 2021 for significant differences of number of fruits per plant under drought stress. Tom 54 showed medium fruit weight followed by Tom 16 (11.67g), Tom 64 (11.13g) and Tom 61 (11.04g). Amalia Tetrani Sakya *et al*. 2020 observed non-significant variation for biomass and significant for number of fruits per plant among the evaluated genotypes under drought stress. Minimum average fruit weight was observed in Tom 30 with value of 0.56g. The result for fruit yield per plant shows that Tom 6 and Tom 28 recorded highest fruit yield per plant of 133.33Kg and 106.67Kg. Tom 35 revealed minimum fruit yield per plant (1.67Kg), indicating susceptible to moisture stress. These results contradict the results of Amalia Tetrani Sakya *et al*., 2020 for average fruit weight and fruit yield per plant (Akhoundnejad, 2020). Both researchers reported significant variations for average fruit weight and fruit yield per plant.

Rank Summation Index

For the purpose of selection, Rank Summation Index (RSI) according to Mulamba and Mock (1978) was used to determine the rankings of the genotypes with regard to their overall performance based on twelve agronomic traits under moisture stress (Table 2). Based on number of branches per plant, biomass, number of fruits per plant and fruit yield per plant, the results revealed that genotypes with higher index recorded low number of branches per plant, biomass, number of fruits per plant and fruit yield per plant, indicating to be drought sensitive genotypes, whereas genotypes (Tom 6, Tom 28, Tom 21, Tom 62 and Tom 64) with lower index values showed high number of branches per plant, biomass, number of fruits per plant and fruit yield per plant revealing drought tolerance genotypes (Table 2). Similar findings were observed by Vieira Nascimento *et al.* (2020), Finzi *et al.* (2020) and Oliveira *et al*. (2021).

CONCLUSIONS

The genotypes revealed significant variation for most of the traits studied under moisture stress, indicating sufficient genetic variability among the genotypes from which selection can be imposed. Considering biomass, number of fruits per plant, number of marketable fruits and fruit yield per plant; Tom 6, Tom 25 and Tom 28 genotypes performed better under moisture stress. Rank summation index revealed that Tom 6, Tom 28, Tom 21, Tom 61 and Tom 64 stand out to be superior genotypes based on high number of branches per plant, biomass, number of fruits per plant and fruit yield per plant indicating tolerance to drought.

ABSTRACT

Uneven distribution of rainfall and limited water resources calls for an irrigation management and scheduling scheme that enable crops cope better with the variable and changing climate. The experiment studies the effects of moisture stress conditions on two Okra cultivars (Ibadan local and Jokoso). The moistures stress conditions vary from continuous flooding (FLD), wetting after three days (W3D), wetting after five days (W5D), wetting after seven days (W7D), and wetting after ten days (W10D). The experimental design was a Completely Randomize Design (CRD)fitted into split plot with three replications. The agronomic parameters (leaf width, leaf length, plant height, numbers of leaves and leaf area) and yield data (weight, fruit diameter, fruit length) were subjected to analysis of variance and treatment means separated using Least significant different. Okra growth and fruit yield were significantly ($p<0.05$) affected by moisture conditions, it significantly ($p<0.05$) affect fruit yield characters with FLD recorded highest fruit weight of 13.97g and 0.87g for Ibadan Local and Jokoso correspondingly while W7D recorded 0.78g for Ibadan Local and 0.00g for Jokoso. Also, FLD recorded highest fruit diameter in Jokoso with 6.43cm and 2.63cm for Ibadan Locals while W7D recorded 2.23cm for Ibadan Local and 0.0cm for Jokoso. The trend for Fruit length was similar with FLD producing longest fruits in Ibadan Local with 5.51cm and 4.67cm for Jokoso while W5D produced 4.62cm in Ibadan Local and 3.00cm in Jokoso. It could be concluded from the study that moisture conditions such as FLD, W3D and W5D were suitable for growth and fruit yield of okra cultivars; Ibadan Local and Jokoso in the study area while moisture stress beyond W5D appeared detrimental.

Key words: Okra, Moisture stress, growth indices, flooding

INTRODUCTION

Agricultural crops are watered periodically during the growing season, either by natural rainfall or by irrigation. In the intervals of each watering, soil moisture stress sometimes becomes severe and limits plant growth and development. This is particularly true in rain-fed agricultural areas where the amount of rainfall is insufficient for the plant to complete growth, and also in irrigated agricultural areas where the amount of available water is limited. Most of the studies have indicated that even brief water shortage is likely to interfere with the normal function of vital processes of plants, thereby to influence their vigor and productivity. Timing of water stress during crop growth and development is an important factor in determining the magnitude of the effect of stress (Begg and Turner (1976), Kramer, (1983).

Generally, annual crops are particularly sensitive to stress at a critical stage of development (Kramer,1983). Salter and Goode (1967) suggested that most of the determinate crops are sensitive to water stress especially at the time of floral initiation and during flowering and, to a lesser extent, during fruit and seed development. In indeterminate and perennial crops, in which vegetative growth and reproductive processes overlap, the situation is not very clear. (Begg and Turner, 1976). Due to the economic importance of Okra in food security, it is crucial to understand how drought conditions potentially affects okra yield under climate change and to explore appropriate adaptation measures to maintain or increase okra production. Previous studies indicate that irrigation is the most efficient adaptation measure to mitigate the negative effects caused by drought in crop production (Li*et al*., 2005; Olesen*et al*., 2011; Ji*et al*., 2012).

However, due to the uneven distribution of rainfall and limited water resources calls for an irrigation management and scheduling scheme that accounts for effects of actual soil water content to better cope with the variable and changing climate. Although okra is usually grown as an annual plant, it is a perennial plant. In this crop, after short vegetative development, reproductive growth including flower opening and fruit development, and vegetative growth occur concurrently. In such crops, the relationship between the stage of plant growth and effect of water deficit is not clearly understood yet. This experiment was conducted to analyze the responses of two okra cultivars to moisture stress conditions in a forest-savanna transition zone of Nigeria.

MATERIALS AND METHODS

Experimental site Descriptions

The experiment was conducted in a screen house at Federal University of Agriculture, Abeokuta (FUNAAB) behind College of Environmental Resources Management (COLERM), located between Latitude 7° 2' 23'' N and Longitude 3° 4' 03'' E. The study area is characterized by a tropical climate with distinct wet and dry seasons. The wet season is associated relatively with the prevalence of the moist maritime southerly monsoon from Atlantic Ocean and the dry season by the continental North Easterly harmattan winds from the Sahara Desert. The area is located within a region characterized by bimodal rainfall pattern (April to July being the wettest months, followed by August to October). The annual rainfall ranges between 1400 and 1500mm in Abeokuta ant its environs. Isolated and scanty rains usually start in mid-March and steadily increase to reach the peak values in July followed by a short break in August. The dry season is normally from October to March and often characterized by hot days.

Experimental Procedure

The experimental crop used was two Okra varieties (Ibadan Local and Jokoso) obtained from National Horticultural Research Institute (NIHORT), Ibadan. Top soil collected from the FADAMA wetlands of the university was sieved to fine particle before filled into plastic pots. Eighteen (18) plastic pots were used, they were pierced at the bottom before use to enable free drainage of water. 3kg of sieved soils were measured to into each plastic pot. The plastic pots containing soil was watered and left for a day, after which seeds of two (2) okra varieties (Ibadan Local andJokoso) were planted in each plastic pot and they were arranged in a Completely Randomized Design (CRD) fitted into split plot with three replicates. The experiment was laid in 5x2 factors consisting of five water regimes and two varieties of okra. The moisture conditions are flooding (FLD) (the plastic pots were kept flooded throughout the crop growth period), wetting after three days (W3D) (the plastic pots were kept flooded at three days interval throughout the crop growth period), wetting after five days (W5D) the plastic pots were kept flooded at five days interval throughout the crop growth period), wetting after seven days (W7D) the plastic pots were kept flooded at seven days interval throughout the crop growth period), and wetting after ten days (W10D) the plastic pots were kept flooded at ten days interval throughout the crop growth period). while the two varieties used were Ibadan Local and Jokoso. Three weeks after planting the plants were thinned to one per pot and weeded manually. Herbicide was applied in the screen house for the protection against pests and diseases.

Data collection and analysis

The data set for number of leaves, plant height, leaf area and fruit yield characters were subjected to analyses of variance (ANOVA) using SAS software package 9.1 (SAS Institute, 2003). Comparison among the treatments combination were carried out at 0.05% probability level and treatment means were separated using Least Significance Difference (LSD).

RESULTS AND DISCUSSION

Plant height of okra (Ibadan local)

The difference in plant height of the Ibadan local and Jokoso at 3,4,5,6 and 7 weeks after plant (WAP) is shown in Table 1. The plant height of the Ibadan Local was significantly different at all sample occasions. The plant height at 3WAP ranged from 15.63cm in W10D, followed by 17.23cm in W3D, then by 17.37cm in W5D, followed by 17.90cm in W7D while the highest plant was obtained in FLD with 19.17cm. Equally the plant height at 5WAP ranged from 21.03cm in W10D followed by22.47cm in W7D, followed by 23.93cm in W5D and 25.67cm in W3D while the highest value was obtained in FLD with 27.97cm. Also the plant height at 7WAP ranged from 24.47cm in W10D, followed by 25.20cm in W7D, followed by 28.87cm in W5D and 34.03cm in FLD while the highest value was obtained in W3D with 35.63cm.

Plant height (Jokoso)

Also from Table 1, the plant height of Jokoso was statistically significant at all sampled occasions. The plant height at 3WAP ranged from 11.00cm in W10D, followed by 14.00cm in W7D, then 14.83cm in W3D while the tallest plant with 16.33cm was obtained in FLD. Similar pattern was observed at 7WAP when the plant height was from 19.00cm in W10D, 32.83cm in W5D while the tallest plant with 42.17cm was obtained in FLD.

Leaf area of Okra (Ibadan local)

The difference in the leaf area of the Ibadan local and Jokoso at 3,4,5,6, and 7 weeks after plant (WAP) is shown in Table 2. The leaf area of the okra varieties was significantly difference at all sample occasions. The leaf area of the Ibadan Local at 3WAP increased from 38.67cm^2 in W10D, followed by 57.69cm^2 in W7D, then 60.83cm^2 in W5D, and 74.87cm^2 in FLD while the highest value was obtained in W3D with 76.64cm2. Also the leaf area of the okra variety at 7WAP ranged from 144.05cm^2 in W10D, followed by 181.95cm^2 in W5D, followed by 182.22cm² in W7D and 224.23cm^2 in FLD while the highest value was obtained in W3D with 298.51cm^2.

Leaf area of Okra (Jokoso)

Table 2 also revealed that the Leaf area of Jokoso at 3WAP increased from 21.25cm^2 in W10D, then 35.34cm^{2}in W7D and 40.30cm^{2}in W5D while the largest area of 42.92cm^{2}was obtained in FLD. The leaf area recorded at 5WAP were in the order, 170.48cm^2 in FLD followed by 160.42cm^2 in W5D, then 147.50cm^2 in W7D and 135.45cm^2 in W3D while the least value of 106.23cm^2 was obtained in W10D. Again, at 7WAP it ranged from 78.83cm^{2}in W10D, then 140.33cm^2 in W3D and 183.33cm^2 in W5D while the largest value of 249.75cm^{2}in FLD. The result implies that the leaf area of Jokoso and Ibadan local was not influenced by moisture stress of less than 7 days, this may be due to the nature of okra plants to survive under moderate water supply, this agrees with Lawlor and Leach (1985) who opined that a decrease in leaf area is majorly a common effect of drought.

Number of leaves of Okra (Ibadan local)

The difference in number of leaves of the Ibadan Local and Jokoso at 3,4,5,6 and 7 weeks after plant (WAP) is shown in Table 3. The number of leaves of the okra variety was significantly different at all sample occasions. The number of leaves of Ibadan Local at 3WAP in FLD, W3D and W5D are the same with 6.00 leaves while the number leaves in W5D and W7D was 5.00. Equally the number of leaves at 5WAP ranged from 4.67 leaves in W10D and W7D, followed by 8.00 leaves in W5D and W3D while the highest value of 8.67 leaves was obtained in FLD. Also the number of leaves at 7WAP ranged from 2.67 leaves in W10D and W7D, followed by 3.67 leaves in W5D, while the highest value was obtained in FLD and W3D with 5.00 leaves.

Number of Leaves Okra (Jokoso)

Also from Table 3, the number of leaves of Jokoso at 3WAP were 4.67 leaves in FLD and W7D, 4.33 leaves in W5D, 4.00 leaves in W10D while W3D had 3.67 leaves. The observations at 5WAP shows that FLD had highest number of leaves with 6.67 leaves, followed by W5D with 6.33 leaves, then W10D with 6.00 leaves while the lowest value of 5.67 leaves was obtained in W3D and W7D. At 7WAP, FLD again had highest number of leaves with 9.00 leaves, followed by W5D and W7D with 7.00 leaves, then W3D with 6.33 leaves while the least value of 2.33 leaves was recorded in W10D. Generally, number of leaves of both varieties showed high resilience to moisture stress conditions of wetting intervals of three, five and seven days (i.e. W3D, W5D and W7D).

Soil temperature of Okra (Ibadan local)

Table 4 shows the soil temperature data recorded for the growing seasons, it was differed considerably at various stages of the crop growth. The soil temperature trend for Ibadan local at 3WAP from the table shows that W7D had 32.33^{o}C, followed by 31.53 ^{o}C in W10D, then 30.93 ^{o}C in W3D and 30.80 ^{o}C in FLD while the least temperature of 30.67 ^{o}C was obtained in W5D. Also at 5WAP the highest temperature of 37.90 ^{o}C was obtained in W7D followed by 37.87 ^{o}C in W10D, then 34.40 ^{o}C in W3D and 34.27 ^{o}C in W5D while the least temperature of 33.27 ^{o}C was recorded FLD. Equally at 7WAP the highest temperature of 31.27 ^{o}C was obtained in W10D followed by 30.43 ^{o}C in W7D, then 28.03 ^{o}C in FLD and 28.00 ^{o}C in W3D while the least temperature of 27.87 ^{o}C was obtained in W5D.

Soil temperature of Okra (Jokoso)

The soil temperature trend for Jokoso at 3WAP from the table shows that FLD had 31.37^{o}C, followed by 31.17^{o}C in W10D, then 30.93 ^{o}C in W7D and 30.57^{o}C in W5D while the least temperature of 30.47 ^{o}C was obtained in W3D. Also at 5WAP the highest temperature of 34.30 ^{o}Cwas obtained in W10D followed by 31.07 ^{o}C in W5D, then 30.80 ^{o}C in W7D and 30.63^{o}C in W3D while the least temperature of 30.27 ^{o}C was recorded FLD. Equally at 7WAP the highest temperature of 27.23^{o}C was obtained in W10D followed by 26.87^{o}C in W7D, then 26.77^{o}C in W5D and 26.53^{o}C in W3D while the least temperature of 26.17 ^{o}C was obtained in FLD. The range of temperature observed fell within the optimum temperature required for optimum crop production (Downes, 1972). For instance, Downes (1972) indicated that air temperature above 30^{o}C during vegetative stage delayed floral development, particularly initiation of panicle meristem. Consequently, the vegetative phase became longer than usual.

Presented in Table 5 are the yield characteristics of okra cultivars for both Ibadan Local and Jokoso. There was significant difference in fruit diameter, fruit length and number of fruits in all samples of the fruit harvested. The fruit weight of Ibadan Local ranged between 0.87g in FLD and 0.78g in W7D while forJokoso cultivar it ranged between 13.97g in FLD and 0.00g in W7D. Fruit diameter of cultivar Ibadan Local ranged between 2.63cm in FLD and 2.23cm in W7D while forJokoso cultivar it ranged between 6.43cm in FLD and 0.00cm in W7D. The fruit length of Ibadan Local ranged between 5.51cm in FLD and 4.62cm in W5D while for Jokoso cultivar it ranged between 4.67cm in FLD and 3.00cm in W5D. The mean number of fruits for both cultivars; Ibadan Local and Jokoso was 0.67 fruits across all moisture conditions that produce yield.

CONCLUSION

It could be concluded from the study that moisture conditions such as flooding (FLD), wetting after three days (W3D), wetting after five days (W5D) and wetting after seven days (W7D) were suitable for growth and fruit yield of Ibadan Local while moisture stress from wetting after ten days (W10D) appeared detrimental. Contrastingly, Jokoso cultivar showed high tolerant to flooding (FLD), wetting after three days (W3D) and wetting after five days (W5D) while moisture conditions from wetting after seven days (W7D) appeared detrimental to its growth and fruit yield quality. Also, the results have shown that reduced level of water to the plant has an increasing negative effect on the early growth, development, yield and plant survival depending on the magnitude of excess or deficit of the water. Wetting after three days (W3D) was shown to give maximum performance for Ibadan Local while flooding (FLD) gave maximum performance for Jokoso cultivar. The results of thisstudy suggest that using these two okra cultivars (Ibadan Local and Jokoso) as a crop in water-limited environments, may enable farmers of these regions to use deficit irrigation, preventingshort-term decreases in gas exchange and plant growthwhen soil dries, and improving irrigation efficiency. It is recommended that this could be further verified using different genotypes in fieldexperiments for asustainable agriculture.

ABSTRACTS

Terminalia mantaly commonly called Step tree is an important ornamental plant widely used for avenue planting and provision of shade in the landscape. It Commercial seedling production remains low due to poor germination thereby negatively affecting its availability for environmental gratification. This study was conducted to investigate the best sowing orientation for seeds collected during dry and wet season for optimum emergence and seedling growth. Step tree seeds collected in wet and dry seasons were sown using three sowing orientations: Horizontal, vertical upward, and vertical downwards. Treatments were arranged in Completely Randomized Design (CRD) with four replications. Data collected on number of days to seedling emergence, plant height(cm), number of leaves, root length(cm), root fresh weight(g), root dry weight (g), shoot fresh weight (g) and shoot dry weight (g) were subjected to Analysis of Variance (ANOVA) and means were separated using Least Significant Difference(LSD) at 5% level of probability. The results of the experiment revealed that seeds collected in dry season and sown in horizontal orientation had the highest (73 %) seedling emergence, tallest seedling (97.3 cm) and highest (0.06 g) dry matter accumulation than other treatments. It was therefore concluded that time of collection of seed and sowing orientation affected emergence and early growth of Step tree. Seeds collected in dry season and sown in horizontal position were considered better for optimum emergence and early seedling growth of Terminalia mantaly.

Key words: Seed orientation, *Terminala mantaly*, germination percentage, environmental beautification.

INTRODUCTION

Terminalia mantaly commonly called Step tree is an ornamental evergreen plant with conspicuous layered branches. Leaves are smooth, bright green when young, in terminal rosettes of 4-9 unequal leaves on short-thickened stem. It belongs to the family Combretaceae (Tanzania Tree Seed Agency, 2004) and it is widely distributed globally. *Terminalia* trees can tolerate light to moderate shade, when young but thereafter, they should receive full overhead sunlight for optimal growth (Veenendaal *et al*. 1999). *Terminalia* trees are able to grow at high altitude; most species perform well at altitude less than 2000 m a.s.l. The climate in which *Terminalia* grows varies from area with year round rain for species occurring in forest areas (>2000 mm per annum) to seasonal with moderate rainfall (<1,200 mm per annum) for those occurring in savanna zones (Tanzania Tree Seed Agency, 2004).

It can be propagated naturally by seeds but could also be raised through vegetative methods. Step trees are planted in several countries be it tropical and sub-tropical regions primarily for ornamental purposes as avenue plants, shade providing tree, noise reduction and as containerized/bonsai tree. It is also useful as a source of high quality hard timber for carpentry, joinery, building, flooring, ply wood manufacturing (Singapore Flora and Fauna web,2019) and in a mixed crop system "taungya" agri-silvicultural system in which they provide shade and play a major role in increasing soil fertility (Nichols *et al*., 2001; Norgrove and Hauser, 2002). Furthermore, members of the genus *Terminalia spp* are among some of the plants most widely used for medicinal purposes in Africa (Masoko *et al*., 2005).

Step tree seeds vary in the length of time they remain viable. The seeds can be stored in sealed containers at 2-4 degree Celsius for one year, adding to its suitability for commercial exploitation (Grolez and Wood, 2001). Seeds of *Terminalia mantaly* undergo a period of dormancy before germination occurs. The seeds are covered by a hard protective coat, the physical dormancy ends when the seed coat is opened through different process such as mechanical abrasion, nicking or soaking water (Tanzania Tree Seed Agency, 2004). Most often, for some species of *Terminalia*, seeds are pre-treated by soaking in water for 12-46 hour. The physiological dormancy of *Terminalia* seed end within two weeks after sowing and is followed by epigeous germination which lasts two to five weeks. Pricking out should be done early enough to avoid disturbing the rapidly developing taproots (Lemmens *et al*., 1995).

Groulez and Wood (2001) reported that seed orientation affects greatly seedling emergence. However, information about proper seed orientations is scanty. To ensure good germination, rapid emergence and quality growth performance, seeds must be placed in a position and in an environment with adequate supply of nutrients and water from the soil.

This study was carried out to investigate the best time for collection of seeds and sowing orientation for optimum seedling emergence and growth of *Terminalia mantaly* in the commercial ornamental plant nursery.

MATERIALS AND METHODS

Trials were conducted in the experimental nursery of Horticultural Department, Federal University of Agriculture, Abeokuta, Ogun State, Nigeria during the dry and wet seasons of the year 2019 and 2020, respectively. The site is located on Latitude 7'15 ° N, Longitude 325 ° E and altitude 100 m above sea level with annual mean temperature ranging from 26.90 ° C to 29.20 ° C. Fresh seeds of Step trees were collected from randomly selected mature plants at the Federal University of Agriculture, Abeokuta. Then, from the seed lots in each season, 1,500 viable ones were selected and sown in a polythene bags (20 cm x12 cm) filled up with sawdust at 1 seed/pot. Treatments were seeds sown using horizontal (seeds sown flat) orientation, vertical up-wards (sown with stalks placed upwards) and vertical down-wards (sown with stalks placed down) orientations laid in a Completely Randomized Design (CRD) with four replications. Each replicate had 25 seeds per replicate.

Data were collected on germination percentage (%), days to 1st emergence, plant height, number of leaves, root length, root fresh and dry weights. All data were subjected to analysis of variance (ANOVA) using Statistical Analysis Software (SAS) and the treatment means separated using Least Significant Difference (LSD) test at P=0.5% level of probability.

RESULTS AND DISCUSSION

Effect of sowing orientation on percentage germination of seeds of step tree was significant (P=0.5) in dry season only at 4 and 10 weeks after sowing (Table 1). Seeds of step tree sown in a horizontal orientation had highest (33 and 73%) germination percentage at 4 and 10 WAS respectively. Then, followed by those sown in a vertical downward (24 and 58 %) and vertical up (28 and 67 %) positions. There was no significant difference in percentage germination of seeds sown in either vertical up or vertical downward position. However, for seeds collected during the wet season, statistically similar germination percentage value was recorded for seeds sown in the three sowing orientations. (Table 1).

Table 1: Effect of sowing orientation on the germination percentage of step tree in wet and dry season

Treatments	Percentage germination (%) 4WAS	10WAS
	Wet season	
Vertical up	18.0	33.8
Vertical down	18.3	31.0
Horizontal	15.0	36.3
LSD	NS	NS
	Dry season	
Vertical up	28.0	67.0
Vertical down	24.0	58.0
Horizontal	33.0	73.0
LSD	8.19	10.11

WAS = Weeks After Sowing, NS = not significant. LSD =Least Significant Difference at P=0.5 %

Effect of sowing orientation on height of strep tree seedlings was not significant (P=0.5) for seeds collected during dry and wet seasons, except at 4 and 6 WAS during wet season (Table 2). Tallest seedlings were observed from seeds collected during wet season sown in horizontal position at 4 (9.9 cm) and 6 (11.3 cm) WAS, followed by those sown in vertical down (9.10 cm)

ISSN: 2814-0508

and vertical up (7. 9 cm) orientations, respectively. Production of leaves by step tree seedlings was not affected by sowing orientations in either dry or wet season (Table 3). Sowing orientation had no significant effect on root length, dry root and shoot weight irrespective of the time of collection of seeds (Table 4). This could be linked to the age of harvest of seedlings for data collection and being a tree with slow growth of seedlings. This could mean that the seedlings collected and sown in wet season had better moisture as rain fed compared to those of dry season which were irrigated.

Table 2: Effect of sowing orientation on height (cm) of step tree in wet and dry season

Treatments	4WAS	6WAS	8WAS	10WAS
			Wet season	
Vertical up	7.72	9.15	10.39	11.47

		Dry season	
Vertical up	0.2	0.6	0.1
Vertical down	0.1	0.6	0.1
Horizontal	0.3	0.7	0.1
LSD	NS	0.1	NS

WAS = Weeks After Sowing, NS = Not Significant, LSD =Least Significant Difference at P=0.5 %

CONCLUSION

Sowing seeds of step tree in horizontal orientation enhanced seeds emergence and early seedling growth. Seeds of step tree collected during dry season performed better in terms of germination and seedling growth.

Therefore, it is recommended to collect seeds of *Terminalia mantaly* during dry season and sow in a horizontal orientation for optimum seedling emergence and early growth in the nursery.

ABSTRACT

Seeds for seedling production of coffee have hitherto being processed using mortar and pestle. Increasing demand for coffee seeds and seedlings in Nigeria calls for some better alternatives to produce higher and quality seeds. In view of the above, ripe cherries of coffee of 3 genotypes were harvested viz: open pollinated, C2 and C4 which were processed using mortar and pestle (MT); manually operated pulper (MN) and motorised pulper(NCAM). These were evaluated in 3 x 3 factorial combinations laid out in Completely Randomised Design in three replicates. There were 27 treatment units in all. The treatments are: Mortal & pestle for OP, C2 and C4 (MTOP, MTC2 &MTC4); CRIN Manual Driven Pulper (MN) for the three genotypes (MNOP, MNC2 & MNC4) and NCAM motorised pulper (NCAMOP, NCAMC2 & NCANC4). The seeds generated were sown in a 50:50 soil/sawdust mixture under a 50% natural shade of palm fronds. Data were taken on Day to 50% germination; percentage germination and growth of generated seedlings (height, Stem diameter, number of leaves and leaf area) from each treatment. There was significant difference($P \leq 0.05$) on days to 50% germination in the order: MNC2(92.33)>MTC4(89.33)>MNC4(88.0)>NCAMOP(83.67>MTC2(79.67)>MTDE(77.0)>MNOP(75.67)>NCAMC2(0)>NCAMC4(0)- an indication that 50% germination was not attained by NCAM processed C2 and C4 seeds. On percentage germination, there was no significant difference ($P \leq 0.05$%). However, percentage germination for MNOP, MTC2 and NCAMOP were respectively 56.2, 54.33 and 54.01. The other treatments had germination below average (33-49.84%). The growth parameters viz; Length x Width (L x W) of leaves and plant height were significantly different with NCAMC4 and NCAMC2 being outstanding (404.57cm^2) and (297.12cm^2), the least being from MTC2, MNOP, MNC4, NCAMOP and MTOP in that order with value ranging between 143.64cm^2 to 200.72cm^2. Plant height followed similar pattern while other growth parameters of stem diameter and number of leaves were not significantly different. Manually operated pulper, mortal & pestle processed seeds germinated better probably because of less damage to the seeds while NCAM motorised pulper processed seeds got the least germination due to damage on seeds' endosperm except for NCAMOP where seeds size was the smallest, hence undamaged. Growth was better in NCAMC2 and C4 probably because seeds were scarified thereby encouraging faster germination and growth. CRIN manually operated pulper promoted higher germination as against NCAM motorised pulper which needs further adjustment based on variation in berries and seeds sizes.

Key words: coffee, genotypes, pulpers, seeds, germination, growth

INTRODUCTION

Coffee is one of the agricultural products that is of economic importance and serve as a means of income to farmers (Muleta, 2007). In Nigeria, many farmers established their coffee plantation using seedlings derived from seeds. Coffee cherry is a drupe containing two flat seeds which are used for propagation. Germination of the coffee seeds under field condition is defined as emergence of seedling from soil, with radicle extending downward. Report had revealed that presence of patchment delay early germination of coffee seeds and its removal will hasten germination. Da-Silva *et al.* (2004) carried out studies on the mechanism and regulations concerning coffee seed germination. It was observed that parchment causes the cell wall not to expand on time or making surrounding endosperm from being inactive.

Coffee cherries can be processed after harvest by the removal of both the pulp and husk either by dry, wet or semi-dry method. Mucilage is removed by fermentation, followed by washing or machines processes Brando and Brando (2015). Selmar *et al* (2006) reported that germination process of coffee seeds starts after post-harvest processing which involved removal of fruit flesh (pulp) either manually or mechanically. They further corroborated their findings through the use of germination-specific isocitrate lyase (ICL) test with b-tubulin, a maker for cell division or elongation Selmar *et al.,* (2006).

Traditionally, the exocarp (pulp) is manually removed during seed processing by farmers as it is widely being practiced and believed to be devoid or at least reduces seed damage. Traditional coffee processing method of de-pulping requires soaking of cherries, use of mortar and pestle or even matching or tramping on cherries to remove pulp. This is followed by separation of pulps from the beans (scooping) and drying of beans. The process is however very tedious with attendant drudgery and low work rate, specifically separation of pulp (scooping) is very difficult and discouraging. Damage is a very vital index to be considered in seed production approach. Improved process of pulping coffee cherries using mechanical methods with the aim of reducing labour, time and cost should be focused for the purpose of increasing coffee production (Weinberg *et al.*, 2001). According to Murthy and Naidu (2011), removal of pulp from fresh berries; using a pulper is one process to achieve increased coffee seed production. The use of machine has been immemorial for increased efficiency and for large scale production with little or no drudgery. Proper understanding of coffee seed germination will help in improvement of agricultural activities and increase in production of coffee needed for international market. Work done on coffee seed germination with regards to seed production using mechanical pulper is very scarce considering the economic important of coffee crop in the world market. In Nigeria, some mechanical pulpers (motorized and manual) have been developed toward processing coffee seeds (*C. canephora* pierre ex Froehner.and *Coffea arabica* L.) for planting. The purpose of this study is to determine the effectiveness of these pulpers for coffee seeds production compare to the usual traditional manual method of mortar and pestle. Findings from this study will provide basic information needed for large scale viable coffee seeds production.

MATERIALS AND METHODS

Ripe matured Robusta coffee cherries were harvested from three genotypes and sorted to obtain good ones at CRIN Headquarters plantations. Harvested cherries were de-pulped using manually-operated mechanical pulper and I.C engine powered mechanical pulpers while the traditional manual method of mortar and pestle commonly used was the control. The standards procedures of wet processing method of soaking, depulping and separation of pulp were followed. Wet coffee beans obtained were air dried for about one week good (undamaged) seeds were selected and sown on pre-nursery seedbed mixed with 50:50 topsoil and sawdust mixture.

The drum pulper consists of a perforated cylinder rotating against an adjustable plate and a fixed plate where depulping (through abrasion force) and separation take place respectively. The cylinder is rotated by hand through a handle joined to a wide flywheel. The engine powered pulper is a screw shaft rotating inside a cylinder lined with metal plate and operated by a medium petrol engine. Depulping occurred through rupturing and shearing actions of the cylinder, screw and plate. The pulp was then separated manually from the beans. Equal weights of each genotype of cherries were fed into the pulpers at the appropriate feed rates and machine speeds which were pre-determined before the actual operations. Manual depulping using mortar and pestle was done by pouring the soaked cherries inside the mortar and using the pestle to press out the seeds. Each treatment was replicated thrice. The treatments are designated as follows: Mortal & Pestle (MT) for OP, C2 and C4 (MTOP, MTC2 &MTC4); CRIN Manual Driven Pulper(MN) for the three genotypes (MNOP, MNC2 & MNC4) and motorised pulper (NCAM)also for the three genotypes (NCAMOP, NCAMC2 &NCAMC4). Equal weights of 20g of seeds from each treatment were sown on pre-nursery bed in Completely Randomized Design (CRD). The sown seeds were watered at every other day. Weeding was done as and when due and shade provided using palm fronds. The pre-nursery was protected from rodents and lizards by fencing it round during the experimental period. Data were taken on germination count at 3 days' intervals 2 months after sowing. Healthy and well grown germinated seeds were transplanted (at one seed per bag) into black polythene bags filled with forest topsoil and arranged under the shade in a complete randomized design (CRD). Watering and weeding were carried out at regular intervals. Data were taken on plant morphology of height, leaf length by width, leaf number and stem diameter at monthly intervals for the period of 4 months. Data collected were analysed using SAS, Version 9.1. Means that were different were separated using Duncan Multiple Range Test at $P \leq 0.05$.

RESULTS AND DISCUSSION

Both the seed germination rate and percentage were affected by de-pulping methods and genotypes as indicated by Tables 1 and 2. This was also true of agronomic characters such as leaf number and plant height, but these were not significantly different as in Tables 3 and 4. But, both C2 and C4 genotypes showed the highest means of about 9.7 and 11cm respectively for leaf numbers and plant height for NCAM, while genotype DE had the lowest mean values of 8.6 and 9.3cm for these agronomic parameters and the method of pulping. Engine powered (motorized) pulper were

ISSN: 2814-0508

significantly different from other methods in respect to germination rate, having the least mean of 29.67 for NCAMC2. However, germination percentage was not different significantly for all the treatments while NCAMC2 had the lowest mean of 33%. Genotype OP had the highest mean of 44 and 54% for engine powered (motorized) pulper (NCAM) in terms of germination rate and percentage respectively. Manually operated mechanical pulper(MN) gave the highest germination rate of 65.3 and germination percentage of 56.2% for OP genotype. The implication is that germination rate was somehow affected by methods of pulping while percentage germination was not seriously affected by the three pulping methods studied. Manual pulper (MN) showed the best performance for germination rate and percentage. This may be as a result of removal of parchment and the endocarp layer by the machine which had been earlier reported as a factor to improve germination by Rosa *et al* (2005) and Da-Silva *et al* (2004). Genotypes can also determine both the rate and percentage of germination; this may be due to variation in genotypes sizes which may be affected by the clearance of the pulping unit of the machine, resulting in possible bruises and damage to the seeds. Although, pulping methods tested did not seriously affect agronomic characters, the trend of response by the genotypes in the nursery indicated that engine powered pulper may have best developmental quality which is also affected by the genotype itself (probably seed size).

ABSTRACT

Orchid tree (Bauhinia monandra) is a shrub widely used for provision of shade and environmental beautification. This studywas carried out at the Federal University of Agriculture Abeokuta, Ogun State, Nigeria in 2017 to determine the effect of sowing orientation and medium on seedling emergence and growth of orchid tree (Bauhinia monandra) seedlings. Treatments were sowing orientations (vertical and horizontal) and media (sawdust, topsoil and river sand) in a factorial arrangement laid out in Completely Randomized Design (CRD) with five replications. Data collected on seedling emergence and growth were subjected to Analysis of variance procedures (ANOVA) and treatment means were compared using Duncan's multiple range test (DMRT) at 5% probability level. Effect of sowing orientation on the emergence and height, number of leaves and weight of Orchid tree seedlings was not significant. Seeds sown in sawdust medium had highest percentage of emerged seedlings and dry weight. This study has shown that the germination percentage and seedling growth of B. monandra improves significantly when sown in sawdust and topsoil. Thus, floriculturist can use sawdust as an alternative medium to topsoil for commercial production of seedlings of orchid tree.

INTRODUCTION

Bauhinia monandra also known as orchid tree is a flowering plants in the subfamily Caesalpinioideae and family Fabaceae with a pan tropical distribution. There are about 300 species of this genus found in tropical and subtropical climates usually in most types of vegetation ranging from evergreen lowland rain forest to mountain forest, savanna, dry deciduous forest to swamp forest on various soils. The genus includes trees, vines, and shrubs that are frequently planted for their showy flowers and ornamental foliage. *Bauhinia monandra* is a small to medium-sized deciduous fast-growing shrub or tree with a round, symmetrical, moderate dense crown to 10 m tall. In dry forests, the size is much smaller. The bark is pale grey brown, fairly smooth to slightly fissured and scaly. The twigs are slender, light green, slightly hairy, and angled, becoming brownish grey. Leaves are simple, alternate, basecordate to rounded, apex of lobes acute, ovate blades and long (1.5 – 4 cm) petiole.

Orchid-Tree is festooned with many showy and delightfully fragrant, five-inch-wide blossoms, the narrow purple, pink, and lavender petals arranged to closely resemble an orchid. It has 6-10 flowered racemes in terminal panicles and are a beautiful sight to see, creating a vivid splash of color in the landscape. The flowers are followed by 12-inch-long, slender, brown, flat seed pods which usually persist on the tree for few months. The pods should be collected when they are brown before they dehisce. The seeds are extracted by drying the pods in the sun to release seeds (Orwa*et al* 2009). Seeds of *B.* species possess an undeveloped rudimentary embryo that requires an extended period of high temperature for breaking the dormancy.

Many species are widely planted in the tropics as ornamental tree in parks, gardens and homesteads, and along avenues for its showy fragrant, purple flowers. *B. monandra* is useful as food and medicine for man and animals, source of edible gum, dyestuff, tannins, linolenic, oleic and mytristic fatty acids particularly in India, Vietnam, China and several other countries.

Seedling emergence and growth of plants are affected by many factors. Orientation of seeds and other plant propagules is known to influence the germination and seedling growth (Thapliyal, 1979). For example, maximum germination and better emergence of seeds of *Balanites aegyptica* were achieved in a horizontal position (Elnour and Massimo 1995) while Sal (*Shorea robusta*) seeds placed in an inverted position had the best germination and emergence than in horizontal or upright position (Sharma and Purohit, 1980). Depth of sowing and growing medium was also important for optimum seedling emergence and growth of *Polyalthia longifolia* (Olosunde, 2015). Too shallow or too deep placement would affect both seed germination and seedling vigour (Singh and Wilson, 1974; Masilaijnani and Dharmalingam, 1998). In general, incorrect position, growing medium and depth of seeding could delay or suppress seed germination and seedling emergence adding to sowing expenses. Therefore, the present study was conducted to determine the best sowing orientation (positioning) and medium for emergence and growth of *B. monandra* seedlings to enhance its commercial production.

MATERIALS AND METHODS

The experiment was carried out in 2017 at the Horticultural Nursery, Federal University of Agriculture Abeokuta (7° 15N and 3 ° 25 E), Ogun State, Nigeria. Brown mature pods collected from the mature *B. monandra* trees at the Federal University of Agriculture, Abeokuta were broken to get 1000 seeds. Then six hundred (600) seeds were randomly selected and planted in vertical and horizontal positions in three different media

The experiment was laid out in 2 x 3 factorial arrangement in a Completely Randomized Design (CRD) with 5 replications. The factors were sowing orientation (horizontal and vertical) and growing media (top soil, river sand and sawdust) giving a total of six treatment combinations. There were thirty-seven litres calibrated pots and twenty seeds were planted in each pot. Pots were filled with topsoil, river sand and sawdust to 3 litre points and a ruler was used to determine 2 cm height. Then, seeds were evenly sown horizontally on their sides and vertically by making the tip of the seed upright and covered with different media to predetermined point on the pots (2 cm height). Seedling emergence was determined using the formula derived by Fakorede and Agbana, 1983 as adopted by Olosunde, (2015).

Seedling emergence percentage: $\frac{\text{Number of seedlings emerged}}{\text{Number of seeds planted}} \times \frac{100}{1}$

Three representative plants were tagged for observation. Data were collected on number of days to emergence, seedling height, number of roots, length of the longest root, fresh and dry weight of root and shoot. Three plant samples per treatment were carefully removed from the growing medium by placing them under flowing water to wash off the medium particles from the roots. Then, fresh root and shoot samples were oven dried at 70 ºC to constant weight before weighing with the aid of the sensitive scale to obtain the dry weights. The data collected were subjected to analysis of variance (ANOVA) treatments means were separated using Duncan's Multiple Range Test (DMRT) at $p \leq 0.05$.

RESULTS AND DISCUSSION

Effect of sowing orientation on percentage emergence, height, number of leaves, length of longest root and dry matter accumulation of *B. monandra* seedlings was not significant ($p \leq 0.05$). However, percentage seedling emergence, height and number of leaves of *B. monandra* were significantly influenced by different growing media (Tables 1, 2). Highest (65, 70 and 76%) seedling emergence was recorded from seeds sown in sawdust, followed by those sown in river sand (56, 60 and 65%) and then those sown in topsoil (50, 54 and 58%) at 8, 11 and 14 days after sowing (DAS). Conversely, seeds sown in topsoil medium had tallest (27 – 30 cm) seedlings, followed by seeds sown in sawdust (22 - 26 cm) and least in river sand (20 – 22 cm) at 4 and 14 weeks after sowing (WAS). Seedlings from seeds sown in topsoil and river sand produced more (3 – 9) leaves than those sown in sawdust (3 - 8) across the sampling period. Differences in the growing media had no significant effect on the length of longest root and dry matter accumulation of *B. monandra* irrespective of the sowing orientation.

Effect of sowing orientation x medium interactions on percentage of seedling emergence, height and number of leaves of *B. monandra* was significant (Table 1). Generally, seeds sown in sawdust either in vertical or horizontal position had more emerged seedlings compared to other treatments. However, similar percentage seedling emergence was observed from seeds planted in river sand or sawdust medium. Conversely, tallest seedlings with more leaves were recorded from seeds sown in topsoil either in vertical or horizontal position and least in river sand medium. Seedlings grew in river sand and sawdust at both sowing orientations were similar in terms of height and production of leaves. Length of longest root and shoot dry weight of *B. monandra* was not significantly affected by sowing orientation and medium (Table 2).

ABSTRACT

The research was conducted at the Horticultural Technology Department Site of the Federal College of Horticulture Dadin kowa, Gombe State. The effects of pre-planting treatments on germination and early seedling growth of Ximenia americana were studied in 2020 rainy season. The experiment was laid out in a completely randomized design (CRD) with four treatments replicated four times. A rate of 1.2kg/pot (244.8kg/ha.) 0.25ton/ha. of dried and ground cow and bull droppings and top soil 1.5kg/pot (306kg/ha.) 0.31ton/ha. Was mixed with river sand at 1.6kg/pot (326.4kg/ha.) 0.33ton/ha and river sand only at 4.8kg/pot as control were applied as the potting mixtures in equal proportion (1:1:1). With the spacing of 7x7m for Ximenia americana tree fitted into the design. The treatments consisted of seeds scarified with fire, seeds soaked in normal tap water for 24 hrs, seeds boiled in hot water and untreated seeds serving as control. Growth parameters such as number of days to first seedlings germination, germination rate and germination percentage were investigated for 3 weeks while plant heights (cm), leaf counts, stem collar girths (cm) were investigated at 12 weeks at 2weeks interval and seedlings vigour index (SVI) was calculated at the end of the 12 weeks' period. The result showed that seeds soaked in normal tap water for 24 hrs was the first to germinate in 7 days followed by seeds boiled in hot water in 10 days, seeds scarified by fire in 12 days and untreated seeds germinated last between the treatments in 14 days respectively. Seeds soaked in normal tap water for 24hrs has the highest germination percentage of 87.5%. followed by seeds boiled in hot water with 75%, seeds scarified by fire had 62.5% and untreated seeds with the least of 50%. The result also revealed that seeds soaked in normal tap water for 24hrs was still the highest in means of plant height (48.0 cm), leaf count of (33) and stem collar girth of (3.0cm) and seedlings vigour index (4200) respectively. Analysis of variance indicated a significant difference at 5% level of probability (P=0.05) on number of days to first seedlings germination (LSD = 1.16), germination percentage (LSD = 6.41), plant height (LSD = 2.47) and stem collar girth (LSD = 2.94). This result indicated that soaking Ximenia americana seeds in normal tap water for 24hours should be adopted for quick germination and early seedlings growth of Yellow plum by breaking the seed dormancy to produce more seedlings in nurseries by researchers/farmers for seedlings multiplications in plantations for food production, solving the problem of unemployment, soil erosion control, industrial uses and to save the crop from extinction in Africa.

Key words: Dormancy, seed coats, germination, *Ximenia americana*

INTRODUCTION

Ximenia americana, commonly known as sour plum, yellow plum, sea lemon or Tsada in Hausa language is a small sprawling tree of woodlands native to Australia and Asia. Ximenia is a genus of flowering plants in the family Olacaceae.The generic name honours Francisco Ximenez,.a Spanish priest.The specific name is the latin form of 'American'(Wikipedia,2021).The tree grows as a bush –forming shrub/small tree to between a height of 2m-7m(6.5-23feet).The leaves are oval shaped ,bright green and have a strong smell of almonds,simple ,alternate or clustered on spur shoots of 2.5-8cm having a lanceolate (spear-like)to elliptic shape and retuse at the apex with a texture similar to leather.

The trunk has a diameter of less than 10cm which is used as kitchen hand tools and the wood is used as fuel wood. The bark has a colour of dark brown to pale grey together with the roots are used as dyes. The sour sweet fruits about 1.5-4 cm long have orange fleshed resembling plum and vary in colour from dark red to brown to bright orange with sour sweet flavour. Equally, it can be eaten raw and are used to make a sour preservatives or an intoxicating drinks. In Asia, the young leaves are cooked as a vegetable. Flowering and fruiting varies between locations, but flowering typically occurs in the dry season. However, the leaves also contain Cyanide and need to be thoroughly cooked and should not be eaten in large amounts (International Cyanide Management Institute, 2009). The seeds kernel contains oil which is edible and used for cooking, hair care etc. The seeds contain 10 fatty acids, 7unsaturated yielding a total unsaturation of 92.42%. The oil contain essential fatty acids of Linoleic (1.34%) Linolenic (10.31%), Arachidonic (0.60%) and varying levels of unsaturated higher fatty acids, specifically

Eicosatrienoic (3.39%), erucic (3.46%) and Nervonic (1.23%) acids, yellowish green or brown at maturity (Wikipedia, 2021).

Ximenia americana oil is also known particularly for its anti-inflammantory properties local medicines and cosmetics. The non drying oil is suitable for soap making and lubrication, lips and dry skin cares, softening leather, soothes dermatitis and eczeama skins (The illustrated encyclopedia of essential oil,1995). The presense of active ximenynic acid has been shown to be beneficial for the skin, it is also used as soap. A mostly solitary tree dispersed in open country, savannahs, gallery forest along coastal areas, in the under storey of dry forests, in dry woodlands or on river banks, drought resistant. It requires an altitude of 0-2000m, mean annual temperature is 14-30^{0}C, rainfall 300-1250mm, soil type is poor and dry, including clay loam and sands. The tree starts flowering in September to December and fruiting through out the year (World Agroforestry, 2021)

The tree is propagated by seeds and cuttings, regenerates naturally from seed and coppice, fresh seed should be sown for good germination, can also be used for life fencing purposes. The tree contributes to better crop yields as it reforms organic matter to the soil, thus improving the water holding capacity of the soil preventing soil erosion. Growth of trees depends on the environmental and genetic factors. The leaves are green during drought which can be emergency fodder to grazing livestock when grasses dry up. scarcity of all types of its value.Some valuable species are becoming rare, and some endangered in their wild habitats (World Agro forestry, 2021).The seed is orthodox and should be stored at low moisture content and as cold as possible and for short term storage ,the seeds can be stored moist,It is essential for the successful moist storage of orthodox seeds that the seeds are ventilated frequently, furthermore, the Dormancy and pretreatment can be done by removing of the seed coat prior to germination or sterilization of the seeds (e.g by immersion in sodium hypochlorite for 5 minutes) can increase germination (Pritchard et al., 2004). Pre-germination treatments become necessary to enhance its quick germination. However, to get the seeds emerged within few days required breaking the seed dormancy through seed coat treatment, hence the need of this study in view of importance of the crop.

MATERIALS AND METHODS

This research work was conducted at Horticultural research and training site of the Federal College of Horticulture Dadin Kowa, Gombe state. The research area is located at latitude 11^0 30^{1}N and longitude 10^0 20^{1}E in the Northern guinea savannah. The annual rainfall of the area is 760 – 850mm with mean daily temperature ranges from 30^{0}c – 36^{0}c and the soil type of the area is loamy (Kowal and Knabe, 1973). The experimental design was laid out in a completely randomized design with four treatments replicated four times, each treatment with 2 medium size polythene pots (4x4x2).

The potting mixture has the ratio of one part of top soil to one part of cow and bull droppings to one part of river sand (1:1:1) mixed together for treatments A, B and C that is seeds that were pre-treated and river sand only for treatment D serving as control. 32 seeds were sown in all the polythene pots for the whole treatments and replications. Each treatment has 8 polythene pots stacked at the experimental site (6x7 metres) the treatment were: scarified seeds with fire (T_1), seeds soaked in normal tap water for 24hrs (T_2), seeds boiled in hot water (T_3) and un-treated seeds serving as control (T_4). Dried and grounded cow and bull droppings was applied at the rate of 1.2kg/pot (244.8kg/ha) 0.3 ton/ha. Top soil 1.5kg/pot (3.06kg/ha) 0.3ton/ha was mixed with river sand at 1.6kg/pot (326.4kg/ha) 0.33ton/ha and river sand only at 4.8kg/pot as control under Espacement of 7x7 meters for Yellow plum fitted into the design. Zero fertilizers were adopted in control (T4). The seeds were tested by floatation to determine the viability. Growth parameters such as number of days to first seedlings germination, germination rate and germination percentage were investigated for 3 weeks at 3 days' interval while plant heights (cm) leaf counts, stem collar girths (cm) were investigated for 12 weeks at 2 weeks' interval and seedlings vigour index (SVI) was calculated at the end of the 12 weeks' period. The data collected was analyzed using genstat and the means were separated by least significant difference (LSD) at 5%.

RESULTS AND DISCUSSION

The Effects of Pre- planting treatments on germination and early seedling growth of *Ximenia americana* were represented in table 1, where treatment B (seed soaked in normal tap water for 24 hours was the first to germinate in 7 days between the treatments on number of days to first seedlings germination. This is followed by seeds boiled in hot water, seeds scarified by fire and untreated seeds. Table 2 shows the influence of seed coat treatments on germination percentage where seeds soaked in normal tap water for 24 hrs has the highest germination percentage of 87.5%. This is followed by seeds boiled in hot water, seeds scarified by fire and untreated seeds with the least percentage of 50%.

Table 1: Number of days to first seedling germination of *Ximenia americana*

Treatment	No. of days
A=T1: seeds scarified with fire	12.0
B=T2: seeds soaked in normal tap water for 24hrs	7.0
C=T3: seeds boiled in hot water	10.0
D=T4: untreated seeds (control)	14.0
LSD (5%)	1.16

LSD = Least significant difference, NDFSG = Number of days to first seedlings germination.

Table 2: Germination percentage for 3 weeks' period after 1st germination of *Ximenia Americana* seedlings

Treatment	Emergence percentage
T1	62.5
T2	87.5
T3	75.0
T4	50.0
LSD (5%)	6.41

LSD = Least significant difference, GP = Germination percentage

Table 3 shows the effects of pre-planting treatments on plant height of *Ximenia americana* where the treatments differed significantly with the control through out the period of sampling. At 2 weeks after sowing (WAS), taller seedlings were recorded on seeds soaked in normal tap water for 24 hrs and still up to 4,6,8 and 10 WAS, the same treatment was leading in taller seedlings up to 12 weeks where the same treatment produced taller seedlings of 48.0cm followed by seeds boiled in hot water, seeds scarified by fire and untreated seeds respectively. The effects of pre-planting treatments on number of leaves on *Ximenia Americana* seedlings is represented in table 4. The results show that higher number of leaves of 33 at 12WAS was achieved with the seeds soaked in normal tap water for 24 hrs followed by seeds boiled in hot water, seeds scarified by fire and untreated seeds respectively.

Table 3: Effects of pre-planting treatment on cumulative mean plant heights (Cm) of *Ximenia americana* for 12 weeks at 2 weeks' interval

Number of Weeks						
Treatments	2WAS	4WAS	6WAS	8WAS	10WAS	12WAS
T1	4.0	7.1	12.0	16.0	23.0	32.0
T2	6.6	12.0	20.0	28.0	39.0	48.0
T3	58	10.0	14.0	20.0	27.0	36.0
T4	3.0	5.0	9.0	12.0	18.0	24.0
LSD (5%)	0.34	0.60	0.97	1.35	1.89	2.47

LSD = Least significant difference, PH = Plant height (cm), WAS= weeks after sowing

ISSN: 2814-0508

Data on table 5 shows the effects of pre-planting treatments on stem collar girths at 2, 4, 6, 8 and 10 WAS where higher collar girths was produced by seeds soaked in normal tap water for 24 hrs of 2.6cm followed by seeds boiled in hot water, seeds scarified by fire and untreated seeds respectively. While at 12 WAS seeds soaked in normal tap water for 24 hrs was still leading the trend with 3.0cm collar girth compared with the other treatments, this is followed by seeds boiled in hot water, seeds scarified by fire and untreated seeds which differed significantly at P=0.05. The priority of pre-planting treatments is perhaps due to soaking the seeds in normal tap water for 24 hrs due to imbibitions through the hard seed coat of *Ximenia americana* that enhanced the seed germination and early seedlings growth than the other treatments adopted in this research.

Table 4: Effects of pre-planting treatments on cumulative mean number of leaves of *Ximenia americana* for 12 weeks at 2 weeks' interval.

Number of Weeks						
Treatments	2WAS	4WAS	6WAS	8WAS	10WAS	12WAS
T1	5.0	8.0	12.0	14.0	17.0	20.0

T4	0.3	0.5	0.6	1.1	1.3	1.7
LSD (5%)	0.08	0.14	0.15	0.19	0.24	0.29

LSD = Least significant difference, SCG = Stem collar girth (cm), WAS= weeks after sowing

CONCLUSION AND RECOMMENDATION

Based on the results of this experiment, soaking of the hard seed coats of *Ximenia americana* in normal tap water for 24 hrs performs better in its germination and early seedlings growth as per the parameters measured above. It was considered to be the best treatment out of the four treatments adopted in this research. It is, therefore, suggested that farmers and researchers should soak the hard seeds for 24 hrs prior to sowing to break the dormancy and thus enhancing germination and early seedlings growth of *Ximenia americana*

ABSTRACT

Seedling growth and nodulation in African yam bean were studied in a potted experiment at the experimental farm of the Department of Agronomy, Michael Okpara University, Umudike. The experiment involved twelve (12) accessions of African yam bean, which were sourced from five locations, namely: Abia, Enugu, Ebonyi, Kogi and Benue states. The experiment was laid out in a completely randomized design and replicated three times. Data were collected on the following parameters: number of leaves, number of nodules, plant height, root dry weight, shoot dry weight, nodule weight and total dry matter. These parameters were recorded at 3, 6, 9 and 12 weeks after planting. Data collected were subjected to analysis of variance using the GLM module of SAS, while mean separation was done using least square difference at 5% level of significance. Correlation analysis was done to show relationship among traits. The results showed that at 3, 6, 9 and 12 WAP, most of the traits studied were significant (p<0.05). The results further showed that as the plants progressed from 3,6, 9 and 12 WAP, there were significant increases in most of the traits measured. It further revealed that at 12 WAP, Nsukka accession gave significantly higher number of leaves, number of nodules and root dry weight. Similarly, Onicha accession gave significantly higher shoot dry matter and total dry matter, while Igbo-Etiti accession gave plant height. On the other hand, the accessions, Ogbadibo and Ikwuano gave significantly lower values for most of the attributes studied. From the correlation analysis, shoot dry weight had strong positive relationship with total dry matter weight. Accessions such as Nsukka and Onicha with higher agronomic attributes, especially at 12 WAP are encouraged for further selection and improvement studies to ensure improved and sustained production of African yam bean.

Key words: Seedling growth, nodulation, genetic potentials, Agronomy

INTRODUCTION

The African yam bean- *Sphenostylis stenocarpa* (Hochst ex. A. Rich) Harms, locally known and identified as "Odudu" among the Igbos, "Sese" among the Yorubas and "Girigiri" among the Hausas, of the family *Fabaceae,* is a well-known West African leguminous crop (Duke *et al.,* 1997). It is believed to have originated from Ethiopia. Both wild and cultivated types occur in Tropical Africa as far south as Zimbabwe, throughout West Africa from Guinea to Southern Nigeria (Baudoin and Mergeai, 2001; GRIN, 2009). It is a vigorous, herbaceous leguminous plant, growing and adaptable throughout tropical Africa (Poster, 1992). It is a vigorous, climbing vine, reaching 1.5 – 2 m in height with trifoliate leaves; the leaflets being up to 14 cm in length and 5 cm broad (Adewale *et al.,* 2010). The stems may be prostrate or climbing and range from 1 m to 3 m in length (Adewale and Odoh, 2013). The crop is mostly cultivated on a small scale throughout tropical Africa and it is especially suited to lowland conditions, though it can be grown up to 1,800 m. It performs well on almost all soils, provided they are slightly acidic; i.e. pH 5.0-6.5 (Baudoin and Mergeai, 2001). It is propagated by seeds or tubers (Adewale *et al.,* 2010). The duration of the crop cycle ranges between 150 – 300 days. In Southern Nigeria, it is usually interplanted with yams and other twining beans and usually trained up with long stakes (Ene-Obong and Okoye, 1992).

Based on its nutrient composition, ripe seeds contain an average 2.1% protein, 1.2% fat, 74.1% carbohydrates and 5.7% fibre, of which the calculated percentages relate to dry matter (Arogundade *et al.,* 2014). The tubers contain an average of 11-19% fibre, of which the calculated percentages also relate to dry matter (Baudoin and Mergeai, 2001). The amino acid content of the protein is similar to that of the soybean, though rather higher in histidine and iso-leucine. The energy content of the seeds per 100 g dry matter is 1, 640 KJ (Utter 2007). The seeds are also rich in minerals such as potassium, phosphorus, calcium, Iron and Zinc, but low in sodium and Copper (Utter, 2007). The dry seeds serve as a source of protein in various food preparations. Therefore, they can be used to fortify other foods low in protein to address protein malnutrition among the susceptible population. The bean has been touted for use in

ISSN: 2814-0508

addressing the problem of food insecurity in Africa because they are indigenous (Klu *et al.,* 2000). Similarly, it currently serves as a security crop due to its potentials to meet year-round protein requirements, if grown on a large scale. The tubers are cooked and eaten in the same manner as potatoes, which they resemble in flavor. The tubers are regarded as an important source of starch and protein in tropical Africa (Baudoin and Mergeai, 2001).

The plant has a large genetic variation (Klu *et al.,* 2000) with new accessions investigated recently (Baiyeri *et al.,* 2018). The crop also nodulates profusely and probably has very high ability to fix nitrogen (Oboh *et al*., 1998), thereby helping to replenish soil nitrogen. It is therefore an important crop which merits significant consideration for land reclamation. The nitrogen-fixing symbiosis makes it possible for the nitrogen that is supplied by the rhizobia to the legumes replace the expensive and chemical industrial fixed nitrogen (Otsoseng *et al.,* 2012). The AYB enjoys a symbiosis with bacteria that naturally fix nitrogen from the air (Busson, 2001).

Despite its rich nutrient base and its capacity to serve as a security crop, AYB is still being regarded as an underutilized crop owing to the poor distribution and utilization of its rich genetic and nutritional resources. Recent studies have mainly emphasized on the nitrogen fixing ability of AYB with little or no attention given to the nodule formation and how they influence seedling growth and total yield of AYB; hence, the backbone of the study. AYB is a potential crop that needs to be explored and developed because of its biological nitrogen fixation ability and adaptability to a variety of soils. Therefore, the main objectives of the study were to: determine the growth and seedling development in AYB and to determine the nodulation pattern among various accessions of AYB.

MATERIALS AND METHODS

The research was conducted at the research farm of Department of Agronomy, Michael Okpara University of Agriculture, Umudike from April – August, 2009. It is located at latitude 05^{0}29'' North and longitude 07^{0}33'' East (Nwokocha and Onwuka, 2002). It has an altitude of 122 m (400 Ft.) above sea level. It falls within the humid rainforest zone of West Africa, which is characterized by a long duration of rainfall. Twelve accessions of AYB were sourced from five locations, namely: Enugu, Ebonyi, Kogi, Abia and Benue states. The seeds were sown at a depth of 3-4 cm to allow for early germination and emergence. The experiment was a potted experiment and was laid out in completely randomized design (CRD) which was replicated three times. Well perforated polythene bags were filled with well composed soil comprising top soil, organic manure and sharp river sand mixed in the ratio of 3:2:1, respectively. Each plot comprised of 12 poly bags and 12 accessions, giving a total of 144 bags per replication and a total of 432 poly bags used in the experiment. Seeds were sown at the rate of two seeds per hole, with spacing distance of 0.5 m x 0.8 m. Data were collected at three weeks' intervals of 3, 6, 9 and 12 weeks after planting (WAP) on the following parameters: number of leaves, number of nodules, plant height, root dry weight, shoot dry matter weight and total dry matter weight. Weeding was done at weekly intervals and the accessions were staked at 3 WAP. This was done after destructive sampling of which the whole plant is being harvested after wetting the soil. The root region was subsequently immersed in a bucket of water and washed gently, then excised from the shoot region and later oven dried. This was done at 3, 6, 9 and 12 weeks after planting (WAP). Analysis of variance was performed on plot means using GLM module of SAS software on plot means. Separation of means was done using Fishers' Least square difference (F-LSD) at 5% level of significance.

RESULTS AND DISCUSSION

According to Bareke (2018), seedling growth is the developmental period of the young plant from time germination is completed until it can manufacture enough food through photosynthesis to sustain growth. The seedling root (radicle) is the first structure to emerge from the seed during germination. From the results obtained, it was observed that Nsukka accession gave significantly ($p<0.05$) higher number of leaves at 9 and 12 WAP. It was statistically similar to Ikwuano accession for this attribute. For plant height, similar result was obtained at 3 WAP, of which Nsukka accession gave significantly higher result (Table 1). However, it was statistically similar to Onicha accession at 6 and 9 WAP and statistically similar to Igbo-Etiti accession at 12 WAP for same trait (Tables 2,3). At 9 and 12 WAP, it was observed that Nsukka accession also recorded significantly ($p<0.05$) higher number of nodules (Tables 3, 4). It was statistically similar to Isuikwuato and Dekina accessions. It differed slightly at 3 and 6 WAP, with Igbo-Etiti and Isuikwuato accessions recording higher results. For nodule weight, there were no significant weight differences (p>0.05) at 3 WAP. However, at 6 and 9 WAP, Tarka accession gave significantly higher nodule weight while Ogbadibo accession gave higher result at 12 WAP. For root dry weight and shoot dry weight, it was observed that especially at 6 WAP, Nsukka accession gave significantly (p<0.05) higher results. It recorded higher result at 12 WAP for root dry weight, while Onicha accession gave higher result for shoot dry weight. Similar result was recorded for total dry weight of the plant, with Onicha accession recording significantly (p<0.05) higher results at 9 and 12 WAP, while Nsukka accession gave higher result at 6 WAP. It was statistically similar to Isi-Uzo accession at 3 WAP. In contrast, it was observed that Ogbadibo and Ikwuano accessions gave lower results for most of the agronomic traits estimated especially at 9 and 12 WAP. This development especially with Nsukka and Onicha accessions which gave higher significant results, especially at 9 and 12 WAP could be as a result of the rich genetic resource and high adaptive potentials of these accessions. Assefa and Kleiner (1997) recorded similar trend with some accessions having more pronounced dominance over others in expression of major agronomic and yield attributes in some accessions of AYB.

Where; NL= Number of leaves, NOD= Number of nodules, PH= Plant height, NODWT= Nodule weight, RDWT= Root dry weight, SDWT= Shoot dry weight, TDWT= Total dry weight.

Furthermore, the result showed that the number of leaves, plant height, nodule weight, root dry weight, shoot dry weight and total dry weight of the plant increased significantly from 3 WAP to 12 WAP. This agrees with the findings of Assefa and Kleiner (1997) and Otsoseng *et al*. (2012) on Jicama (*Pachyrhizus erosus* (L.)), a relative of African yam bean which showed significant increase in foliage, fresh and dry matter weight, number of leaves per plant, main stem length, nodes and internodes of the main stem. In terms of nodulation pattern in the plant, it was also observed that as the growth of the plant progressed from 3 WAP to 12 WAP, the nodules became bigger, with corresponding increase in their weights. It also follows similar trend for root dry matter, even as they increased progressively from 3 WAP to 12 WAP. This conforms with the report of Crespi and Galvez (2000). It was also observed in the course of the study that root nodules decreased progressively in number from 3 WAP to 12 WAP, with corresponding increase in nodule weight. This could be that the root nodules kept merging progressively to form edible root tubers (Crespi and Galvez, 2000). From the correlation analysis, plant height had a negative correlation with number of nodules (r = -0.585*), while shoot dry weight had a strong positive correlation with the total dry matter weight (Table 5). This implies that, an increase in plant height resulted in reduction in number of nodules. In contrast, an increase in shoot dry weight gave a corresponding increase in the total dry matter weight. This agrees with the findings of Otsoseng *et al.* (2012) of which they explained that increase in number of leaves, number of root nodules, stem girth and shoot weight influenced positively the total biomass of the plant.

CONCLUSION

African yam bean, though under exploited and less popular among notable food crops and legumes, is gradually gaining ground in terms of recognition as a good source of food protein with protein percentage exceeding that of the well-known cowpea (Baudoin and Mergeai, 2001). Currently, the crop is being cultivated as a root vegetable, though on a small scale, despite its protein-rich nutrient base (Gruneberg *et al.,* 2003). From the results obtained, the accessions Nsukka and Onicha gave significantly higher values for number of leaves, plant height, root dry weight, shoot dry weight and total dry matter weight of the plant. These accessions thus provide promising potentials to exhibit higher yield and productivity, and are therefore recommended for further improvement studies so as to greatly harness their potentials to boost production and wider availability. With regards of number of nodules and nodule weight, Nsukka and Isuikwuato accessions gave significantly higher values. Selection and further improvement studies on these accessions could improve the potentials of AYB to efficiently produce root tubers which are highly relished alternatives to other starchy root products such as potatoes, especially in the tropics. However, the results have shown that nodulation is low in AYB compared to some popular legumes such as cowpea and mungbean. Therefore, concerted effort should be made to increase nodulation in AYB; as further studies and research work would ensure optimum utilization of the great nutrient potentials of this crop, as this would ensure increased food security and improved productivity.

ABSTRACT

Field experiment were conducted in the Sudan Savanna of Nigeria during the 2017/2018 dry season at the research farms of National Institute for Horticultural Research, Bagauda (11^{0}53'N 8^0 14'E, 440m above sea level) and Institute of Agricultural Research Ahmadu Bello University Kadawa, Kano state (11^{0}39,08^0 02'E, 500m above sea level) to determine yield parameter sand yield of Irish potato as affected by cultivars and sowing date in the sudan zone of Nigeria. The treatment combinations consisted of five Irish potato verieties (Nicola YL, Nicola GL, Bertita Ditta and marabet L and four levels of sowing date (early November, middle November, end of November end middle December) respectively treatments were laid down in a split plot design with three replications. The varieties were assigned to the main plots and sowing dates to the sub plots. All agricultural practices for dry season production of Irish potato were observed the data collected were subjected to analysis of variance (ANOVA) using SAS version statistically, the result obtained from measured yield parameter and yield were taken from sampled plants. The parameters measured include; number of tubers per plant, tuber weight per plant (Kg) and tuber yield in Kg/ha. The result based on comparison between five varieties of Irish potato and four levels of sowing dates showed that variety and sowing date have statistically significant effects. Varieties Nicola GL and Nicola YL, when sown in the middle of November had higher yield.

Keywords: Sudan Savanna, Irish Potato Varieties, Sowing Dates and Yield.

INTRODUCTION

Irish Potato (*Solanum tuberosum* L.) is an annual, herbaceous, tuber crop of the Solanaceae family that contains all the essential food ingredients required for maintaining proper health (FAO, 1986). The potato plant produces swollen underground tubers when mature. Potato has its region of origin in the high plains of the Andes Cordillera where the Incas cultivated the plant largely for food. In Africa, it was not cultivated until the end of the 19th century that potato was imported from Europe by missionaries and thereafter by colonial administrations (Raemaekers, 2001). Irish potato was introduced into Nigeria early in the 20th Century by European miners in Jos Plateau (Obighesan, 1976). In Nigeria, the area under potato cultivation during 2014 stands at 142, 600 ha of land with an average production of 1,184, 865 metric tons (Muhammad et al., 2018; Ugonna et al., 2013). Over 85% of potato produced in Nigeria comes from Jos plateau (Muhammad et al., 2015). Jos Plateau has a high altitude and thus a cool climate, which is favorable for the development of the crop in the area (Obighesan, 1976). Being a hardy plant, potato is cultivated the world over under different growing conditions. Irish potato has a shorter growing cycle of about 95 days than most other root crops in the tropics (Wuyep et al., 2013).

MATERIALS AND METHODS

Field experiments were conducted in Sudan savanna of Nigeria during 2017/2018. Dry season at the two locations National Institute for Horticultural Research, Bagauda (11^{0}53'N 8^0 14'E, 440m above sea level) and Institute of Agricultural Research Ahmadu Bello University Kadawa, Kano state (11^{0}39,08^0 02'E, 500m above sea level) respectively. Treatments consisted of five varieties of Irish potatoes (namely: Nicola YL, Nicola GL, Bertita, Ditta and Marabel) with four levels of sowing dates (early November, middle November, end of November and middle December) for each of the locations. They were laid down in a split plot design with three replications with variety in main plots and sowing date in sub plots. Before sowing, each of the experimental sites was cleared, harrowed, demarcated and prepared in ridges of total plot size of 150 m^2. It was further divided into three replications with an alley of 2 m between them. Replications were transformed into main plots of 10 m × 1 m with an alley of 1 m between them. Main plots were further divided into sub plots of 1 m × 2.5 m containing six rows of 3-m length. Seed tubers of uniform size were treated with soil-borne disease-preventing chemical and sown at a depth of 5 cm and 20 cm between stands. Planting was carried out on 7th November 2017. First farrow watering was on sowing and at weekly intervals, and was stopped 2 weeks before harvesting; weed and pest control were followed. Harvesting was carried out on 14th February 2018 using hoe to uproot the tubers from the soil. Data were collected at harvest on yield attributes (number of tubers per plant, tuber weight per plant (kg) and tuber yield kg/ha. in kg/ha) were subjected to analysis of variance (ANOVA) as described by Snedecor and Cochran (1976) using a SAS. Significant means of treatments were separated using LSD All-Pairwise Comparisons Test.

RESULTS

Table1 shows the Effect of variety and sowing date on number of tubers per plant of Irish potato (*Solanum tuberosum* L.) at Bagauda, Kadawa and combined. At both locations and combined effects on numbers of tubers produced per plant were highly significantly affected by variety. Nicola YL and Nicola GL produced higher number of tubers per plant (kg). They were followed by Ditta, Marabel and Bertita, which respectively produced almost similar number of tubers per plant. Sowing date shows insignificant effect on number of tubers per plant produced. Potato sown at middle of November produced higher number of tubers per plant. Other sowing dates produced similar number of tubers per plant. Interaction between variety and sowing date shows insignificant effect on number of tubers produced per plant.

Table 2 shows the effect of variety and sowing date on tuber weight per plant (kg) at Bgauda, Kadawa and combined during the 2017/2018 dry season. From the Bagauda location, tuber weight per plant was significantly affected by variety. Nicola YL and Nicola GL measured higher tuber weight per plant (kg). They were followed by Ditta, Marabel and Bertita, which were similar in tuber weight per plant (kg). Tuber weight per plant was significantly affected by sowing date. The effect of sowing at the middle of November outnumbered other sowing dates in tuber weight per plant (kg). This was followed by early November, middle of December and lowest from end of November. At Kadawa the effect of variety on tuber weight per plant (kg) was not significant. Effect of sowing date was highly significant at Kadawa with effect of middle of November at a higher level than other sowing dates in tuber weight per plant (kg). This was followed by early November, middle of December and end of November in a respective manner. Interaction between variety and sowing date at Kadawa location was insignificant.

Interaction between variety and sowing date on tuber weight per plant (kg) at 4WAS from Bagauda is shown in Table 3. Interaction between variety and sowing date was significant. Nicola YL sown at the middle of November produced higher tuber weight per plant (kg); while the lowest weight was from Marabel sown at by the middle of December.

Table 4 shows the effect of variety and sowing date on tuber yield in kg/ha at Bagauda, Kadawa and combined during the 2017/2018 dry season. Statistically from Bagauda location, the effect of variety was significant. Nicola YL produced the highest tuber yield at Kadawa and combined followed by Nicola GL and the lowest yield was produced by Bertita at Kadawa and combined.

Similarly effects of sowing date on tuber yield was only significant at Kadawa and combined with middle of November producing the highest tuber yield at both Kadawa and combined. While middle of December produced the lowest tuber yield. The interaction between variety and sowing date in tuber yield was significant at Bagauda, sowing Nicola YL producing the highest tuber yield at middle of November while the lowest tuber yield was produced by marabet at middle of December.

DISCUSSION

Results from both locations and combined measured yield parameters show that variety and sowing date have an effect on yield attributes of Irish potato. Measured parameters show yields were higher from Nicola GL followed by Nicola YL at Bagauda, Kadawa and combined. These two varieties generally performed substantially better than other varieties. This could be due to their better adaptation, including tolerance to harsh weather conditions of the new environment (experimental sites). The differences could also be due to the varying levels of adaptation of the cultivars to local temperature and soil conditions. Moreover, other inherent traits like green leaf for photosynthetic efficiency from Nicola GL and more leaf area for better light interception from Nicola YL may also contribute to their better yield performance in the new environment over other remaining varieties. This is in line with an assertion that: maximum productivity depends primarily on rates of light interception and carbon assimilation by the crop surface (Watson, 1978). The significance effects of the variety could be attributed to genetics and ability of the crop (Irish potato) to utilize available environmental resources such as water, nutrients, temperature, light and agronomic practices. These factors, however, could vary in their effect across different locations as well as among different potato species (Watson, 1978).

Effects of sowing date on yield of Irish potato were observed in the dry season of 2017/2018 from two locations. Measured parameters on yield were higher when a sowing date of middle November was used. This could be attributed to effects of mean maximum and minimum temperatures during the month of November which favored the crop during earlier stages of crop development. This is in line with assertion made by Nash et al. (2008) that the highest yields are currently produced in areas where the daytime temperature is often over 38°C during the hottest part of growing season and nights are cool 18°C. Wurr et al. (1990) also reported that the final yields of crop are in many cases dependent on satisfactory growth during earlier stages of crop development, which is achieved through planting at the most suitable time. Sowing at middle of November that is, under irrigation, Irish potato production in Nigeria should coincide with the coldest month (November – January) so that the time of tuber bulking will coincide with the period of low temperature. Time of sowing also determines time of flowering and it has a major influence on dry matter accumulation, seed set and seed yield (Sofield, 1977). Gallagher and Biscoe (1978) also reported that crops sown at the optimum time make the best use of the available growth factors such as temperature and solar radiation at different stages of growth for high productivity. Wurr et al. (1990) also stated that for each type of crop, appropriate and proper time of sowing is one of the basic requirements for obtaining maximum yield and high profit returns. For example, Mortazavi-bak and Ramin-pour (2009) recommended that potato planting date should be calculated based on the length of the growing season, because the number of tubers produced per plant is affected by optimum sowing date.

CONCLUSION

The experimental results show that two varieties, Nicola GL and Nicola YL, have higher yields at Bagauda, Kadawa and combined. Similarly, an optimum sowing date that gives better yield is the middle of November.

RECOMMENDATION

It is suggested that for dry season production, varieties Nicola GL and Nicola YL are preferred, with corresponding sowing date of middle of November, and these varieties could be used to improve yields of Irish potato production in the Sudan savanna zone of Nigeria.

ABSTRACT

Saba senegalensis (L.) is an indigenous shrub like fruit tree still in the wild. The fruit is nutritionally endowed, containing high quantity of ascorbic acid and often used as food additive. Horticultural practices to enhance seed germination and produce certified seedlings were carried out in a high tunnel. Practices included the effect of the substrates (sawdust and rice husk), pre-planting seed preparation (seeds with or without mucilage), and seed storage duration (0, 3, 6, 9 days' delay in planting). Seeds were sterilized with 10% dilution of NaOCl, and seeds for the experiment on storage duration were stored at room temperature. Data were collected on days to seedling emergence, percent seedling emergence, seedling height and number of leaves produced. The data collected were subjected to analysis of variance in a completely randomized design (CRD). The results showed that sawdust was a better substrate for emergence of Saba seedlings; removal of seed mucilage before planting supported earlier and more seedling emergence; seeds sown without mucilage and stored for six days gave a better percent seedling emergence. Seedling height and number of leaves per plant eight weeks after sowing were similar for all seed storage duration except for nine-day delays. Information herein could provide basis for further research on the production of Saba senegalensis plants.

Keywords: Pre-Nursery; Delay seeding; Substrates; Seedling emergence

INTRODUCTION

Saba (*Saba senegalensis* L.) is a fruit plant yet to be domesticated, it however plays a vital role in the diets of the local residents where it grows. Restriction in consumption of the fruits is probably due to unawareness of its nutritional endowment and therapeutic effects (Kini *et al.*, 2008). The Saba fruits are consumed widely where they are found in the West Africa countries, mostly in the forest areas. It is an indigenous shrub-like fruit tree of the family Apocynaceae, native to the Sahel of Africa. Burkill (2000) reported that the tree does grow principally on riverbanks and in woodlands in Burkina Faso, Senegal, and Ivory Coast. It has been observed growing as vine up trees, and usually growing to the size of a large tree. Baiyeri (2003) reported that seedling emergence speed and growth could be enhanced by use of a suitable growth medium. Generally, of all nursery factors determining seedling quality, growth medium have been identified as most extremely important (Baiyeri, 2006).

In Nigeria, there is little or no horticultural documentation on all aspects of Saba plant, most critical being development of protocols for raising certified seedling for plantation establishment. This paper reports on the findings of study on seedling emergence as influenced by substrate, pre-planting seed preparation and duration of seed storage on seedling emergence.

MATERIALS AND METHODS

The experiment started was conducted in a high tunnel at the Teaching and Research Farm of the Department of Crop Science, University of Nigeria, Nsukka. Nsukka is located in the derived Savanna zone (latitude 7.4, longitude 6.9 and altitude 475m). The location is characterized by lowland humid conditions with bimodal annual rainfall distribution that ranges from 1155 - 1955mm. A mean annual temperature of 29 - 31^{0}C and relatively humidity that ranges from 69 - 79% (Uguru *et al.*, 2011).

Saba fruits used for the experiment were sourced from Kogi state, Nigeria. The seeds were extracted and sterilized with 10% dilution of sodium hypochlorite. Seeds were shared into two portions and a portion had the mucilage removed before sowing in two substrates. The substrates were sawdust and rice hull. Substrates were soaked in water for 24 hours and washed twice to remove organic residue. The second experiment was a study on duration of seed storage (0, 3, 6, & 9 days) on seedling emergence. Fifty seeds were sown into five containers each storage day. Pre-nursery growth container was perforated plastic pots. Experimentation was in a high tunnel with an average temperature of ≈30.1^{0}C, and watering was daily.

RESULTS

Removal of seed mucilage before planting enhanced higher seedling emergence in sawdust substrate in contrast to the rice hull. There was 100% seedling emergence in sawdust substrate 7 weeks after sowing in contrast to 83.3% in rice hull. But when mucilage was not removed before seed-sowing emergence was higher (96%) in rice hull substrate and 84% in the sawdust (Table 1).

Delays in seed sowing significantly ($p < 0.05$) influenced percent seedling emergence all through the duration of study. Planting seeds till six days after extraction had statistically similar emergence pattern (Table 2). Planting nine days after extraction relatively had lower percent seedling emergence. Duration of delays in seed sowing significantly ($p < 0.05$) reduced number of leaves per seedling and height of seedlings eight weeks after planting (data not sown).

$LSD_{(0.05)}$	15.3	25.1	22.5	23.0	15.1	16.1	8.7

Delays = How long the seeds were kept to determine their effective storage period before the time of the last sowing; LSD = Fisher's least significant difference; WK = Week.

DISCUSSION

Non-removal of mucilage before planting delayed seedling emergence. About 68% seedling emergence was recorded two weeks after sowing when mucilage was removed before seed sowing in contrast to no emergence when mucilage was not removed. Seedling emergence became substantial six weeks after sowing with mucilage; seed mucilage probably degraded over time such that seedling emergence was no longer delayed. The delay was probably associated with the mucilage reducing moisture and air permeability; and so low water imbibition into the endosperm delayed initiation of metabolic activities that could eventually lead to germination and seedling emergence. It is imperative therefore, that an after-ripening procedure of mucilage removal is recommended for Saba seeds before planting. Sawdust was a better substrate probably due to less compaction and thus more aeration, relative to rice hull.

Pre-sowing treatments (of mucilage removal and sterilization with 10% dilution of sodium hypochlorite and storage under room temperature) indicated that Saba seeds could be stored up till six days before planting (with 100% emergence reachable). In fact, nine days after these pre-sowing treatments up to 78% seedling emergence was attainable. This probably suggests that these pre-sowing practices are panacea to seedling production in *Saba senagalensis* and so recommended for adoption.

EFFECT OF VARIETY, PERIOD OF POD DELAY AND WITHIN-POD BEAN POSITION ON VIABILITY AND GERMINATION OF COCOA (*THEOBROMA CACAO*) UNDER DIFFERENT SHADE CONDITIONS

*[1]Oyeledun, K.O., [2]Atayese, M.O., [2]Adeyemi, N. O., [1]Idrisu, M., [1]Olorunmota, R.T. and [1]Ugioro, O.

ABSTRACT

Two trials were conducted under two different shade conditions in 2021 to evaluate the effect of variety, period of pod delay and within-pod bean position on viability and germination of cocoa (Theobroma cacao) at the central nursery of Cocoa Research Institute of Nigeria, Ibadan. The experiment was a 3×3×2 factorial experiment laid out in a Complete Randomized Design (CRD) with 18 treatment combinations replicated three times. In the main plot was the variety denoted V1 (F3 Amazon) and V2 (WACRI) while in the sub plot, the period of delay (D0-Cocoa pods planted on the day of harvest; D1- Planting 7 days after harvesting; and D2- planting 14 days after harvesting) and the sub-sub plot contained the bean position in the pod (P1-distal, P2-middle and P3- proximal). Varietal difference was only significant on days to end of germination with F3 Amazon variety (3.322) ended the process of germination earlier than WACRI under natural shade condition. Germination variables were significantly influenced by period of delay at both shade conditions as cocoa beans planted immediately at harvest (D0) were significantly ($P < 0.01$) highest (80.0 and 70.0 respectively) on percentage germination compared with beans delayed for 7 and 15 days before planting. The effect of within-pod bean position was significant ($P < 0.05$) in the order proximal > middle > distal on number of days to germination, days to end of germination, percentage germination and speed of germination under the two shade conditions. Period of delay beyond seven days should be discouraged by cocoa farmers because of the probable reduction in the quality of seed, while the F3 Amazon and seeds from proximal position are best for consideration when delay is inevitable.

Key words: bean position; period of delay; varietal difference; germination

INTRODUCTION

Cacao (*Theobroma cacao*) is one of 17 species of Theobroma and it is the most widely cultivated (Opoku-Ameyaw & Baah, 2010) amongst them. The economic product (i.e. the beans) whose number ranges between 20 and 60 per pod (Ortiz, 2016) are basic raw material for the production of chocolate (Motamayor *et al*., 2008; Amma *et al*., 2011). Cacao is well adapted to and thrives productively in the rainforest ecology of West and Central Africa-the region which accounts for the largest proportion of global production, especially from Cote d'Ivoire, Ghana, Cameroon and Nigeria. In Nigeria, cocoa is primarily propagated through seed by farmers. Mathew *et al*. (2012) identified the use of low quality seed for raising seedlings, low emergence and poor seedling vigor as some of the factors responsible for low productivity within the plantation. However, factors like variety and postharvest pod management for succeeding propagation are crucial to achieving improved productivity. Seed viability maintenance especially under storage, and their nursery and/or field performance is crucial to the sustenance of cocoa production most especially amongst smallholder farmers. Access and proximity to source of good planting materials usually compel farmers to delay planting as a result of distance to farmers' destination. Ahenkora and Halm (1977) recommended a limited storage period of one (1) week before planting. However, most farmers go beyond the one-week period as a result of crucial social engagement of smallholder farmers (unpublished Smallholder Cocoa Farmer Survey Report in Ghana, 2012). Similarly, cocoa seed planting is seasonal, and since cocoa pods are unavailable to all farmers at the appropriate time for raising seed nurseries, the storage of pods beyond one-week period has become inevitable for farmers (Opoku-Ameyaw *et al*., 2010). In spite of the above, farmers still indiscriminately use all seeds within the pod irrespective of bean size differences and the location (proximal, middle and distal) within the pod environment.

It is quite a natural phenomenon that cocoa seed loses its viability and vigor over a long period of delay before planting (both within the pod and scooped fresh beans/seed), as any other biological material does. This is attributed as storage environment conditions and the length of handling or storage during the period of delay which usually results into low germination of the seed from such pods. According to work done by Redshaw (1965), germination capacity of cocoa appears to be short lived, and that viability is lost within 10-15 days after the seeds are harvested, unless they are placed under special storage conditions which permit their germination. Therefore, cocoa beans meant for propagation to raise seedlings are expected to have completed their structural and functional development within the pod (the fruit) before they are plucked for use in raising seedlings (Opoku-Ameyaw *et al*., 2010).

The pod apart from been an apartment to house the beans, equally regulates seed growth and maturation. The location/apartment where different seeds appear within the fruit has a role to play in the resource distribution and sharing scheme within the pods (Lee, 1988). In cocoa, Ibikunle (1967) noted that seeds which developed in the expanded (i.e. middle) part of the cocoa pod produced bigger-sized beans and hence seedlings with better vigor. Researchers have been able to work on the bean position within the pod and post-harvest handling in relation to size of pods and physiological maturity. However, these previous related works have not examined the effect of pod delay and within-pod bean position as its affect cocoa seed viability and germination. The objective of this study is therefore to evaluate effect varietal differences, period of pod delay and within-pod bean position on seed viability and germination of cocoa under two different shade condition.

MATERIALS AND METHODS

Two trials were conducted during the wet season of 2021 under two different shade conditions-standard nursery shade net and natural shade (cacao tree canopy). The experiment was 3×3×2 factorial arrangement laid out in a Completely Randomized Design (CRD) with 18 treatment combinations and three replications. In the main plot is the variety denoted V1 (F3 Amazon) and V2 (WACRI)-both are common varieties in farmers' farms. In the sub-plot was the periods of delay (D0-Cocoa pods planted on the day of harvest; D1- Planting 7 days after harvesting; and D2- planting 14 days after harvesting) and the sub-sub plot was the beans position in the pod (P1- distal, P2-middle and P3-proximal). Similar physiologically mature pods of both varieties were used for the respective periods of delay. The pods were weighed using an electronic weighing scale to determine the weight of each pod, whilst a measuring tape was used to measure the length and girth (center, proximal and distal end) of the pods to ensure that uniform pods size were selected. The respective delayed pods after harvest were kept on an open platform in the laboratory. All the treatment combinations were planted the same day with one seed per standard polythene pot having been filled with top soil near full. Sawdust was used to mulch after planting. In an experimental unit was comprised four pots for observation. Observations were made on the germination-related parameters vis: 1) Days to germination: Number of days between planting and germination; 2) time (days) from start of germination to the final germination (at primary leaf emergence); 3) germination percentage: number of seedlings germinated per treatment divided by the total no of seedlings planted for each treatment and then multiplied by 100 percent and 4) speed of germination: Speed of germination= n1/d1+n2/d2+n3/d3+---------- n. Where, n = number of germinated seeds, d= number of days (Czabator, F. J. (1962)). Observation were made on the crops on a daily basis. All data collected were subjected to analysis of variance (ANOVA) procedures using GenStat Discovery latest Edition. Differences between the treatments means were compared using Least Significant Difference (LSD) test at 0.05 significance level

RESULTS

The number of days to germination of cocoa was significantly *(P < 0.05)* influenced by varietal difference, period of delay and within-pod bean position (Table 1). The beans from pods planted at harvest under standard shade net germinated significantly *(P < 0.01)* fastest (12.422 days) compared to beans from pods delayed for seven and fifteen days before planting, while pods delayed for seven days before planting germinated significantly *(P < 0.01)* fastest (13.222) when compared to 0 and 14 periods delay under natural shade condition. However, beans planted from proximal position at both shade conditions germinated significantly *(P < 0.05)* fastest (12.556 and 13.433) compared to distal and middle beans positions. Similarly, the interaction of variety, period of delay and within-pod bean position had significant *(P < 0.05)* influence on number of days to germination under standard shade net condition while under natural shade condition only the interaction of variety and period of delay significantly *(P < 0.05)* influenced number of days to germination (Figures 1 and 2).

Table 1 also shows that the effect varietal difference, period of pod delay and within-pod bean position were significant *($P < 0.05$)* on days to final germination of cocoa under different shade conditions. F3 Amazon variety planted under natural shade condition completed germination significantly *($P < 0.05$)* faster (3.322) than WACRI variety (3.530) while there was no significant *($P < 0.05$)* difference between the two varieties under standard shade net condition. However, at both shade conditions the effect of period of delay on final germination showed that beans planted from pods delayed for seven days significantly *($P < 0.01$)* ended germination the earliest (2.939) compared to 0 and 15 periods of delay under standard shade net while beans from pod with no delay were significantly *($P < 0.01$)* fastest (3.206) to complete germination under natural shade condition. However, beans planted from the proximal position completed germination significantly *($P < 0.05$)* fastest (3.278) compared to others only under natural shade condition.

Table 2 shows the significant *($P < 0.05$)* effect of variety, period of pod delay and within-pod bean position on percentage germination of cocoa under different shade conditions. At both shade conditions cocoa beans planted immediately at harvest were significantly *($P < 0.01$)* highest [80.0% (standard shade net) and 70.0% natural shade)] compared with beans delayed for 7 and 14 days before planting. Similarly, the beans from proximal position had significantly *($P < 0.05$)* highest germination percentage values of 72.2% and 66.7% at standard shade net and natural shade conditions respectively.

The effect of variety, period of pod delay and within-pod bean position were significant *($P < 0.05$)* on speed of germination of cocoa bean under different shade conditions (Table 2). The speed of germination was significantly *($P < 0.05$)* highest in beans planted from proximal position under the natural shade condition alone. However, interaction of variety and period of delay were significantly *($P < 0.05$)* highest on the speed of germination under shade net while interaction of variety, period of delay and within-pod bean position was significant *($P < 0.05$)* on the speed of germination under natural shade (Figures 3 and 4).

DISCUSSION

Of the various methods of seed viability test, germination test is proven to be the most reliable. The germination of the seeds is a complex process where several reactions and individual factors are involved (Copeland and McDonald, 1995). These include physiological maturity and accumulated resource components of the seed, which are pivotal to seed germination. In the present study, the response of the varietal difference as a factor was not conspicuously expressed on germination indices tested except on days to end germination under natural shade condition where F3 Amazon variety ended germination significantly earlier (3.322) than WACRI (3.530); and similarly varietal difference effects were revealed in some few interactions with the other factors under both shade conditions. This may suggest that the most important factor that could determine germination when it comes to variety is the attainment of physiological maturity-the stage at which resources in seed within the pod are sufficient before planting. This was corroborated by Opoku-Ameyaw *et al*. (2010) that cocoa beans meant for propagation to raise seedlings are expected to have completed their structural and functional development within the pod (the fruit) before they are plucked for use in raising seedlings. However, F3 Amazon variety showed prospect over WACRI variety with higher values more than WACRI. This could also be attributed to the genetic makeup of F3 Amazon as an improved variety and the impact of the enviroment (Crossa *et al*., 1991; Mortazavian and Azizinia, 2014). The impact of period of delay was conspicuous on germination indices as period of delay beyond seven days had negative effect on germination parameters. Seeds planted at harvest, and seeds delayed for just seven days before planting were significant on germination indices which could be due to greater food reserve within the bean, at the early part of the storage, which was catalyzed and metabolized to provide the needed energy to quicken the germination process. However, with continued delay, the stored food reserves in the beans could have been used up through respiration during germination and therefore could not be readily available for the seedling to emerge when storage was delayed (Olympio and Kumah, 2009) at both shade conditions. Similary, the impact of delay in the present study agrees with Onakoya (2011) that Cocoa seeds lose viability on extraction from the pod within five to seven days, unless specially treated; and Redshaw (1965), that germination capacity of cocoa appears to be short lived, and that viability is lost within 10-15 days after the seeds are harvested, unless they are placed under special storage conditions which permit their germination.

Seed growth and development are dependent on the biomass investment from the mother plant, such that seeds with high resources have bigger size (Susko and Lovett-Doust, 2000; Khan *et al*., 2014). In the present study the effect of within-pod bean position was significant in the order

ISSN: 2814-0508

proximal > middle > distal under the two shade conditions. The beans from proximal position recorded lowest days to germination and earliest day to end germination. The probable factor for the performance of seeds drawn from proximal position could be due to better resource accumulation being closer to the stylar compared to other positions, which could inform its size and potential viability as corroborated by Nakamura (1988) who identified proximity of the ovules to the stylar end as another an important factor in *Phaseolus vulgaris* L.; noting that seeds closer to the style (proximal) end were significantly better in size (endosperm content) than those nearer to the receptacle (the distal) end. Seeds with high resources have bigger size and the endosperm content determines seed sizes.

The interactions resulted in a reduction of the time taken for the sown seeds to start germination and also reduced the time taken from start of germination. This situation could be accounted for by the effect of internal respiration within the pod, which metabolic process may not have reached a level so high as to reduce the bean size within the first few days of delay and therefore did not affect the surface area of the bean. (Dwapanyin and Frimpong, 2003). This subsequently resulted in faster germination, reducing the time associated with the germination process.

CONCLUSION

In line with the objectives of this study, the study revealed that period of delay beyond seven days should be discouraged by cocoa farmers because of the probable reduction in the quality of seed to be sown. However, the seed from proximal position was the best for consideration when planting, most especially when pods are unavoidably delayed. The F3 Amazon variety can also be recommended to farmers when unavoidable delay in planting is envisaged.

ABSTRACT

An experiment was carried out to study the effects of stem girth size on roots number and length of roots of marcotted sweet orange (Citrus sinensis) at the Federal College of Agriculture, Ishiagu, Ebonyi State, Nigeria. Ishiagu is in a tropical environment which lay on Latitude 5^0 57^1N and longitude 7^0 34^1E with an annual rainfall of 1350 mm. It has an average humidity of 88 %, a mean annual temperature of 29 ^{0}C and is situated on a gentle slope. The design was a randomized complete block design, replicated four times. One-year-old stems of sweet orange made up of different girth sizes (1 cm, 2 cm, 3 cm and 4 cm) were measured, selected and marcotted at different periods of the year, in 2019. The numbers of developed roots were counted and their lengths measured with a meter rule. Numbers of adventitious roots and their lengths were significantly ($p \leq 0.05$) increased by the girth size of the stems. The 4 cm girth stems had the highest number of roots and also longer root lengths than others, while the least in performance was the 1cm girth. The time of marcotting significantly ($p \leq 0.05$) increased the roots number and length. The month of July had more root and longer root lengths than the months investigated.

INTRODUCTION

Citrus is a hesperidium a many celled fleshly fruit which developed from a syncarpous pistil with axil placentation. It is a juicy fruit which is tasty, stomachic and rich in vitamin C. It is a shrub, growing less than ten meters tall with few shoots arising from the base. It begins to bear fruits between 2 - 5 years of planting especially when propagated vegetatively, while seeded stands bear fruits at 12 - 15 years after planting (Opeke, 2012.) *Citrus* species can be propagated by seed or budding / grafting. *Citrus* plants are polyembroyonic and apogamic. There is generally large proportion of the seedling that are identical with the mother plant thereby providing propagation plants as clones for pure lines. Cross pollination, however, do occur between the species resulting in variations seed lots of a pure line. Good varieties are propagated by bud grafting on a hard variety or by gootee (Phillips, 1971; Mathew *et. al.,* 1990). Uniformity in character is a desired feature obtained by budding.

Commercial propagation of citrus desire budded plants. Budding is the union of scion and root stock. Citrus is raised by budding and grafting to avoid gummosis, a fungi disease and tristeza a deadly virus disease (Opeke, 2012). Most root stocks have advantage of been disease resistant, vigorous in growth and adaptable to soil and climatic conditions (Hartmann *et. al.,* 2007). Though there is scion and root stock interaction which is hidden but taste and nutrient constituents of budded oranges are affected. Some root stocks were observed to affect the uptake of different nutrients like P, K, Ca, Cu, and Mg. Marcotting which is the manipulation of the plant stems to initiate roots has become a way of producing a clone of plants in which there is no genetic variation from the parent plant (Umeokechukwu *et. al.,* 2019). Unlike budding or grafting, where there is an interaction between scion and root stock which affects the plant, marcotting does not. While height and dwarfness of budded plant is influenced by the position of the scion on root stock, in marcotted plants, the new plant maintains a posture in growth like the mother plant.

Citrus sinensis probably originated in northeastern India in Burma and the adjoining areas (Opeke, 2012). Cross pollination between citrus species results in heterogeneity of seeds making it difficult to obtain seeds of pure line. As a result of these short comings coupled with the long delay in fruiting in seed propagated stands, air layering also called marcotting becomes the alternative in seedling multiplication. This is a system of vegetative propagation in which stems are manipulated to produce roots while still attached to the mother plant (Hartmann *et. al.,* 2007). The rooted stems / shoots are genetically identical with the parent stock. Marcotting is rarely employed in

Nigeria in seedling multiplication, due to constraints of technical know-how, slow in process and non availability of controlled environment. This experiment was designed to determine the effect of stem girths size on the rooting or root formation of marcotted citrus orange stems.

MATERIALS AND METHODS

This experiment was conducted at the citrus orchard of Federal College of Agriculture, Ishiagu Ebonyi State, Nigeria. Ishiagu is a derived savanna zone of South eastern Nigeria which lies between longitude 5^0 57' N and 7^0 31' E with mean annual rainfall of 1350 mm to 2500 mm, relative humidity of about 67 % during the dry season and 91 % during the rainy season (Nwite *et. al.,* 2008). The design was a randomized complete block replicated three times. During the 2019 rainy season in the months of April, May June and July 2019, a stand of sweet orange was selected. A year-old stems of different thickness were selected. Using a vernier caliper the stem thickness / sizes of 1 cm, 2 cm, 3 cm and 4 cm were identified through the appearance of the lenticels. Each stem was marcotted using fresh coconut shaft, ball of earth, with transparent polyethene and twine / rope. A notch (girdles of about 2 cm) was made on each stem of the orange. The ringed back was removed exposing the phloem vessels and the cambium. These were scraped with a sharp blade to avoid premature healing (Hartmann *et. al.,* 2007). The ball of earth was made using the coconut shaft and the soil which was placed on the scraped portion of the stem covered with transparent polyethene of 1 cm thick, tied together with a twine and allowed to incubate for 3 months. After the end of three months, the marcotted stems were severed washed with clean water to count the number of roots whose lengths were measured using a meter rule.

RESULTS AND DISCUSSION

Number of roots of marcotted sweet orange (*Citrus sinensis*).

The analysis of variance indicated a significant ($p \leq 0.05$) difference in the number of roots of the marcotted stems as shown in Table 1. Stems with girth of 4 cm had the highest number of roots followed by 3 cm, 2 cm and 1cm had the least. Stem thickness indicated proportionality with the cambium size (Microsoft® Encarta®, 2009). Thick stem sizes were able to produce more roots than the thin stems. Callus formation is necessary for the roots initiation (Hartmann *et. al.,* 2007). This is obtained from a thick cambium cells making thicker stem sizes better for marcotting of *Citrus sinesis* possible than thin stems.

Root length of marcotted sweet orange (*Citrus sinensis*)

The roots lengths were significantly ($p \leq 0.05$) affected by the time of marcotting. Stems marcotted in the months of July had longer stems than those of other months. This may be attributed to the reduced air temperature with increased relative humidity (Hartmann *et. al.,* 2007). July, 2019 has a low atmospheric temperature and high relative humidity in Ishiagu, Ebonyi State. Hartmann et. al., (2007) Observed that while germination require increased temperature, rooting requires a reduced temperature.

ABSTRACT

A preliminary investigation was conducted to study the effects of stem pruning on growth and leaf yield of three accessions of bitter leaf. The research was carried out at the Teaching and Research Farm of Department of Crop Science and Horticulture, Nnamdi Azikiwe University, Awka, Anambra State, Nigeria. The three bitter leaf accessions were 'Nise', 'Umueze-Anam' and 'Nimo', which received four stem pruning levels namely no pruning, pruning to one stem, pruning to two stems and pruning to three stems. The experiment was laid out as a 3 x 4 factorial in randomized complete block design (RCBD) replicated six (6) times. Results showed that stem pruning had significant (P<0.05) effect on the growth and leaf yield of bitter leaf. The highest number of leaves, tallest plants, widest leaves, highest fresh (3.65 t/ha) and dry (1.97 t/ha) leaf yield were significantly (P<0.05) observed in plants that were pruned to three stems while the lowest mean values of these parameters were significantly recorded in unpruned plants. Growth and leaf yield varied among the accessions with 'Nise' accession producing most vigorous plants with the corresponding highest fresh (3.92 t/ha) and dry (2.07 t/ha) leaf yield. Combined effect of accession and stem pruning indicated that pruning 'Nise' accession to three stems significantly (p<0.05) produced highest fresh (5.99 t/ha) and dry (3.30 t/ha) leaf yield. Hence, 'Nise' accession was recommended as good planting material for farmers in Awka, Nigeria. Stem pruning of bitter leaf to three stems was also recommended to be adopted by the farmers since it accounted for most vigorous plants and highest fresh and dry leaf yield.

Key words: Bitter leaf, pruning, accession, growth, leaf, yield.

INTRODUCTION

Vernonia amygdalina, a member of the Asteraceae family, is a small shrub that grows in tropical Africa (Ijeh and Ejike, 2011). *Vernonia amygdalina* grows primarily in tropical Africa especially in Nigeria, Zimbabwe, and South Africa (Farombi, 2003). It is adapted and domesticated in parts of West Africa. The leaves are green and have a characteristic bitter taste. Every part of the plants is useful, notably the stems, leaves and roots (Adaramoye *et al*., 2008). The leaves of the plant may be consumed either as vegetable (macerated leaves in soups) or aqueous extract as tonics for the treatment of various illnesses (Atangwho *et al*., 2007). The leaves of *Vernonia amygdalina* are commonly used as soup condiments after washing and boiling to get rid of the bitter taste (Abosi and Raseroka, 2003). Specifically, it is used to prepare the popular Nigerian bitter leaf soup, 'onugbo' or Cameroon dish 'ndole' after the removing its bitter taste. Other popular use of *Vernonia amygdalina* in Africa includes traditional treatment of diseases, such as malaria, infertility, diabetes, gastrointestinal problems and sexually transmitted diseases (Farombi and Owoeye, 2011).

Plant accession is a distinct uniquely identifiable sample of seeds or planting material representing a breeding line or population which is maintained in storage and conservation for use (NPGS, 1991). Accession is described as a group of related plant material from a single specie which is collected at one time from a specific location. Each accession is an attempt to capture the diversity present in a given plant population. There are numerous accessions of bitter leaf but they are largely uncharacterized making it impossible to ascribe specific attributes to known accessions to facilitate industrial-scale production. There is scarcity of agronomic information on the accessions which are in existence in Nigeria and Anambra state in particular, where the plant exists virtually in every homestead both in the urban and rural areas because of its nutritional and medicinal importance.

Pruning is an agronomic practice which has been reported to increase branching in plants resulting to increased leaf production (Hossain *et al.,* 2007). Pruning is a horticultural practice involving the selective removal of certain parts of a plant, such as branches, buds, or roots (Nelson, 2017). It focuses more on the removal or reduction of parts of a plant, tree, or vine that are not requisite to growth or production, and are no longer visually pleasing, or are injurious to the health or development of the plant. Pruning is common practice in orchard and vineyard management for the improvement of flowering and fruiting. It is an important gardening skill, as it involves the trimming and cutting of plants to rid them of any injured, dead, or infected roots and wood. In some cases, pruning is also used as a preventive measure to make space for any new seedling or growth. It is important to prune trees and shrubs at the proper time (MaximumYield Inc, 2019).

In Anambra state, Nigeria, there is scarcely any household without deliberate efforts to maintain bitter leaf plant within the homestead because of the obvious nutritional and medicinal importance. However, there is scarcity of recommended agronomic information for optimum production of the crop (Ndukwe *et al*., 2020). There may be accessional variations and there are no recommendable accessions for higher leaf yield at present. In addition, stem pruning is a horticultural practice that increases plant productivity, it will be pertinent to determine its effect on the growth and leaf yield of bitter leaf. Hence, the objectives of this study were to evaluate the growth and leaf yield of three accessions of bitter leaf and to determine the effect of stem pruning on growth and leaf yield of bitter leaf.

MATERIALS AND METHODS

The experiment was conducted at the Teaching and Research Farm of the Department of Crop Science and Horticulture Nnamdi Azikiwe University, Awka, Anambra State Nigeria. Awka is a tropical rain forest with an average temperature of 27^0C - 30^0C. The area is located between latitude 06^0 151´N and longitude 07^0 081´E, with an average rainfall of 1810.3 mm per annum and a relative humidity of 75-80% (GEOMET-NAU, 2019). The experiment was carried out during the rainy season.

Stem cuttings of two bitter leaf accessions ('Nise and Umueze –Anam') were obtained from the research farm of Anambra State University Igbariam, Anambra while stem cuttings of 'Nimo' accession was obtained from Crop Science and Horticulture Teaching and Research Farm at Nnamdi Azikiwe University Awka. The stems were cut into an average length of 15 cm, bearing 3-5 nodes. The factors comprised of three bitter leaf accessions (Nise, Umueze-Anam, Nimo), which received four pruning levels which were no pruning, pruning to one stem, pruning to two stems and pruning to three stems. The experiment was laid out as a 3x4 factorial - in a randomized complete block design (RCBD) replicated six (6) times.

Ridges of 5 m long were manually made with a furrow space of 1 m between ridges. Planting was done by inserting the stem cuttings into the soil at 45° position to the soil level with at least two nodes underneath the soil while two nodes were above the soil. Six (6) stem cuttings were planted on the ridges with a spacing of 0.5 m by 1 m within and between rows respectively. At two weeks after planting, poultry manure was uniformly applied to the soil at 20 cm diameter away from each plant at the rate of 10 t/ha using ring method of application.

Data were collected on growth and leaf yield. Growth data were collected at two weeks' interval. They comprised height of tallest branch, stem girth of tallest branch, measured leaf area and total number of leaves. Height of tallest branch was obtained using a flexible measuring tape while stem girth was recorded with digital vernier caliper. Total number of leaves was obtained by counting the number of leaves on each branch of the plant while measured leaf area was obtained by measuring the length and width of the broadest leaves using a meter rule. Fresh and fully opened leaves were harvested by picking at 4 weeks' interval.

All the data collected were statistically analyzed following the procedure outlined for factorial experiment in randomized complete block deign using GENSTAT (2012) statistical software package. Treatments means were separated with least significant difference at 5% probability level.

RESULTS

Main effect of accessions and pruning on the number of branches of bitter leaf

The number of branches did not significantly (P>0.05) vary among the accessions at 9 and 11 weeks after planting (WAP) (Table 1). However, at 13, 15 and 17 WAP, there were variations in the number of branches of the accession. Nimo and Nise accessions significantly (P<0.05) produced higher number of branches at 13, 15 and 17 WAP than Umueze-Anam accession.

Pruning significantly (P<0.05) influenced number of branches of bitter leaf in all the sampling periods (Table 1). Expectedly, highest number of branches (4.50) was significantly recorded in the unpruned plants, followed by plants pruned to 3 branches, and then plants pruned to 2 branches. The least number of branches were recorded in plants pruned to 1 stem. This trend was observed at all periods of data collection.

There was significant (P<0.05) interaction effect of accession and pruning on the number of

ISSN: 2814-0508

branches at 9, 11, 13, 15 and 17 WAP (Table 2). Highest number of branches (4 - 5) was consistently produced by unpruned Nimo accessions while lowest number of branches was significantly recorded in plants pruned to one branch in all the three accessions.

Main effect of accession and pruning on number of leaves of bitter leaf

The number of leaves of bitter leaf significantly ($P<0.05$) varied among the accessions in all the sampling periods (Table 3). Nise accession significantly produced higher number of leaves than either the Nimo or Umueze-anam accessions. On the other hand, unpruned plants and plants pruned to three branches consistently produced highest number of leaves across the sampling periods (Table 3) while lowest number of leaves was recorded by plants pruned to one stem.

The combined effects of accession and pruning indicated significant influence on the number of leaves (Table 4). Pruning of Nise accession to three branches significantly enhanced the production of highest number of leaves at 9, 11, 13, 15 and 17 WAP whereas pruning of Nise to one

ISSN: 2814-0508

branch on the other hand produced fewest leaves at all periods of data collection.

Main effects of accession and pruning on plant height of bitter leaf

There was significant difference (P<0.05) among the accessions as regards plant height (Table 5). Nise accession produced tallest plants (21.2, 35.6, 64.9, 70.6 and 79.60 cm at 9, 11, 13, 15 and 17 weeks after planting, respectively). Nimo accession, on the other hand, significantly produced shortest plants in all the sampling periods but the mean values were significantly at par with those observed in Umueze-anam accession.

Plant height was significantly (p<0.05) influenced by pruning (Table 5). Expectedly, shortest plants were observed in plants that were not pruned while tallest plants were produced by plants that were pruned to three branches, although the mean values obtained did not significantly differ (P>0.05) with those recorded in plants pruned to either one or two branches. The interaction of

ISSN: 2814-0508

accession and pruning had significant influence on plant height at 9, 11, 13, 15 and 17 WAP (Table 6). Pruning Nise accession either 2 or 3 branches significantly (P<0.05) gave rise to tallest plants while the shortest branch were obtained from unpruned Umueze-anam and Nimo accessions.

Main effects of accession and pruning on stem girth of bitter leaf

There was a significant difference (P<0.05) among the accessions in their stem girth at 9, 13, 15 and 17 WAP (Table 7). At 9 WAP, Umueze-anam and Nimo accessions produced similar but significantly wider stems compared to Nise accession. But at 13, 15, and 17 WAP, significantly (P<0.05) widest stems were obtained from Nise accession. During these growth periods, Umueze_anam and Nimo accessions produced narrower stems compared to Nise accession.

On the other hand, pruning significantly (P<0.05) influenced the stem girth of bitter leaf at all the growth periods (Table 7). Widest stems were obtained from the plants that were pruned to one stem in all growth periods although the mean values were significantly similar with mean values observed in plants pruned to 2 and 3 stems. Unpruned plants had significantly (P<) thinner stems than the pruned plants.

The interaction of accession and pruning significantly affected the stem girth of the bitter leaf especially at 17 WAP (Table 8). Widest stems at 17 WAP were notably observed in pruned plants from Nise accession but no pruning resulted in thinnest stems across all the accessions.

Main effects of accession and pruning on measured leaf area of bitter leaf

Measured leaf area of the accessions was significantly different only at 15 WAP (Table 9).

ISSN: 2814-0508

Widest leaves were produced by Nise accession. Effect of pruning showed that plants pruned to 3 stems significantly produced widest leaves (Table 9). Interaction of accession and pruning did not have significant (P>0.05) effect on the measured leaf area.

Main effects of accession and pruning on total fresh and dry leaf yield of bitter leaf

The main effect of accession on leaf fresh and dry leaf yield indicated that Nise accession significantly (P<0.05) produced highest fresh leaf weights (196g), dry leaf weights (103.6g), fresh and dry leaf yields (Table 10). Lowest leaf fresh and dry yield were consistently observed in Nimo accession. Pruning significantly (P<0.05) influenced the fresh and dry leaf yield (Table 10). Pruning stems to 3 branches resulted in highest fresh and dry leaf yield, while unpruned plants significantly had lowest fresh and dry leaf yield. The interaction of accession and pruning had significant (P<0.05) influence on the fresh and dry leaf weights of bitter leaf (Table 11). Pruning the stems of Nise accession to 3 stems resulted in highest leaf fresh and dry yield while lowest leaf yield was obtained from unpruned plants of Umueze-anam accession.

DISCUSSION

The growth and yield differences among the accessions in our results is an indication that there could be inherent genetic variability among them. There could be further breeding investigations on these accessions for further improvement through breeding. Most vigorous plants and highest leaf yield were produced by Nise accession followed by Nimo while Umueze-anam accession performed poorest. This implied that Nise and Nimo accessions had easier adaptation to Awka environment than Umueze-anam accession. Nise and Nimo are suburbs and villages around Awka, Anambra State, Nigeria and these villages belong to the same agroecological zone (Awka agroecological zone) with Awka metropolis.

Our result showed that pruning had a significant effect on plant height, number of leaves and measured leaf area with pruning to three stems recording significantly highest mean values for these variables. Shortest plants in unpruned plants could be attributed to the effect caused by competition for solar radiation by many branches in the unpruned plants. This corroborates with reports of Ayala-Tafoya *et al*. (2019). Pruning modifies light distribution within canopy and increases their photosynthetic capacity and quantum yield of leaves (Hossain *et al.,* 2007). In addition, there must have been reduced competition for resources due to pruning to three stems. Similar finding had been reported by Sahu *et al*. (2018) who opined that pruning directly encourages the formation of enlarged leaves, increases mesophyll size and moisture content and also lengthens the period of stomata opening. It has also been reported that pruning helps to reduce transpiration per unit ground area (Alcorn *et al*., 2013; Chen *et al*., 2016) which would have also enhanced moisture utilization for higher assimilate production as evidenced in the pruned plants especially pruning to three stems which had more biomass and highest leaf yield.

CONCLUSION AND RECOMMENDATION

This study showed that pruning had significant effect on the growth and yield of bitter leaf. Pruning to three stem produced the highest leaf yield throughout the haevesting periods, especially in Nise accession. Therefore, stem pruning of bitter leaf especially pruning to three branches was recommended for adoption by the farmers. Nise accession was recommended to be a promising planting material for farmers within the study area.

ABSTRACT

Cashew plant is an economic and tropical evergreen tree known most especially for its edible nuts and apple. It is mostly propagated by seeds which could be nursed before transplanting to the field. Pruning which is an important cultural management practice that helps in manipulating branching, light utilization, canopy formation, flowering and fruit production. Varying views from farmers on pruning call for a scientific investigation on its effects on the growth and development of young cashew plants. The experiment consists of 6 treatments which include Jumbo control (CtJ), Medium control (CtM), Pruned-out Jumbo (PoJ), Pruned-out Medium (PoM), Pruned-return Jumbo (PrJ) and Pruned-return Medium (PrM) all replicated three times in a randomized complete block design. Data on seedling emergence and morphology with particular reference to height and stem diameter were collected. After pruning treatments application at 12 weeks after sowing (WAS), the control had the highest plant height in both jumbo (45.63 cm) and medium (40.42 cm) biotypes at 24 WAS though the differences were not significant ($p \leq 0.05$) over the pruning treatments. Prior to application of pruning treatments, PrM and PrJ that ranked 6th and 4th position in plant height growth rate now ranked 2nd and 3rd respectively afterwards. This could be an indication that the mineralization of pruned branches over a longer period could enhance plant height of cashew seedling in both biotypes. Pruning seemed not to enhance the rate of stem diameter in medium biotype as PrM degenerated from 2nd position ranking to 4th and PoM from 1st to 3rd before and after pruning treatments application respectively.

Key words: Biotype, cashew, growth, pruning, seedling

INTRODUCTION

Anacardium occidentale L. (Cashew) is a tropical evergreen tree that produces true fruit called nut and a pseudo-fruit called apple. It is an essential commodity crop that provides food, employment and economic growth to many developing countries including Nigeria. Propagation in cashew is mainly by seed raised in the nursery for 2 to 3 months prior to field transplanting though *in-situ* sowing is equally recommended (Adeyemi and Nduka, 2019). A successful field establishment of cashew starts from the nursery. Pruning is the correct and cautious removal of plant parts such as shoots, spurs, leaves, roots or nipping away of terminal parts, to correct or maintain tree structure and increase its usefulness. It is one of the vital management practices in tree crops like cashew (Adeyemi, 2017) that entails modifying plant form and structure. Management of plant growth, canopy architecture, flower and fruit production are enhanced through pruning. Pruning increases stem potential, induces canopy transpiration and improves water status of plant. Branch, stem and trunk pruning of young trees induce the movement of photosynthates or plant nutrients towards the canopy of the plant for improved productivity. The small nodes on each plant structure contain growth hormones and if pruning is done directly above them, the hormones are activated to fix or regrow plant tissues (Bosque, 2021).

Some of the claims by cashew farmers on the effects of shoot pruning on young cashew plant needed to be investigated scientifically. Shoot pruning also results in the loss of plant nutrients contained in the prunes. It is equally imperative to determine the effect of prunes re-applied to the seedling. This study is therefore aimed at examining the effects of shoot pruning on the morphological parameters of young cashew seedlings when removed completely or resupplied as manure.

MATERIALS AND METHODS

The investigation was conducted under cashew trees, a semi-nursery environment, behind Agronomy block of the office complex at CRIN, Ibadan. The factorial experiment was laid out in a randomized complete block design consisting of two factors. Factor A was cashew nut biotype at two levels of jumbo (J) and medium (M). Factor B was pruning at three levels of: pruned branches removed (Po), pruned branches returned (Pr) to the seedling pot and un-pruned as control treatment (C). Consequently, there were 6 treatment combinations as follows: Control Jumbo (CtJ), Control Medium (CtM), Jumbo pruned returned (PrJ), Medium pruned returned (PrM), Jumbo pruned out (PoJ), Medium pruned out (PoM).

The treatments were replicated three times. Topsoil obtained under cashew plantation within the Institute was sieved using a 2 mm sieve to remove stones and debris. The prepared soil was put into 10.0 kg capacity plastic buckets perforated at the bottom for free drain off excess water. The soil was watered to water holding capacity two days prior to sowing of cashew nuts. Current season nuts obtained from CRIN were sown one nut per pot at the centre of the pot at 3.0 cm depth. Watering of the pots was done thrice a week at every other day interval. Data taken were on rate of seedling emergence, total emergence at 4 weeks after sowing (WAS) and morphological parameters of seedlings from 4 WAS at fortnightly till 12 WAS when pruning treatments were applied and data collection at a month interval afterward. Pruned branches were mashed using a mortar and pestle for ease of mineralization before being returned into the pots as manure. Data collected were analyzed with both descriptive (percentage) and analytical (analysis of variance) statistics. Means separation was done by the use of DMRT and LSD.

RESULTS AND DISCUSSION

Rate of seedling emergence in cashew biotypes

Cashew seedling emergence was earlier in medium biotype than in jumbo as indicated in Table 1. This is in concordance with the reports of Adeyemi *et. al*., (2017).

Table 1: Mean emergence (%) in cashew biotypes

Period (WAS)	Mean Germination % Medium cashew	Jumbo cashew
2	2.8a	0a
3	69.4a	38.9b
4	77.8a	66.7a

Emergence in medium cashew (2.8 %) commenced at 2 WAS while that of jumbo was at 3 WAS. However, the difference was not significant ($p \leq 0.05$) at 2 WAS as shown in Table 1. Mean emergence increased from 2 WAS to 4 WAS in both cashew biotypes. Highest rate of emergence (%) which was 96 and 100 for medium and jumbo respectively occurred at 3 WAS (Table 1). Emergence in medium was both superior and significant ($p \leq 0.05$) over jumbo at 3 WAS. The rate of emergence in the two cashew biotypes understudy was 2 WAS < 3 WAS > 4 WAS. At 4 WAS, the highest emergence (77.8 %) was obtained in medium biotype while its counterpart jumbo recorded 66.7 % but the difference was not significant ($p \leq 0.05$) as shown in Table 1. These observations agree with the reports of Adeyemi, et. al. (2017).

Morphological parameters of cashew as affected by pruning and biotypes

Pruning and biotypes effects on plant height of cashew seedling

At the completion of seedling emergence (4 WAS), jumbo cashew seedlings, had the highest plant heights than medium (Table 2). Order of plant height observed was at this stage: CtJ > PoJ > PrJ > PoM > CtM > PrM. In each of the treatments and throughout the period of observation, the height of jumbo seedling was higher than its corresponding medium but the differences were significant ($p \leq 0.05$) only from 8 – 20 WAS in the control treatments. These observations are in consonance with earlier reports by Adeyemi, et. al., (2017). In all the treatments, the height increased with the age of the seedling. This is expected of living and growing organisms like cashew seedling. However, the rate of increase was consistently at a decreasing rate till 12 WAS being the recommended maximum seedling age for field transplanting.

Table 2: Mean Plant Height (cm) of cashew seedling as affected by pruning and biotypes

Treatment	Seedling height 4 WAS	6	8	10	12	16	20	24
CtJ	18.27	25.83	32.87	36.27	38.80	40.70	42.80	45.63
CtM	16.17	20.50	24.03	25.50	27.00	29.83	31.10	40.42
PrJ	17.00	23.33	26.27	28.07	29.97	32.33	34.47	37.53
PrM	16.00	19.67	22.83	23.37	24.37	24.90	26.80	32.33
PoJ	18.10	24.67	29.47	31.88	33.03	36.03	37.73	39.48
PoM	16.67	22.93	27.70	29.77	30.47	33.27	36.63	38.57
LSD	**2.84**	**6.22**	**7.41**	**6.13**	**7.43**	**7.76**	**8.36**	**10.55**

As from 16 WAS till the end of the investigation, an irregular pattern was observed in the rate of growth of cashew seedlings as indicated by their heights. At recommended cashew seedling maximum age (12 WAS) and prior to pruning treatments application, jumbo seedlings maintained the higher plant heights over the medium with the order: CtJ > PoJ > PoM > PrJ > CtM > PrM.

After pruning treatments were effected at 12 WAS, the control seedlings maintained the highest plant height in both jumbo (45.63 cm) and medium (40.42 cm) biotypes at 24 WAS as shown in table 2. The order of seedling height 3 months after pruning treatments were applied was: CtJ > CtM > PoJ > PoM > PrJ > PrM. However, growth rate (%) from 16 – 24 WAS, which was 3 months, after the application of pruning treatments was in the order: CtM (26.20) > PrM (22.98) > PrJ (13.86) > PoM (13.74) > CtJ (10.80) > PoJ (8.74). Prior to the application of pruning treatments, 4 – 12 WAS, it was: CtJ (52.9) > PoM (45.29) > PoJ (45.20) > PrJ (43.28) > CtM (40.11) > PrM (34.35). This showed that PrM and PrJ that ranked 6th and 4th position before application of pruning treatments now ranked 2nd and 3rd respectively afterwards. This is an indication that the mineralization of pruned branches over a longer period could enhance plant height of young cashew plant.

Pruning and biotypes effects on cashew seedling stem diameter

The mean stem diameter (0.57 cm) of medium biotype cashew seedling was greater than that of jumbo (0.52 cm) prior to the application of pruning treatments (4 – 12 WAS) as shown in Table 3 contrary to what was observed in seedling height above. However, 3 months after the application of pruning treatments, jumbo was greater (1.05 cm) in seedling stem diameter than medium biotype (0.96 cm). Mean stem diameter from 4 to 12 WAS was in the order: CtJ > PoM > PrM > PoJ > CtM > PrJ. At 24 WAS, 3 months after the application of pruning treatments, the order was: CtJ > PoJ > PoM > CtM > PrJ > PrM.

Considering cashew seedling growth rate (%) from stem diameter perspective, that of medium biotype before (39.36) and after application of pruning treatments (22.79) were greater than jumbo (32.36) and (16.77) respectively. The order at 4 – 12 WAS was: PoM > PrM > CtM > PoJ > PrJ > CtJ. Three months after the application of pruning treatments, it was: CtM > PoJ > PoM > PrM > PrJ > CtJ as shown in Table 3. Pruning returned to seedling seemed not to enhance the rate of stem diameter in medium biotype as PrM degenerated from 2nd position ranking to 4th. Likewise, PoM that was in the 1st position ranking prior to the application of pruning treatments degenerated to the 3rd position afterwards. Furthermore, control medium that ranked 3rd 4 – 12 WAS advanced to the 1st at 24 WAS. Growth rate of control jumbo was least both before and after pruning treatments application. Stem diameter increased as seedling advanced in age as observed in seedling height reported earlier.

Table 3: Mean Stem diameter (cm) of cashew seedling as affected by pruning and biotypes

Treatment	Seedling diameter 4 WAS	6	8	10	12	16	20	24
CtJ	0.57	0.58	0.65	0.69	0.82	1.02	1.09	1.17
CtM	0.49	0.53	0.65	0.68	0.76	0.84	0.95	1.17
PrJ	0.52	0.55	0.62	0.67	0.77	0.9	0.96	1.08
PrM	0.43	0.48	0.6	0.68	0.73	0.8	0.86	0.99
PoJ	0.56	0.59	0.7	0.74	0.85	0.95	1.05	1.2
PoM	0.48	0.51	0.68	0.74	0.82	0.9	1.03	1.13
LSD	**0.07**	**0.06**	**0.16**	**0.12**	**0.08**	**0.17**	**0.22**	**0.25**

CONCLUSION

Three months after the application of pruning treatments, the control treatments had the highest plant height in both jumbo and medium though the differences were not statistically higher than the pruning treatments. Rate of seedling height growth indicated that the mineralization of pruned branches over a longer period could enhance plant height of

ISSN: 2814-0508

cashew seedling in both biotypes. However, pruning returned to seedling seemed not to enhance the rate of stem diameter in medium biotype. These will be validated with further investigation which in on-going.

ABSTRACT

Field trials were conducted during the 2017 wet season at the Research farms of the Institute for Agricultural Research, Samaru and Kadawa in the Northern Guinea and Sudan savanna Agro-ecological zones to study the "Correlation Analysis of Seed Yield with Growth and Yield Components of Kenaf (Hibiscus cannabinus L.)". Growth parameters studied include plant height, number of leaves, leaf area index, butt diameter, shoot dry weight, crop growth rate and relative growth rate while yield parameters include 100 seed weight, seed weight plant^{-1} and seed yield (kg ha^{-1}). Results obtained showed a significant and positive correlation between seed yield hectare^{-1} and plant height, number of leaves, leaf area index, butt diameter as well all yield characters studied in both locations. However, shoot dry weight; crop growth rate and relative growth rate were negatively correlated with seed yield of the crop. These characters should not be considered in breeding for increase/improve seed yielding ability of kenaf.

Key words: Correlation, Savanna, Kenaf, Rainfed, Yield

INTRODUCTION

Kenaf is a fast growing annual crop of the malvaceae family known for both its economic and nutritional importance. Kenaf is believed to have its origin in Africa (Western Sudan), occurring as early as 4000BC, where diversified forms of its species are widely grown (Mostofa *et al,* 2013, Dempsey, 1975, Kobayashi *et al*. 2003 and Cheng *et al*., 2004). It is an erect annual shrub, 1- 4 meters in height, with well-developed tap root, leaves straight and slender stems. It has large cream-colored, flowers characterized by a reddish-purple neck. The seeds are cylindrical or kidney-shaped, pubescent, grey in colour (Purseglove, 1974 and Dempsey, 1975). Kenaf is the most economically important fiber crop after cotton and jute. It is specifically grown for its fiber and seeds but some varieties have edible leaves consumed by humans and animals (USDA, 1986 and Webber *et al*., 2002). Kenaf fiber is used in the production of sacks, mats, carpets, ropes roofing and canvass; while the stalk is used in paper pulp production. The seeds contain about 20% oil which is extracted and used as lubricant and for illumination, soaps, paints and varnishes (Purseglove, 1968).

Kenaf is now commercially cultivated in more than 20 countries, particularly China, India and Thailand, which accounted for 90% of the sown area and more than 95% of the total production in the world (FAO, 2006). However, in 2015, India and China accounted for 44% and 29% of the world kenaf production (INFO, 2016). FAO statistics in (2016) revealed that kenaf production in Nigeria has been fluctuating since 2004 when the development of the crop started receiving attention in Nigeria's agricultural development programmes. Kenaf production peaked in 2005 and started declining between 2007 to 2010. In 2011, production started improving once more and peaked in 2012 after which it started declining gradually till 2015.

Therefore, the objective of this study is to determine the simple correlation coefficient between seed yield with growth and yield components of Kenaf (*Hibiscus cannabinus* L.)

MARTERIALS AND METHODS

The experiment was conducted at the Institute for Agricultural Research (I.A.R) Farm, Samaru, (Latitude 11^{0} 11N Longitude 07' 38 E, 686m) above sea level in Kaduna State and at Kadawa, (Latitude 11^{0} 39 N Longitude 08' 27 E, 500m) above sea level in Kano State, in the northern Guinea and Sudan savannah ecological zones of Nigeria, respectively during the 2017 wet season (Kowal and Knabe, 1972).

The treatments consisted of three varieties of kenaf (Ifeken 400, Ifeken D1 400, and Girin danani). The treatments were laid out in a Randomized Complete Block Design (RCBD) and replicated three times. The gross plot size was 4m x 3 (12m^{2}) while the net plot was 2 x 3 (6m^{2}).

Required cultural practices were conducted as per treatment. The relationship between the parameters was determine by correlation coefficient using the procedure described by Little and Hills (1978). Data were observed and collected on plant height, number of leaves, leaf area index, butt diameter, crop growth rate, relative growth rate, 100 seed weight, seed weight plant^{-1} and seed yield hectare^{-1}.

RESULTS AND DISCUSSIONS

The correlation coefficient for the different variables assessed for seed yield of Kenaf per hectare showed that kenaf seed yield per hectare was observed to be significantly and positively correlated with all the parameters assessed except shoot dry weight, crop growth rate and relative growth rate at both locations in 2017 wet season (Tables 1 and 2). This may indicate the importance of these parameters as yield contributing factors in kenaf. The correlations between most factors in kenaf were significant and positive except that between plant height with leaf area index, butt diameter, shoot dry weight, crop growth rate and relative growth rate, number of leaves and other factors except with seed yield hectare^{-1} , butt diameter with shoot dry weight, crop growth rate, relative growth rate and 100 seed weight. No significant correlation was observed between shoot dry weight and other factors except with crop growth rate, while the correlation between crop growth rate with 100 seed weight, seed weight plant^{-1} and seed yield hectare^{-1}, relative growth rate with 100 seed weight, seed weight plant^{-1}, and seed yield hectare^{-1} was not significant at Samaru during the 2017 wet season (Table 1). The correlation between plant height, number of leaves, shoot dry weight, crop growth rate, relative growth rate and 100 seed weight number of leaves and crop growth rate , butt diameter with crop growth rate and 100 seed weight, shoot dry weight and other factors, crop growth rate with 100 seed weight, seed weight plant^{-1} and seed yield hectare^{-1}, relative growth rate with 100 seed weight, seed weight plant^{-1} and seed yield hectare^{-1} ,100 seed weight and seed weight plant^{-1} was not significant at Kadawa during the 2017 wet season (Table 2). These observations show the contributory role of these factors in enhancing seed yield in kenaf, as the coefficient between two variables is the sum of the paths connecting them as reported by Agbaje et al. (2011).

The positive and significant correlation observed between most of the growth and yield characters studied signifies their significant in improving seed yield seed yield of kenaf varieties (Akinrotimi and Okocha, 2018). The increase in plant heights, number of leaves and other positively correlated characters to the seed yield, indicate their role in facilitating assimilate production and subsequent translocations to the sink and hence increase in seed yield of the crop. Similar results have been reported by Babaji (1997). The negative and insignificant association between shoot dry weight, crop growth rate and relative growth rate on seed yield in both locations implies that any increase due to selection for shoot dry weight, crop growth rate and relative growth rate would be accompanied by a corresponding decrease in seed yield. These characters should therefore not be considered for improvement for high yielding kenaf crop. This conforms with earlier finding by Agbaje *et al.* (2011).

CONCLUSION

The result has shown that a significant and positive correlation was observed between total seed yield ha^{-1} and other growth and yield characters except shoot dry weight, crop growth rate and relative growth rate in both locations. Hence, improvement programme for kenaf should not consider those characters with negative correlations as factors for improvement of the yield of kenaf

ABSTRACT

A field study was conducted in a research farm opposite the Feed-mill of School of Agricultural Technology Samaru-Kataf Campus of Nuhu Bamalli Polytechnic Zaria to assess the growth and yield responses of varieties of cowpea [Vigna unguiculata (L.) Walpers] to compound fertilizer and sprinkling irrigation systemwith the primary objective of comparing the growth and yield responses of varieties of cowpea grown.The treatments consisted of a 3 x 3 factorial experiment laid out in a Randomized Complete Block Design (R.C.B.D.) with three replicates and blocks each that gave a total of nine (9) plots. Thus, the sources of variations for the experiment treatments consisted of three varieties of cowpea, namely honey beans, black-eyed pea and grey mottled cowpea seeds commonly grown in the area of study. The varieties were coded as Hb, Bp and Gm. for honey beans, black-eyed pea as well as grey mottled beans, respectively – with cow dung manure and sprinkling irrigation system applied in Samaru-Kataf campus. In addition to the treatments, half a fertilizer bag of cow dung manure was well air-dried before incorporating it into each of the nine (9) plots during land preparation. The assessment of growth and yield responses of three varieties of cowpea [vigna unguiculata (L.) Walpers] to cow dung manure and surface irrigation was compared during the 2020 dry season (synonymous to the winter that spanned from December, January to February). All the findings were subjected to a statistical analysis "analysis of variance (ANOVA). It was found that only flowering percentage was significantly different while plant height, pod dry weight per plant, seeds per pod weight, 500 seeds weight and 500 seeds weight were not significantly different at p>0.01 and p>0.05 levels of significant error. The results indicated that all the three cowpea varieties had equal chances of performance in the study area in terms of growth and yield in irrigation system using cow-dug manure.

***Key words*:** Cowpea, Growth, Yield, Cow Dug Manure, Irrigation

INTRODUCTION

Cowpea [*Vigna unguiculata* (L.) Walpers] is one of the most important versatile and nutritive grain legume crops native to Africa (Omoigui*et al.*, 2020; Yaw, 2015). The crop exhibitsdifferent morphological forms such as erect, semi-erect, climbing, prostrate or creeping and usually indeterminate under favourable environmental conditions (Bates*et al.*, 2015). The annual world cowpea production area was estimated at 11.8 to 14 million ha with an annual production of 4.5 to 5.4 million tons of dried grain and an average potential yield of 1.5 to 6 MT per ha (Boukar*et al.*, 2018). Africa alone accounts for about 91% of the global production; West Africa, with 10.7 million ha, represents 75%of Africa's production (FAOSTAT, 2013). The principal cowpea producing countries areNigeria, Niger, Brazil, Senegal, Mali, Burkina Faso and Ghana withNigeria, Niger and Mali leading the production in Africa (Ojiewo*et al.*, 2018; Belt*et al.*, 2015). In West and Central Africa, cowpea is usually cultivated by subsistence farmers on small scale as intercrop, in rotations or relay cropping with cereals such as sorghum, millet, and maize (FAOSTAT, 2010).

Cowpea is cultivated in all the Local Government Areas of Kaduna state based on local preferences for yield, maturity period and grain size or colour. Moreover, the bulk of the cowpea production in Nigeria is largely found in the Guinea Savanna and Forest zones (Abdou, 2018; Adusei *et al.*, 2015). The crop plays a very important role in achieving food security due to its high nutritional content of 23-30% protein, 50-67% carbohydrate, 1.9% fat, 6.35% fiber and small percentage of the B-vitamins such as folic acid, thiamine, riboflavin as well as somemicro-nutrients (Iron, Phosphorus, Zinc and Calcium) that improve human nutrition and health status (Kassambara, 2017; Adetonah *et al.*, 2016). Cowpea isbeing considered as a healthy alternative to soya bean as consumers look for more traditional food sources that are low in fat and high in fiber, and that have other health benefits (Singh, 2016). Protein from cowpea grain has good functional properties, including solubility, emulsifying and foaming activities and could be a substitute for soya bean for persons (especially infants) with soya bean protein allergies (Snapp*et al.*, 2018; Karikari and Arkorful, 2015). Processed food products of dry cowpea grain such as cowpea-fortified baked foods, extruded snack foods and weaning foods have been developed to reduce malnutrition among children in Nigeria (Boukar *et al.*, 2016). According to ICRISAT (2012) report, malnutrition and infant mortality are expected to drop significantly through increased consumption of cowpea from the current level of 9 kg per capita to 15 kg per capita by most house-holds in Nigeria.

The dry haulms of cowpea are used as fodder for livestock particularly during the dry season when animal feed is scarce making the crop an essential and integral part of sustainable crop-livestock farming systems in Nigeria (FAOSTAT, 2013). Cowpea is used in crop rotation, intercropping and as cover crop or green manure in relay cropping with cereals (Bates*et al.*, 2015). Moreover, cowpea is a shade-tolerant crop, hence compatible as an intercrop with a number of cereals and root/tuber crops, as well as cotton, sugarcane and most plantation crops (Burridge*et al.*, 2017).

Cowpea grows quickly, permits establishment of a good ground cover, and improves the cropping systems as well as soil fertility by suppressing weed andreducing soil erosion. Cowpea cultivation plays a very significant role in sustainable farming system in Nigeria due to its nitrogen fixing ability. It fixes nitrogen up to 240 kg/ha and leavesabout 60 –70 kg for succeeding crops and therefore contributes to increased yields of nitrogen demanding crops grown in rotation with it on the poor soils of Nigeria (Ojiewo*et al.*, 2018). It is obvious that, the importance of cowpea in the farming systems and as nutritious diet for millions of people and livestock makes it an ideal crop for achieving Sustainable Developmental Goals (SDGs) of reducing poverty and hunger, improving human health and nutrition as well asenhancing ecosystem resilience.

MATERIALS AND METHODS

The treatments consisted of a 3 x 3 factorial experiment laid out in a Randomized Complete Block Design (R.C.B.D.) with three replicates and blocks each that gave a total of nine (9) plots. Thus, the sources of variations for the experiment treatments consisted of three varieties of cowpea, namely honey beans, black-eyed pea and grey mottled cowpea seeds commonly grown in the area of study. The varieties were coded as Hb, Bp and Gm. for honey beans, black-eyed pea as well as grey mottled beans, respectively – withcow dung manure and sprinkling irrigation system applied in Samaru-Kataf campus. In addition to the treatments, half a fertilizer bag of cow dung manure waswell air-dried before incorporating it into each of the nine (9) plots during land preparation. The assessment of growth and yield responses of three varieties of cowpea [*vigna unguiculata* (L.) Walpers] to cow dung manure and surface irrigation was compared in Samaru-Kataf campus during the 2020 dry season (synonymous to the winter that spanned from December, January to February). The data were analysed using Analysis of Variance (ANOVA)at 5% and 1% levels of significance. Differencesbetween treatment means were determined using the Fisher Least SignificantDifference method. The computer package used for the analysis was SPSS 23.

RESULTS ANALYSIS AND DISCUSSION

Table 1 shows that black-eyed cowpea took the least number of days for its emergence, followed by honey beans and grey-mottled had the highest number of days. The table also shows that black-eyed recorded the highest number of leaves, plant heights and flower plants, followed by honey beans and grey-mottled recorded the least. Table 2 shows that black-eyed beans recorded the highest pod dry weight, followed by grey-mottled and honey beans recorded the least. The table also shows that black-eyed beans could produce the highest seeds per pod weight with honey bean and grey-mottled weighing the same. The table proves black-eyed beans recording the highest plant heights and flower plants, followed by honey beans, and grey-mottled had the least. Tables 3-9 show that the differences observed in Tables 1 and 2 are not statistically different in terms of average number of leaves, average Plant Height, Pod dry weight per plant, Seeds per pod weight, 100 Seeds weight and 500 Seeds weight at $p>0.01$ and $p>0.05$ levels of significant error. This implies that only flowering percentage was found to be statistically different at $p>0.01$ and $p>0.05$ levels of significant error.

Table 1. Effects of growth responses of varieties of cowpea grown in Samaru-Kataf Campus

Varieties	Days of emergence (No)	No. of leaves	Plant heights (cm)	Flower plants (%)
Honey beans (Hb)	47.0^{b}	79.0^{b}	50.1^{b}	53^{b}
Grey-mottled (Gm)	50.4^{a}	72.0^{c}	48.4^{c}	52^{c}

CONCLUSION

Based on the results of the study, it is concluded that all the three cowpea varieties had equal chances of performance in the study area in terms of number of leaves, Plant Height, Pod dry weight per plant, Seeds per pod weight, 100 Seeds weight and 500 Seeds weight, with Black-eyed beans being the best in terms of flowering Percentage in irrigation system using cow-dug manure.

ABSTRACT

*A field trial was conducted at National Horticultural Research Institute, (NIHORT) Mbato, Okigwe, Imo State. During the late rainy season/ dry season period of 2020 to determine effective performance of sixteen pepper lines in Mbato Okigwe Southeast Nigeria. Seeds of pepper lines were sourced from NIHORT headquarters, Ibadan, Oyo State. The pepper lines are Pe12, Bird eye/8, P3/6, Ibels1, P3/23, P3/1, 21-4-1-1/1, 53-1-2/3, 59-3-1-1/1, Egu15, 06-2/3, 34-1-2-1, 27-2-1-3/4, 21-4-1-5/red, 017-1-2 and 06-12/1. The pepper seeds were sown in nursery trays in the screen house at NIHORT- Mbato Okigwe and transplanted on prepared ridges at a distance of 0.5m*0.5m spacing. Basal application of poultry manure was applied to boost the soil nutrients. Manual weeding was done twice during the trial. Also insecticide (attacké) was applied at four, six, and eight weeks after transplanting to control insect pest attack. Data were collected on growth and yield parameters. The data collected were analyzed by computing and comparing the means. The result obtained shows that line pe12 gave the highest mean plant height 81.5cm while Bird eye/red recorded the highest mean of number of leaves and canopy spread 35.75 and 66.75(cm) respectively. Line 0612/1 had the highest leaf area of .675cm2 followed by p3/6 .625cm2. However, Bird eye/8 recorded the highest mean number of fruits of 189/plant with average weight of 360g. Followed by Pe12 which recorded average number of 175.5/plant with mean weight of 350g. In terms of early flowering and fruiting, pe12 and Ibel1 are preferred while bird eye/8, pe12, p3/6, 07-1-2 and Ibels are preferred and recommended in terms of adaptation to Mbato Okigwe environment.*

INTRODUCTION

Pepper (*Capsicum frutescens*) is an important crop grown all over the world with 235,000 metric tons produced from 27,500 hectares of land (FAO, 2003). It is among the most commonly grown crops throughout Africa because of its utilization in soup, stews and salads (Adeyemi, and Ogunsola, 2017). Hot Pepper (*Capscum spp.*) is widely acceptable from the tropical to temperate environment (Adetula and Olakojo, 2006). It is a good source of vitamins and minerals, especially on iron and phosphorus (Salau,2015). It is also used as coloring condiments and flavors. In spite of high nutritional and economic value the average yield of pepper in Africa is still very low. Production of pepper is often reduced by both biotic and a biotic stress, the types of which can vary greatly among region (Barchenger, *et al.,* 2018). Again, high-yield and disease-resistant varieties are one of the most effective ways for farmers to increase productivity. Lines of pepper differ in the extent of their performance and predictable performance such as acceptability, fruit shape, size, heat, and flavors, which are critically important for adoption, benefits farmers and seed producer (Nwosu *et al*., 2019). Consequently, fresh lines are evaluated to assess adaption/ survivability, agronomic performance, yield and phenotypic correlations. In order to identify those lines which, have potential as new cultivars or as parents in localized breeding programs. Thus, the aim of this study was to evaluate sixteen pepper lines at NIHORT Mbato Experimental site, Okigwe, Imo State.

MATERIALS AND METHODS

Sixteen (16) pepper lines was brought from National Horticultural Research Institute (NIHORT), Ibadan for evaluation at the experimental site of National Horticultural Research Institute (NIHORT), Mbato Okigwe, Imo State during late rainy season/ dry season period. The pepper lines are Pe12, Bird eye/8, P3/6, Ibels1, P3/23, P3/1, 21-4-1-1/1, 53-1-2/3, 59-3-1-1/1, Egu15, 06-2/3, 34-1-2-1, 27-2-1-3/4, 21-4-1-5/red, 017-1-2 and 06-12/1. The pepper seeds were sown in nursery trays on 3rd July 2020 in the screen house at NIHORT- Mbato Okigwe. These pepper lines were transplanted on 3rd Sept.2020 (i.e. eight weeks in the nursery) on prepared ridges at a distance of .5m*.5m or 50cm apart. After three weeks of transplanting, basal application of poultry manure was applied to boost the soil nutrients. Manual weeding was done twice during the trial. Also insecticide (attacké) was applied at four, six, and eight weeks after transplanting to control insect pest attack. Mulching was done earlier to enable the plots retain moisture because of the dry season effect. Pre soil samples were collected, processed and analyzed. The site was well drained, non graveled soil but characteristically poor in nutrient concentration. The soil texture was sandy loamy (743g/kg sand, 155g/kg silt. 122g/kg clay) characterized by low organic matter, low CEC and are highly leached with soil pH of 4.76. The soil is low in total Nitrogen (0.90g/kg), Available Phosphorus (6.80 mg/kg), organic Carbon (1.56g/kg), Calcium (3.20 cmol/kg), Potassium (0.90 cmol/kg) and Magnesium (1.60 cmol/kg). Despite the cultural practices maintained in the field, die back of some lines like Ibels1, P3/1, Egu15, 34-1-2-1 and 27-2-1-3/4 were observed. Data were collected on percentage rate of germination, plant height (cm), average number of leaves(cm), leaf area (cm2), number of branches(cm), canopy spread(cm), date of both 50%&100% flowering, number of fruits/plant and weight (g)of the fruits/plant. The data collected were analyzed by computing and comparing the means.

RESULTS AND DISCUSSION

The results in table 1 shows that line Pe12 gave the highest mean plant height of 81.5cm while Bird eye/red recorded the highest mean number of leaves and canopy spread of 35.75 and 66.75cm, respectively. Line 0612/1 had the highest leaf area followed p3/6. This trend of results in the pepper lines shows that some of the pepper lines have some adaptable traits in our environment and these traits are crucial components of a plant species, ecological and carbon gain strategies (Nwosu *et al*., 2016). This is because height is a major determinant of a plant's ability to complete for light and also ensures that a species live, grows and reproduces (Faster and Westoby 2003). However, results obtained from table 2 shows that Bird eye/red recorded the highest average number of fruits (189/plant) with average weight of 360g. This was followed by Pe12 which recorded average number of 175.5/plant with mean weight of 350g. P3/6 had mean number of 98.5 with weight of 310g, 017-1-2 had 97/plant with mean weight of 310g, Ibels1; 67.75/plant with mean weight of 240g; while, line 34-1-2-1 and 59-1-1/1 had the lowest number of mean yield and weight of 32.5/plant, 160g, and 30.75/plant, 150g respectively. The differences in performance of the pepper lines on growth and yield parameters measured is an indication that lines of pepper differ in the extent of their performance which are critically important for adoption (Kahan *et al*., 2013). These differences in performance is important to help identify those lines which have potential as new cultivars or as parents in localized breeding programs (Barchenger *et al*., 2018).

ABSTRACT

Evaluation of pre-commercial hybrids in a germplasm bank is essential for determining its commercial potential and utility as progenitor in okra breeding programme of the National Horticultural Research Institute (NIHORT), Ibadan, Nigeria. The aim of the study was to assess phenotypic divergence and the *per se* performance of selected okra hybrids from the okra breeding programme of NIHORT. Eight okra genotypes were crossed in diallel mating design without reciprocals. Six hybrids and their parental genotypes that gave enough seeds for field trial were however, selected for evaluation in the growing season of 2019 in a randomized complete block design with three replications at National Horticultural Research Institute (NIHORT), Ibadan, Nigeria. Okra fruit yield, growth related parameters and other agronomic traits were measured. Results from Analysis of variance (ANOVA) showed highly significant differences ($P < 0.001$) among the parents and hybrids for all measured traits. The cross NHOK0182/NHOK0190 had the highest yield (152 kg ha^{-1}) above the trial mean. Plant height and number of fruits, ($r = 0.40$; 0.55 respectively) had positive correlations with okra fruit yield for the hybrids. This indicates that selection of these traits would be positive indices for improved okra fruit yield. The study concluded that NHOK0182/NHOK0190 attained the earliest days to first flowering, 50 % flowering and highest fruit weight. This hybrid could be a putative parent in breeding for earliness and increase yield. Further improvement and evaluation need to be carried out on the potential of hybrid NHOK0182/NHOK0190 other desirable traits before recommendation and release to farmers.

Key words: Diallel, hybrids, genetic divergence, *per se* performance, traits

INTRODUCTION

Okra, commonly known as lady finger [*Abelmoschus esculentus* (L.) Moench] is a warm-season annual herbaceous vegetable crop grown primarily for immature fruits. It is also an economically important vegetable crop grown in tropical and sub-tropical parts of the world. Okra belongs to the family Malvaceae, indigenous to tropical countries and grow all over West Africa (Schippers, 2000). It is apparently originated in Ethiopia, the mountainous area of Eritrea (Aladele *et al*., 2008). In Nigeria, it is being ranked third fruity vegetable in terms of consumption and production area following tomato and pepper (Ibeawuchi, 2007). Okra is primarily suitable for cultivation as a garden crop as well as on large commercial farms. West African okra is of economic importance because of its nutritive value. The tender pod of okra at edible stage contains 88 ml water, 2.1 g protein, 0.2 fat, 8 g carbohydrate, 36 calories, 1.7 fibre, 175.2 mg minerals and 232.72 mg vitamin in 100 g of edible portion (Berry *et al*., 1988). Most of the West African okra germplasms available in Nigeria are photoperiod sensitive (Ariyo, 1993). Flowering is prolonged as long as the day length remains short. They are grown during the dry season in the rainfed island ecosystem.

High degree of wide morphological variation exists among okra accessions. However, genetic variability is important in breeding programs for the development of high yielding varieties. The value of germplasm collection depends not only on the number of accessions it contains, but also upon the diversity present in those accessions. Characterization of genetic diversity in okra germplasm is essential in parental selection before hybridization. Diversity based on phenotypic and morphological characters usually varies with environments and evaluation of traits requires growing the plants to full maturity prior to identification. Precise and reliable identification of important plant varieties is essential in Agriculture and plant breeding purposes (Weising *et al*., 2005). Crosses between parents with maximum genetic divergence are likely to produce desirable segregation and recombination in their progeny (Reddy, 1988). Grain yield, being a quantitatively inherited trait, requires an approach of selecting plant characteristics that have significant correlations with yield. Correlation analysis is a handy technique in inter-relationship studies of agronomic traits for the identification of selection index for yield improvement in okra (Arshad *et al.*, 2006).

There is need to focus on the development of indigenously bred okra genotypes adaptable to Nigeria agro-ecologies. The objective of this study was to evaluate pre-commercial okra hybrids for the agronomic *per se* performance for further improvement, selection and commercialization.

MATERIALS AND METHODS

Eight varieties of okra were collected from the gene bank of the National Horticultural Research Institute (NIHORT), Ibadan (Table 1). The experiment was conducted at the screen house in December 2018 and on the field between June - August 2019 both at NIHORT Ibadan, Oyo State, rain forest zone (3^0 56' E, 7^0 33' N; 168m above sea level). The parental genotypes were crossed in all possible combination using diallel mating design with no reciprocal to give 28 direct F1 hybrids. Four full diallel were selected from the 8 x 8 and were evaluated because they had enough seeds needed for field trial. Therefore, 6 direct F_1 hybrids and the 4 parental genotypes giving 10 treatments were evaluated using the randomized complete block design with three replications. the treatments were evaluated on the field using a Randomized complete block design with three replications on a 2-row plot size of 2m x 0.75m. Cultural activities were carried out as when due. Data were collected on five plants withing the plot to eliminate border effect.

RESULTS AND DISCUSSION

The analysis of variance (ANOVA) for the hybrids revealed significant differences ($P < 0.001$) for some of the measured agronomic parameters except for fruit length and width, number of fruits, seed weight and yield (Table 2). Development of superior okra genotypes for desirable traits depend on the amount of variation for the trait existing in the parents (Mohammed *et al*., 2012). From this study, the hybrid of NHOK0182/NHOK0190 were the earliest to flower with average mean yield of 152 kgha^{-1} which was above the mean yield of 112kgha^{-1} for the trial.

Earliness is an important and desirable trait especially now that climate change is a strong limitation to agricultural productivity. Hybrid of NHOK0182/NHOK0190 and NHOK0188/NHOK0190 were the earliest to flower with the mean flowering day of 50 days after planting (Table 3).

Correlation is a measure of relatedness among characters and it plays an important role in crop improvement because of its effectiveness during selection (Afangideh *et al*., 2005; Falconer and Mackay, 1996). Significant positive and negative correlations were observed among the measured parameters (Table 4). The implication of this is that some parameters can be directly selected on while some more difficult to measure can be indirectly selected for when setting up selection criteria. From this study, a strong significant negative correlation was observed between days to first flower and yield (r=-0.36). This suggests that selection based on early maturity may result into lower fruit yield and light fruit weight. This result agrees with the reports of Adiger et al. (2011) and Cramer and Wehner (2000).

CONCLUSION

The study revealed the importance of evaluating the okra hybrids. Okra hybrids NHOK0182/NHOK0190, NHOK0188/NHOK0195 and NHOK0182/NHOK0195 were identified in this study as potential hybrids for further testing with famers. It will be concluded that the okra line NHOK0182 have good combining ability and could be further exploited in okra improvement.

ABSTRACT

Okra (Abelmoschus spp) is an important multi-purpose vegetable crop cultivated and consumed across most tropical and temperate regions of the world. A preliminary evaluation of intra and interspecific hybrids (without reciprocals) from Abelmoschus caillei (A. Chev.) Stevels and A. esculentus (L.) Moench was undertaken to determine their performance for seed set and yield contributing traits under open field conditions. The hybrids were laid out in a randomized complete design and data collected on ten quantitative traits. Significant variation was recorded for most traits except for pedicel length. Varying level of seed set was recorded for all the hybrid combinations with the lowest seed set per fruit recorded among the interspecific hybrid groups. The exhibition of seed viability among all the hybrid combinations even though with varying levels of seed set per fruit indicates the feasibility of improving the two okra species (A. esculentus and A. caillei) through interspecific hybridization. Furthermore, the presence of adequate variability among the hybrids for considered traits shows the possibility of identify promising segregants with best combination of desired traits from the A. esculentus and A. caillei species.

Key words: Okra, crossability, Hybridization, Inter-specific, Intra-specific

INTRODUCTION

Interspecific hybridization is considered a possible mechanism of plant diversification. Hybridization including wild and cultivated species has long been used for transfer of genetic material in crops (Mujeeb-Kazi and Rajaram, 2002). Wild relatives of crops have been recognized as an important source of useful traits for breeding programmes in okra (Udengwu, 2015). On the other hand, identification, harnessing and introgression of alleles associated with biotic and abiotic tolerance through interspecific hybridization between crop species has led to improved genetic gains in pest, disease, nutrient and yield levels of cultivated crops in recent times (Mogili et al., 2013). Interspecific hybridization among locally adapted cultivars and newly selected okra wild relatives harboring desired genes of interest may therefore play a very important role in producing broad-based segregating population from which recurrent selection could be carried out (Hamon and Hamon, 1991). New segregants combining high yield potential with pest and disease resistance of the *A. caillei* and earliness of *A. esculentus* that are of interest to all stakeholders along the okra value chain could be selected from segregating interspecific breeding populations. However, it is noteworthy that the F_1 seeds obtained from most interspecific crosses between *A. esculentus* and *A. caillei* produced hybrid seeds with strongly reduced fertility (Fatokun et al., 1979). The sterility is usually related to chromosomal/genomic differences leading to irregular gamete formation. Various studies have revealed that it is relatively easy to obtain F_1 plantlets irrespective of direction of crossing in some interspecific hybridization but in some cases F_1 plants were highly sterile limiting advancement to subsequent generations or even to obtain backcrosses. Fatokun et al. (1979) identified that when they carried out crosses between members of the two groups (*A. Caillei* and *A. esculentus*), the F_1 progenies were sterile with fruits bearing less than ten well developed seeds as against an average of 60 seeds in normal fruits. Furthermore, percentage germination of the seeds ranged from 4 to 18%. Other reports have highlighted that much input has for long been concentrated on the genetic improvement of *A. esculentus* in both developing and developed countries of the world, with minimal attention directed to the *A. caillei* (West African okra) despite the fact that it contains many desirable traits not found in *A. esculentus* (Singh and Bhatnager, 1976; Martin et al., 1981). This study seeks to investigate the agronomic performance and viability of F_1 hybrids from intra and interspecific hybridization among two okra species.

MATERIALS AND METHODS

The experiment was conducted at the experimental field of National Horticultural Research Institute (NIHORT), Ibadan during the 2020 early (April to July) and late (September to December) planting seasons. Establishment of crossing blocks and crossing activities were carried out during the early planting seasons while evaluation of the F_1 hybrids and their parents under field conditions was carried out during the late season planting.

Genetic materials evaluated in this study comprised of newly developed F_1 hybrids (Interspecific without reciprocals and backcross) and their parents (Table 1). The genetic materials were grown in Randomized Complete Block Design with two replicates during the late planting seasons of 2020. Three seeds per hill were planted directly in 3cm holes and later thinned to two plant per hill after seedling establishment. Plants were spaced at 60 cm x 50 cm between and within rows respectively on a 2 x 1m bed constituting 10 stands per plot. Regular plant protection and other agronomic activities were carried out as when due to ensure full expression of desired traits and safeguard crop from pests. Manual weeding was done at three weeks after planting, while compound fertilizer NPK 15:15:15 was applied at three-week interval after sowing to enhance vegetative growth at the recommended rate of 60 kg/ha. Insect pest control was done by spraying Cyperfits (synthetic pyrethrum) at the rate of 80 g ai/ha.

Data on agronomic attributes were recorded on plot basis according to okra descriptors by Charrier (1984) for days to 50% flowering (DTF), plant height at maturity (cm) (PH), matured fruit width (FW) and length (cm) (FL), average number of fruits (NoF) obtained by the ratio between the total number of fruits and the number of plants in the plot, internode length (cm) (INL) and number of ridges per pod (NoR).

RESULTS

High level of diversity was observed among the studied hybrids and their parents for most of the traits considered. The analysis of variance (Table 2) revealed varying levels of significance among genotypes for all traits except for pedicel length. The ranges of mean revealed sufficient variation for all the traits under study. Maximum range of variability was observed for average number of seeds per pod (7.5-100.5) while the minimum range was recorded for average number of branches per plant (0-3). Ik11 and MB1 x NH47-4 were the earliest to flower at 46 and 47 days respectively while highest number of fruits per plant was recorded for NHCaP3/22 and NHCaP3/22 x IwoNla (6 fruits). Highest stem cross section was observed for MB1 x IwoNla (30.88 cm) while the maximum plant height and fruit length was expressed by NHCaP3/22 x MB1 (77.75 cm) and NHCaP3/22 (12,93cm) respectively. Seed set was observed for all hybrid combinations even though it was minimal with the interspecific hybrids (Table 2). The highest number of seeds per fruit was recorded for NHCaP3/22 (40 seeds) and MB1 (100.50 seeds) for the *A. caillei* and *A. esculentus* parents respectively while Ladyfinger x IwoNla (48.67 seeds) and MB1 x IwoNla (70.5 seeds) had the highest seed set for the inter and intra specific hybrids respectively (Table 2). The least seed set was recorded for hybrids NHCaP3/22 x NH47-4 and NH47-4 x IK11 for the inter and intra specific hybrid combinations respectively.

DISCUSSIONS

The high significant differences observed for most traits indicates the abundant genotypic differences between hybrids and parents which manifested phenotypically. This is in line with the reports of Udengwu (2009) on the availability of high variability among interspecific okra hybrids and their parent in Nigeria. The presence of adequate variability among the genotypes for considered traits shows the feasibility of identify promising segregants with best combination of desired traits from the *A. esculentus* and *A. caillei* species. This could be exploited by okra breeders to FastTrack the incorporation of the heritable traits identified in this study towards development of new resilient okra varieties adaptable to the diverse okra growing regions in Nigeria. Advancing materials from NH47-4 x IwoNla, Ladyfinger x NHCaP3/22, NHCaP3/22 x MB1 and Ladyfinger x NH47-4 might produce promising early maturing progenies with longer fruit length while CaP3/22 x IwoNla, Ladyfinger x NHCaP3/22 and NH47-4 x IwoNla are likely to produce progenies with increased number of fruits per plant.

Different levels of seed set recorded for most hybrid combinations and their parents is a good indication that selection in favour of viable hybrids is feasible from this study. The minimal number of seeds per pod observed among the interspecific hybrids compared to intraspecific hybrids from the *A. esculentus* might be a reflection of some degree of incompatibility between the two species. This supports the reports of Fatokun et al., 1979 and David et al., 2016 who reported poor seed set among interspecific hybrids compared to intra specific hybrids from *A. esculentus* species in Nigeria and Ghana.

Top performing F_1 families for plant height (NHCaP3/22 x MB1, Ladyfinger x NH47-4, NHCaP3/22 x IwoNla) and F_1 hybrids (MB1 x IwoNla, NHCaP3/22 x MB1, Ladyfinger x MB1) with increased stem cross section are good candidates for developing segregating populations with tall plant architecture that are tolerant to lodging. Furthermore, hybrid combination Ladyfinger x IwoNla with highest seed set among the interspecific hybrid group are good candidates for advancement to F_2 generation for further selection to identify promising viable segregants with best combinations of desired traits from the two okra species.

THE GROWTH AND FIELD SEEDLING ESTABLISHMENT OF TEA (*CAMELLIA SINENSIS* (L) O. Kuntze) AS INFLUENCED BY ITS INTERCROP WITH PLANTAIN IN IBADAN, NIGERIA

Adeosun, S.A., Famaye, A.O., Adejobi, K.B., Ugioro, O. and Adeleke, S.A.

Cocoa Research Institute of Nigeria P.M.B. 5244 Ibadan, Nigeria

ABSTRACT

The response of two tea cultivars (143 and 318) to their intercrop with plantain at three planting densities: 1111 plantain/ha (Tea/1111 Plantain), 2222 plantain/ha (Tea/2222 Plantain) and 0 plantain/ha (Tea sole) was evaluated on the field in Cocoa Research Institute of Nigeria, Ibadan. The experiment was laid out in Randomized complete block design arranged in Split-Plots with four replications. Data on Number of Leaves (NL), Number of Branches (NB), Leaf area (LA, cm^2) and Survival Count (SC, %) were obtained from the experiment. The data were analyzed with ANOVA at $\alpha_{0.05}$. Cultivar 143 was significantly superior to cultivar 318 in NL, NB, LA and SC. Tea/2222 Plantain increased NL, NB and LA by 26.6, 57.8 and 179.9%, respectively in comparison with Tea/1111 Plantain, and by 202.1, 228.0 and 2363.7% in comparison with Tea sole. The % survival of tea was significantly higher under Tea/2222 Plantain (79.43) in comparison with Tea/1111Plantain (32.24) and Tea sole (25.74). In interaction, the highest NL and NB was produced by cultivar 143 under 1111 plantain/ha, the highest LA and SC by cultivar 143 under 2222 plantain/ha; while the least NL, NB, LA and SC were produced by cultivar 318 under 0 plantain/ha. The growth and tea seedling establishment were enhanced in C143 grown in intercrop with plantain at 2222 stands/ha.

Key words: Tea cultivars, Intercrop, Growth, Plantain, Tea seedling establishment

INTRODUCTION

Tea is the most consumed beverage worldwide owing to its anti-oxidant property. Tea beverage is obtained from the tea plant (*Camellia sinensis* (L) O. Kuntze) after infusion of its leaves in hot water. Cultivation of tea on commercial scale in Nigeria is limited to the cool Mambilla highland with limiting land area. The need to expand tea production in Nigeria necessitated the exploration of the warm lowland for tea production despite its hot climate which constitutes a major constraint to the growing of tea in the area. The growth of tea was found to be hampered when grown as sole cropping without shade (Adeosun *et al*., 2019). Tea has been reported to be a shade loving plant; its entire photosynthetic apparatus is adapted to function with maximum capacity under shade (Jannedra *et al*., 2007). However, intercropping tea with shade crops has been found to be a veritable means of ameliorating the harsh weather of the lowland in Nigeria. Intercropping is the practice of planting two or more crops simultaneously on the same piece of land (Famaye *et al*., 2017). Benefits of intercropping include: insurance against crop failure through diversification, keeping the farmer busy all year round, improving land use efficiency, increasing income accruing to the farmer as well as increasing profit per unit area of land (Famaye *et al*., 2018). Besides, since tea cannot guaranty commercial scale harvest until 3 years after field establishment, farmers can sustain on plantain harvest before tea reaches maturity with tea/plantain intercrop. Growing horticultural crops under shade plants is practiced in many tea ecologies of the world. Intercropping pigeon pea (*Cajanus cajan*) and *Glyricidia sepium* have been reported to provide shade for growing tea in Sri Lanka and Hawaii (T. R. I., 2003; Valenzuella, 2011). Plantain has been intercropped with cacao (Famaye *et al.,* 2014) and tea (Obatolu and Ipinmoroti, 2000) to provide shade for optimum growth. However, there is dearth of information on the optimum plantain density that could enhance the growth and field seedling establishment of tea in the lowland ecologies of Nigeria. Therefore, this trial was aimed at assessing the effects of tea/plantain intercrop at different plantain planting densities on growth performance and field seedling establishment of two tea cultivars in Ibadan, Southwest Nigeria.

MATERIALS AND METHODS

This field trial was carried out in Cocoa Research Institute of Nigeria (CRIN) Station, Ibadan. Ibadan, a Tropical Rain Forest is located on Latitude 07 10'E and Longitude 03 52'E. Tea clonal materials were obtained from CRIN Station in Mambilla Plateau, Taraba State. Plantain suckers were obtained from CRIN Station, Ibadan. The land was cleared of all vegetation. The trial is a 2 x 3 factorial consisting of two tea cultivars (143 and 318) and tea intercrop with three plantain densities: 1,111 plantain stands ha^{-1} (3 x 3 m planting distance) (Tea/1111 Plantain), 2,222 plantain stands ha^{-1} (3 x 1.5 m planting distance) (Tea/1111 Plantain) and

ISSN: 2814-0508

zero plantain stands ha^{-1} (Tea sole) as control. The experiment was laid out in Randomized Complete Block Design (RCBD) arranged in Split-Plots with four replications (Blocks). Each block comprised 2 main plots and 3 sub-plots: tea cultivars as main plots and plantain/tea intercrop at different planting densities as sub-plots. Each main plot consisted of 3 sub-plots of tea sole, tea intercrop with 1111 plantain ha^{-1} and tea intercrop with 2222 plantain ha^{-1}. In tea intercrop with plantain at 1111 plantain ha^{-1}, tea was planted between 2 rows of 3 plantain stands at 3 x 3 m spacing; while in tea intercrop with plantain at 2222 plantain ha^{-1}, tea was planted between 2 rows of 5 plantain stands at 3 x 1.5 m spacing. At 16 months of plantain establishment, 4 tea sprouted cuttings (clonal material) were transplanted at a spacing of 100 x 60 cm in each sub plot. The following growth parameters were measured on monthly basis: Number of leaves, Number of branches and Leaf area (cm^2); the survival counts (%) were measured at 9 Months After Transplanting (MAT). Data collected were analyzed with Analysis of Variance (ANOVA) and significant means separated with LSD (P=0.05).

RESULTS AND DISCUSSION

Tables 1, 2 and 3 show that C143 performed better than C318 in number of leaves, number of branches and leaf area. Cultivar 143 was significantly (P=0.05) superior to 318 in leaf area at 3-9 MAT, and in number of leaves and number of branches throughout the sampling periods. The better growth performance of C143 in comparison with C318 might be as a result of the fact that the former had been previously adjudged to be more vigorous in growth than the latter (CRIN, 1983). Tea/2222 plantain increased the number of leaves of tea by 13.9, 23.2, 17.7 and 25.6% at 3, 6, 9 and 12 MAT, respectively in comparison with Tea/1111 plantain, and by 24.9, 68.2, 233.6 and 202.1% at 3, 6, 9 and 12 MAT, respectively in comparison with Tea sole. The Tea/2222 Plantain enhanced the highest number of branches and leaf area and it was significantly (P=0.05) different from Tea/1111 Plantain and Tea sole, especially at 6-12 MAT. This indicates that plantain at 2222 plantain ha^{-1} provided adequate shade for tea which is necessary for its growth performance. This implies that imposition of shade on tea, a C3 plant, by plantain canopy favours tea leaf photosynthesis (Wijeratne *et al*., 2008). The tea sole had the least growth performance as it was exposed to the hot weather of the dry season which undermined its growth. When tea is grown as sole crop, it is fully exposed to the hot weather which in turn reduces its growth rate. The possible excessive rise in leaf temperature and build-up of vapour pressure gradients between the leaf and the surrounding area must have led to reduced vegetative growth of Tea sole. This corroborates the report of Famaye (2014 and 2017) which postulated better growth of cacao and coffee in intercrop with plantain and oil palm, respectively. The interactions between tea intercrop with plantain and the cultivars were significantly (P=0.05) different (Tables 1, 2 and 3). The highest number of leaves and number of branches were obtained in C143 under 1111 plantain at 3, 6 and 12 MAT; but at 9 MAT, C143 under 2222 plantain ha^{-1} had the highest number of leaves and number of branches. Moreover, C143 under Tea/1111 Plantain, C318 under Tea/2222 Plantain, C318 under Tea/1111 Plantain and C143 under Tea/2222 at 3, 6, 9 and 12 MAT, respectively had the highest leaf area. However, the least growth parameters were obtained in tea sole, especially in cultivar 318. Table 4 reveals that in field seedling establishment (Survival count), cultivar 143 was superior to 318. The highest survival counts of 82.81% was obtained in C143 under 2222 plantain ha^{-1}, followed by C318 (76.04%) under the same tea/plantain intercrop; while the least survival count was obtained in C318 under Tea sole. The C143 and C318 were not significantly (P>0.05) different in their survival counts. However, the survival of C318 was very low and significantly (P=0.05) lower than that of C143 under Tea/1111 and Tea sole. This implies that the survival of tea cultivars after the first dry season of its transplanting on the field was enhanced by their intercrop with plantain, a shade crop, and that Tea/1111 Plantain and Tea sole undermined the survival of C318. This corroborates the report that C143 tolerates harsh weather more than C318 (CRIN, 1985).

ABSTRACT

An investigation was carried out in Cocoa Research Institute of Nigeria (CRIN), Uhonmora Station, Edo State to evaluate the effect of transplanting positions of cacao (Theobroma cacao L) seedlings with plantains under field condition. Four treatments were evaluated: Plantain suckers on top of cacao seedlings at transplanting (PTCT), Cacao seedlings on top of plantain suckers at transplanting (CTPT), Cacao seedlings transplanted 30 cm apart from plantain suckers (CT30cmP) and Cacao seedlings transplanted 150 cm apart from plantain suckers (CT150cmP) as control. The experiment was arranged in Randomized Complete Block Design (RCBD) with three replications. Plantain suckers were planted at 3 x 3m spacing as shade crop while cacao seedlings (hybrid) were planted on treatment basis. The experiment was monitored for 22 months after transplanting. Data were collected on plant height, number of leaves, stem diameter, number of branches and leaf area at 3, 4, 5, 12, 13, 14 and 15 Months After Transplanting (MAT), and on Survival count (%)at 10 and 22 MAT. The data were analyzed with analysis of variance (ANOVA) as well as descriptive statistics, and significant means separated by Duncan multiple range test (P<0.05). The result showed that cacao seedlings on top of plantain (CTPT) at transplanting had the highest percentage of 91.67 and 75.00 survival count at 10 and22 MAT, respectively, closely followed by plantain on top of cacao seedlings at transplanting (89.00 % and 72.00%). When compared withCT150cmP, CTPT increased the plant height, number of leaves, stem diameter, number of branches and leaf area at 4 MAT, at 15 MAT, at 3, 13, 14, 15 MAT, at 3, 15 MAT and at 13, 14,15 MAT respectively by 1%, 10%, 61%, 2%, 3%, 8%,46%, 11%, 5%, 3% and 13%, respectively. Therefore, cacao seedlings transplanted on top of plantain was the most effective treatment for improving cacao seedling establishment and growth under field condition.

INTRODUCTION

Cocoa (*Theobroma cacao* L.) is a tropical woody species which belongs to the family Malvaceace (Alverson *et al*., 1999). Under natural condition, the tree can attain a height of 20 -25 m (Lachenaud *et al*., 1997), whereas under cultivation, plant height varies from 3 to 5 m. The geographical origin of cacao is South America (Oluwalade, 2018). It is considered as one of the most important perennial crops with an estimated world output of 4.2 million tonnes in 2018 (ICCO, 2007), while FAO (2011) reported an estimated annual yield of 3.2 million tonnes in 2009. It is cultivated in the Humid tropics of the world (Yanelis *et al.,* 2012) with more than 70% production coming from Africa as source of income for producing countries (Simo *et al*., 2018). Cocoa production is dominated by small-scale farmers who live and work in the cocoa belt providing them employment and income (Minimol *et al*., 2015; Ngoh *et al.,* 2015) Cocoa is the most prominent export crop in Nigeria in terms of its production and export capacities.

Traditionally, cacao farmers in Nigeria established their farms with plantains or other food crops, either sown directly at stake or seedlings are transplanted from the nursery in to the field (La Anyane, 1963; Benneh, 1987; Opeke, 2005). Conventionally, cacao seedlings are planted or transplanted in between the plantain suckers (Owusu-Benpah, 1988). The temporary shade provided by plantain provides direct shade to the cacao seedlings for 2 to 3 years after transplanting. Moreover, despite the provision of shade by plantain for transplanted young cacao seedlings, it is a known fact that the highest percentage of these seedlings die between the first and second dry seasons as a result of soil moisture deficit during the peak of dry seasons (Babadele, 2018). It is also established that plantains that are planted to provide shade during the dry period do shed most of their leaves as a result of limited soil moisture in order to survive (Babadele, 2018). In Nigeria, cocoa production is limited to the rainforest and savanna transition zones. Presently, the level of cocoa production stands at 350,000 tonnes per annum

(ICCO, 2015), in spite of the fact that Nigeria is endowed with vast land areas suitable for its cultivation. Adoption of good management practices can bring about increased bean production of up to 100-300% (Famuagun, 2016). According to Famuagun and Agele (2010), the major reason attributed to low productivity despite the huge effort of the government were limited access to modern production technology, limited access to input and credit facilities, low percentage of survival (less than 35%) of transplanted seedlings at the end of the second dry season due to soil moisture stress and poor field management. There are also concerns that the projected global temperature rises and subsequent increase in potential evapo-transpiration and demand for plant water may lead to further drought stress during the dry season and deterioration of cocoa climate condition (Laderach *et al*, 2013; Schroch *et al.,* 2016). To solve the above mentioned problems, more robust farm management strategies are therefore needed.

Effective management of cacao seedlings on the field using agronomic practices like dry season irrigation and optimum shading regime to enhance root development could improve plantation establishment and cacao productivity. However, research efforts that would ensure cocoa sustainable production at the early stage of establishment are seen as steps in the right direction which remains sacrosanct for the survival of young cocoa in the field and the improvement of farmers' income (Agbongiarhuoyi *et al.,* 2016). Moreover, it is a known fact that cacao cultivation in Nigeria is predominantly in the hand of peasant farmers who cannot afford irrigation facilities. Due to climate change, rainfall and humidity have been on a decline progressively since mid-1970s (Omotosho *et al.*, 2000), while global warming has been on steady increase. Given the increasing global demand for cocoa and quest for obtaining sustainable production systems, it is imperative to understand the effects of some agronomic practices on the responses of cacao seedlings to dry season environmental conditions especially the hydrothermal stresses (Daymond and Hardley,2004). Improved insights would be valuable towards the attainment of optimum seedlings establishment and vigor on the field (Famuagun and Agele, 2019). Much of success of intercrops in cacao establishment depends on understanding the role each component plays in the system: cacao/plantain farming system has been recommended, but the transplanting arrangement in the face of global warming and climate change is a gap in research. Therefore, the objective of this work was to evaluate effect of different planting positions of cacao and plantain on survival and morphological growth of cacao on the field.

MATERIALS AND METHODS

Study area

Field experiment was carried out at the experimental farm of Cocoa Research Institute of Nigeria (CRIN), Uhonmora Station in Edo State between 2018 and 2020 covering two consecutive rainy seasons and two dry seasons. The location, a derived savanna zone of Nigeria, lies on latitude 6'5N and longitude 5'50'E. The rain fall is between 1000 – 1500 mm per annum. The maximum temperature ranges between 26 to 35 ^{0}C with an average of about 30 ^{0}C while minimum temperature ranges from 15 to 25^{0}C with an average of 20 ^{0}C. Relative humidity is high during the raining season, ranges from 50 to 85 % with an average of 75%. There are seasonal variations in the values of relative humidity, which varies from 65 to 89% during the rainy season and 46 – 70 % during the dry season. The rainy season which runs from April to October is characterized by heavy rains, low ambient temperature and high humidity; while the dry season runs from November to March and is characterized by little or no rain, high ambient temperature and very low humidity.

Acquisition and preparation of experimental materials

Seedlings of hybrid CRIN TC genotype were collected from CRIN, Uhonmora nursery, while plantain suckers were collected from experimental plots in the station. Experimental plot of 50 by 30 m was mapped out and the experiment was laid out in rows of 3 x 3 m.

Treatments and experimental design.

The field experiment comprised four treatments (four different transplanting positions of cacao seedlings and plantain suckers):Plantain suckers on top of cacao seedlings at transplanting (PTCT), Cacao seedlings on top of plantain suckers at transplanting (CTPT), and Cacao seedlings transplanted 30 cm (between 2 plantain stands) apart from plantain suckers at transplanting (CT30cmP) and Cacao seedlings transplanted 150 cm (between 2 plantain stands) apart from plantain suckers at transplanting (CT150cmP) as control. The experimentwas laid in Randomized Complete Block Design (RCBD) with three replications. Layout of the experimental site (Measurement,

ISSN: 2814-0508

pegging, and holing) was carried out. One hundred and forty-four (144) plantain suckers were planted at 3 x 3m spacing as shade crop. The same number of five months old cacao seedlings (Hybrid) of average height of 50 cm (raised in the nursery) were transplanted on treatment basis. The experiment was monitored for 22 months after transplanting (MAT).

Data collection

Data collected included growth parameters of cacao seedlings (Plant height, Number of leaves, Stem diameter, Leaf area, Number of branches) and their Survival counts. The growth parameters were taken on monthly basis for 22 months commencing from 3 months after transplanting (3MAT). Plant height (cm)was measured using a meter rule from the ground surface to the tip of the main stem. Stem diameter (cm) was measured with Vernier Caliper 30 cm above the ground level. Number of leaves, Number of branches and Survival count were determined by visual count. Leaf area was also measured. The growth parameters were taken monthly for 22 months commencing from 3 MAT. Survival counts were carried out at 10 and 22 MAT. Data collected were subjected to statistical analysis using analysis of variance (ANOVA) as well as descriptive statistics, and significant means were separated by Duncan Multiple Range Test (DMRT) ($P<0.05$)

RESULTS AND DISCUSSION

Effects of transplanting positions of cacao seedlings on survival count are represented in Figure 1. Cacao seedlings on top of plantain suckers at transplanting (CTPT) and Plantain suckers on top of cacao seedlings at transplanting (PTCT) significantly ($P<0.05$) enhanced the survival count of cacao seedlings relative to other treatments at 10 and 22 MAT, while cacao seedlings on top of plantain at transplanting gave the highest survival count in both 10 and 22 MAT (Figure 1). The highest seedlings survival count recorded in 10 and 22 MAT under Cacao seedlings on top of plantain suckers at transplanting (CTPT) could be as a result of commensalism relationship between the transplanted cacao seedlings on top of the plantain suckers in which both shared the same environment and the cacao benefitted from the water and cooler weather around the biosphere especially during the dry season, yet the plantain was not adversely affected. The relationship is called table fellowship. This result also confirmed that the survival of transplanted cacao seedlings did not depend on the spacing adopted but the arrangement of cacao with the plantain. This result was corroborated by Ayegboyin *et al*. (2020), Famuagun and Agele (2019) who reported that the reduction in stand mortality under moderate and dense shaded plots was traced to improved microclimate conditions occasioned by shade plants that aided reduced air and soil temperature, reduced moisture loss through evaporation and increased activities of microbial organism under shaded microclimate. It was also observed that the same CTPT treatment had the lowest percentage mortality rate of 18% after the end of the first dry season; this was closely followed by PTCT (19%) (Figure 1).

Effect of transplanting position of cacao seedlings on growth parameters of cacao seedlings is presented in tables 1 -5. The CTPT also gave the highest plant height, number of leaves, stem diameter, number of branches and leaf area at 4 MAT, at 15 MAT, at 13, 14, 15 MAT, at 15 MAT and 15 MAT, respectively. When compared with the conventional transplanting of cacao seedlings in between the plantains (CT150cmP), CTPT increased the plant height, number of leaves, stem diameter, number of branches and leaf area at 4 MAT, at15 MAT, at 3, 13, 14, 15 MAT, at 3, 15 MAT and at 13, 14,15 MAT respectively by 1%, 10%, 61%, 2%, 3%, 8%,46%, 11%, 5%, 3% and 13% respectively; while CT150cmP treatment significantly enhanced cacao seedlings, number of leaves, number of branches and leaf area at 4 MAT, 4 and 13 MAT, 3, 4,5 MAT, respectively, when compared with the other treatments. This finding could be due to the fact that the cacao seedlings which could have been suppressed by plantain shade were not directly positioned under the plantain suckers but in between which is 150cm apart. This discovery is in agreement with the reports of Famaye *et al*. (2003) that, due to the competition that exists among them, closely spaced cacao seedlings produced smaller morphological parameters than well-spaced ones. Shipat (2001) as well as Famuagun and Agele (2016) also established that the leaves and circumference of plants are among the main factors that determine the vigour needed for the growth of cacao seedlings after transplanting.

CONCLUSION AND RECOMMENDATION

Much of success of intercrops in cacao establishment depends on understanding the role each component plays in the system, cacao/plantain farming system has been recommended, but the transplanting arrangement in the face of global warming and climate change is a gap in research which this work has filled. Furthermore, the long dry season and the wind – storms early March to April in the study area usually devastate the plantains so that effective shade is not actually provided for the cacao in the later part of the dry season when the shade is needed most. According to this work, Cacao transplanting on top of plantain (CTPT) enhanced the best performance of cacao seedlings when compared to other treatments because cacao seedlings would have benefited from the soil moisture available at the base of plantain for survival and morphological growth.

ABSTRACT

A field experiment on intercropping as alley cropping on cashew plantation was conducted at Cocoa Research Institute of Nigeria sub-station Ochaja, Kogi state to evaluate the impact of manure, yield and canopy development on cashew plant. Treatments consisted of intercrops of Bambara, Sesame and manuring using pelletizer fertilizer applied at the rate of 0, 4.84kg/plot and 9.68kg/plot to the soil of the intercrops under the cashew alley. The two-year field experiment was laid out at 6m x 6m in a split plot design with three replications. Data collected includes crown diameter, canopy spread, canopy North-South/East-West direction, canopy volume, canopy radius, canopy ground cover, while the cashew yield attributes are numbers of nut, nut weight, nut length, nut width, nut thickness and nut yield per plot. The results showed that cashew growth characters were influenced by alley crops of Sesame and Bambara nut, not only by improving the yield but also enhance vigorous growth and canopy development of the plants. The study also showed that intercropping with a combination of both Bambara + Sesame and the application of pelletized fertilizer of 9.68kg/plot proved to have the highest cashew yield among the treatments adopted. Cashew tree / crop intercropping in young cashew plantations in this study is an effective measure to increase growth, economic income and yield to the farmers at the early stage of its establishment.

Key words: *Bambara, Cashew, canopy, sesame, intercropping, fertilizer*

INTRODUCTION

Intercropping tree crops during the establishment phase with food crops is an age-long practice in the tropics. The benefits of such a practice includes food security for the household, income generation to partially offset the cost of establishment, weed control, and better use of growth resources (Rodrigo *et al*., 2001; Opoku-Ameyaw *et al*., 2003). Cashew is known to be commonly intercropped with arable crops in Nigeria. Results from intercropping studies indicate that increased crop diversity may increase the number of ecosystem services provided. Higher species richness may be associated with nutrient cycling characteristics that often can regulate soil fertility (Russell, 2002), and limit nutrient leaching losses (Hauggaard-Nielsen *et al*., 2003), by also maintaining their own soil fertility, regulating natural protection against pests, and sustaining productivity (Thrupp, 2002; Scherr and McNeely, 2008). Growing of crops simultaneously also enhances the abundance of predators and parasite which in turn prevent pests build up and minimized the usage of expensive and chemical weed control measures according to Lithourgidies *et al.,* (2011). One of the opportunities growing Cashew brings, especially during the early phase of its establishment is that it has the potential to accommodate intercrops due to the wide plant spacing associated in its cultivation (Carr *et al*., 2014). Planting density and tree canopy have a direct impact on the yield of tree crops (Nayak, 2019). The growth style of perennial trees determines the subsequent architecture of the tree and in cashew tree canopy volume is vital because it shows the bearing area, decides the tree spacing and population density per unit area (Ona *et al*., 2017). The cashew tree develops dome shaped canopy very fast having its foliage on the outside where flowers and fruits are found. Canopy growth pattern is a major factor that decides how fast a cashew tree can enter its economic production phase (Tolla 2004). The present study is proposed to improve understanding of compatibility of cashew with some selected arable, with respect to canopy development and yield enhancement.

MATERIALS AND METHODS

Experiments were conducted at the experimental farm of Cocoa Research Institute of Nigeria (CRIN) Sub-Station Ochaja (Latitude 7°46'N - 7°52' and longitudes 6°38'E – 6°48') Kogi State in the Southern Guinea Savanna Agro-ecological zone of Nigeria. The experiment was conducted within an already established three-year-old young cashew plantation. The cashew genotype in the plot was jumbo which was planted 6m x 6m and replicated three times. Thirty-six cashew trees with border plots were used for intercropping of bambara and sesame as alley crops and fertilized with pelletized fertilizer at the rate of 0, 4.84kg/plot and 9.68kg/plot per plot respectively fitted in a split plot and arranged in a complete randomized block design. All management practised were adopted uniformly. Data collected on cashew vegetative growth parameters includes plant height and trunk girth. Data relating to canopy measurement includes crown diameter, canopy spread, canopy North-South/East-West direction, canopy volume, canopy radius canopy ground cover, while the cashew yield attributes are numbers of nut, nut weight, nut length, nut width, nut thickness and nut yield per plot. Data collected was subjected to statistical analysis using SAS (version 9.4, 2011) Analysis of variance (ANOVA Procedure) was done using the PROC GLM procedure in SAS and mean were separated for significance with Tukey's Studentized RangeTest (HSD) at 5% ($P \leq 0.05$) probability level.

RESULTS AND DISCUSSION

Fruit trees like cashew are considered to have a positive influence on the soil nutrient content because of its tap root system. Bambara and Sesame are also characterized by a tap root system, which absorb waters and nutrients from deep soil layers. The results showed in table 1 was a variation between the use of Bambara nuts and sesame plants planted alone the cashew alley because the Bambara variety TVSu1166 with the application of pelletized organic fertilizer was highest in vegetative growth and canopy development compared to those of the sesame varieties. TVSu1166 Bambara variety planted in the cashew alley significantly influences, Girth and the canopy characters of canopy East - West, North - South, crown diameter, canopy spread, canopy radius, canopy ground cover, while the highest Height measured was recorded with the TVSu999 intercrop. According to Toschi *et. al*. (1993) cashew being a perennial and evergreen in nature with large canopies, can grow to about 10 to 12 meters in height. Similarly, in table 2 the effects of 9.68kg fertilizer was significantly different from 4.84kg in all the measured parameters. The pelletized fertilizer after decomposition resulted in different varietal responses to manuring. Similar observation was made by Ojeniyi *et al*. (2007), MoyinJesu (2007) in their report on manure and fertilizer application as a measure of plant vigor promotion and nutrient enhancement status. On the other hand, Xavier *et al.* (2013) reported that associating legumes with cashew plants reduces weed and herbicides usage, apart from increasing soil carbon, organic matter, and nutrient content. These increases in growth observed in this experiment could be due to the nitrogen fixing nature of Bambara which influenced cashew tree vegetative growth (Esteban, 2001) reposed.

The cashew yield per tree and features of nut characteristics as shown in table 3 *viz.*, number of nuts, weight, length, width, thickness, and nut yield shows that nut length, width and thickness of cashew nuts are highly variable characters depending on their size and age of the cashew plants. However, contrary to the growth pattern observed in this study, the application of manure to the intercrops had no significant influence on cashew yield and its attribute as showed in Table 3 but a higher value of the study parameters was obtained when fertilizers of higher dosages of 9.68kg was applied compared to the control plots. Similar observation was reported by Rathna and Swain (2006) and Pawar *et al.* (2009) works on mango intercropping.

CONCLUSION

Manuring exerted significant effects on cashew growth characters, canopy structure and yield in the presence of alley crops of Sesame and Bambara nut. The application of 4.84 and 9.68 kg/plot pelletized fertilizer enhanced cashew growth character, canopy structure and yield compared with un-manure plot. The interaction between Sesame and Bambara was positive to cashew growth, canopy development and yield. However, to encourage organic agriculture, Pelletized manure should be considered as a valuable fertilizer and can serve as a suitable alternative to chemical fertilizer (NPK). However, other organic fertilizer should be researched on other intercrops planted at cashew alley. While the residual effect of these fertilizers incorporated into the soil before planting and on contrasting environments is recommended for future validations.

ABSTRACT

Usually about two-thirds of the nitrogen fixed by a legume becomes available the next growing season after a legume in a rotation. The objective of this study was therefore to determine the growth and yield of okra planted after the legumes. The experiment was conducted at the Vegetable Research Farm, National Horticultural Research Institute (NIHORT), Ibadan, Oyo state. Legumes comprising cowpea, soybean, bambara nut and groundnut were planted at spacing of 60 cm x 30 cm (55,555 plats/ha), 45 cm x 30 cm (74,074 plants/ha), and 30 cm x 30 cm (111,111 plants/ha). The legumes were incorporated into the soil after harvest during land preparation for okra planting. Seeds of okra (NHAe 47-4) obtained from NIHORT was planted at a spacing of 50 cm x 50 cm. Five plants were randomly selected and tagged for data collection on growth and yield parameters. Data collected were subjected to analysis of variance (ANOVA) and significant means were separated using the Duncan Multiple Range Test (DMRT) ($P \leq 0.05$). Results showed that total nitrogen of soil planted with soybean at 55,555 plants/ha was significantly higher (0.32 mg/kg). The residual effect of different legumes planted at varying population significantly affected growth, fruit yield and yield components of okra. Okra planted on plots previously cropped with cowpea at 74,074 plants/ha had significantly higher fruit yield (1.08 t/ha). It can then be concluded that planting cowpea at spacing of 45 cm × 30 cm (74,074 plants/ha) significantly increased yield of okra.

Key words: Okra, growth, year, sequential cropping system

INTRODUCTION

Sequential Cropping is a form of multiple cropping in which crops are grown in sequence on the same field with the succeeding crop planted after the preceding crop is harvested. Global population will hit 9.6 billion people by 2050 (United Nations, 2013) and will face global challenges among which achieving food security, lowering the risk of climate change by reducing the net release of greenhouse gases into the atmosphere and meeting the increasing demand for energy will be most critical. To meet these challenges, a policy framework needs to be developed in which the sustainability of production/ consumption patterns becomes central. In this context, food legumes and legume-inclusive production systems can play important roles by delivering multiple services in line with sustainability principles. Indeed, legumes play central roles: (1) at food-system level, both for human and animal consumption, as a source of plant proteins and with an increasingly importance in improving humans' health (Tharanathan and Mahadevamma, 2003); (2) at production-system level, due to the capacity to fix atmospheric nitrogen making them potentially highly suitable for inclusion in low-input cropping systems (Lemke *et. al.,* 2007); and (3) at cropping system levels, as diversification crops in agroecosystems based on few major species, breaking the cycles of pests and diseases and contributing to balance the deficit in plant protein production in many areas of the world, including Europe (Westhoek *et. al.,* 2011).

Okra (*Abelmoschus esculentus* (L.) Moench) is a widely cultivated vegetable crop and very important in the diet of Africans (Omotoso and Shittu, 2008). Fresh edible pods provide human supplementary vitamins such as Vitamins C, A, B-Complex, iron, and calcium (Chutichudet *et al.*, 2007). In Nigeria, the limiting factors in okra production and other vegetables among others include weed management, poor soil fertility, tillage practices, low yielding varieties and sub-optimal planting density (Iyagba *et al*., 2012). Bush fallow is the major natural method of replenishing the soil nutrient, this fallow system is gradually collapsing under the pressure of increasing population such that farmers increasingly practice a more or less sedentary agriculture on small land area (Kadeba, 1999). Moreover, the lack of the nutrient will lead to high cost of production whereby farmers would have to apply fertilizer to improve the soil nutrient if something good is to be expected. The use of inorganic fertilizers can improve crop yields but its use is limited due to scarcity, high cost, nutrient imbalance and soil acidity which can lead to environmental pollution. However, alternative cropping system which is environmentally friendly, cheap (reduce cost of production) and present for a longer period of time is to be adopted that could improve the soil nutrient and promote the growth and yield of okra which would increase the farmers' income.

The ability of legumes like cowpea, groundnut, soybean etc. to fix atmospheric nitrogen is perhaps the most notable aspect that sets them apart from other plants. Usually about two-thirds of the nitrogen fixed by a legume becomes available the next growing season after a legume in a rotation. For a long time, legumes have been known as the ―soil building crops because the biological, physical, and chemical properties of the soil are significantly improved when legumes are grown on it (Zhao-Hai Zeng, *et. al.,* 2016). It therefore makes good sense agriculturally to alternate them with cereals and other crops that require large amounts of N. The objective of this study was to determine the influence of leguminous crops at varying population on growth and yield of okra planted after the legumes.

MATERIALS AND METHODS

The experiment was conducted at the Vegetable Research Farm, National Horticultural Research Institute (NIHORT), Ibadan, Oyo state located in the rain-forest agro-ecological zone ($7^0 33^1$N and $3^0 56^1$E 168 m above sea level) between June and November 2019. Soil sampling was done randomly at the depth of 0-15 cm air dried, sieved through a 2mm mesh and taken to laboratory for analysis of physical and chemical properties of the soil. Soil sampling and analysis was also done according to the treatments after harvesting of the legumes.

The legumes comprising cowpea (Ife brown), soybean, bambara nut and groundnut (Kampala) were planted on a plot size of 3.6 m x 1.5 m (5.4 m^2) at 60 cm x 30 cm (55,555 plats/ha), 45 cm x 30 cm (74,074 plants/ha), and 30 cm x 30 cm (111,111 plants/ha). The four legumes, planted at three spacing with a check gave rise to thirteen treatment combinations laid out in randomized complete block design in three replications. Legumes were incorporated into the soil after harvest during land preparation for okra planting. Seeds of okra (NHAe 47-4) obtained from NIHORT was planted at a spacing of 50 cm x 50 cm. Weeding was carried out at 4 and 6 weeks after sowing using hoe. Five plants within net plot were randomly selected and tagged for data collection on Plant height (cm), number of leaves/plant, leaf length (cm), leaf area (cm^2), stem diameter (mm), fruit length (cm), fruit width (mm), average fruit weight (g), number of fruit/plant, fruit yield (t/ha). Data collected were subjected to analysis of variance (ANOVA) using SAS and significant means were separated using the Duncan Multiple Range Test (DMRT) at 5% probability level. Leaf area, Y = 115x – 1050, where Y is the leaf area and x is the length of the leaf (Olasantan, 1999).

RESULTS AND DISCUSSION

Result of analysis of variance (ANOVA) showed that significant differences existed in the amount of nutrients in the soil cultivated with different legumes at varying population. Plots cultivated with soybean at 55,555 plants/ha had significantly higher amount of organic carbon (3.89 mg/kg). Meanwhile, organic carbon of plot planted with bambara at population 74,074 plants/ha had the lowest (2.86 mg/kg) which was not significantly different from the one obtained from plot without legumes (2.99 mg/kg) (Table 1). Total nitrogen of soil planted with soybean at 55,555 plants/ha (0.32 mg/kg), 74,074 plants/ha (0.30 mg/kg) and 111,111 plants/ha (0.31 mg/kg), cowpea at 55,555 plants/ha (0.32mg/kg), bambara at 55,555 plants/ha (0.32mg/kg) and groundnut at 74,074 plants/ha (0.31 mg/kg) were significantly higher but not significantly different from one another. Meanwhile, total nitrogen of plot planted with cowpea at 111,111 plants/ha and 74,074 plants/ha and bambara at 111,111 plants/ha had the least total nitrogen of 0.2 mg/kg (Table 1). This result confirms the importance of legume residue in improving soil condition for the benefit of succeeding crops. The present study concurs with an earlier report, that legumes are excellent components within the various cropping systems (Yusuf and Yusuf, 2008). This revealed the significance of legume in nitrogen fixation and its inclusion to cropping system. It could also be due to the importance of legumes in improving the physico-chemical properties of the soil. This is due to increased availability of nitrogen in the soil and the increase in the amount of nitrogen as a result of nitrogen contributed by the legumes through nitrogen fixation (Ajeigbe *et. al.,* 2005).

Results of analysis of variance (ANOVA) showed that the residual effect of different legumes planted at varying population significantly affected growth of okra. Okra planted in plots previously cultivated with cowpea at 111,111 plants/ha was significantly taller (21.4 cm) while okra planted in plots without previous legumes produced the shortest plant with the least number of leaves

ISSN: 2814-0508

(Table 2). Okra planted on plots previously cultivated with cowpea at 74,074 plants/ha had significantly higher stem diameter while okra planted on plots without previous legumes had the lowest stem diameter (Table 2). These results might be as a result of the fact that nitrogen produced by legumes enhanced growth of subsequent crop and couple with the report in an earlier study that nitrogen has a significant contribution to vegetative growth of plants (Sanginga *et. al.,* 2002). Result of analysis of variance (ANOVA) showed that okra fruit yield and yield components were significantly affected by varying population of legumes planted before Okra. Okra planted on plots previously cultivated with Groundnut at 74,074 plants/ha had significantly longer fruit (6.73 cm) while okra planted on plots without previous legumes had the shortest fruit (4.43 cm). Okra planted on plots previously cropped with cowpea at 74,074 plants/ha had significantly higher fruit yield (1.08 t/ha) while Okra planted on plots previously cultivated with soybean at 111,111 plants/ha had least fruit yield which was not significantly different from okra planted on plots not previously cultivated with legumes (Table 3). These results corroborate the reports of Yusuf *et al.,* 2009 that yield increases of cereals following legumes in rotation have been reported by many studies in the past years. These results could be as a result of nitrogen fixed by legumes into the soil as revealed by several studies that increase in the yield of cereals planted after legumes was mainly due to the N contribution associated with the symbiotic N fixation in the legume (Lo´pez-Bellido *et al.,* 2004).

CONCLUSION

The study showed the potentials of leguminous plants as a renewable nutrient source for soil under continuous usage. Planting cowpea at spacing of 45 cm × 30 cm giving rise to a population of 74,074 plants/ha significantly increased yield of okra and is therefore recommended.

ABSTRACT

Field experiment was conducted in 2020 under Irrigation at the Teaching and Research Farm of the Faculty of Agriculture, Federal University of Kashere (Latitude 9^0, 54 46^{11} N and Longitude 11^0, 0 27^{11} E) to evaluate the agronomic characters of *Sesamum radiatum* (Schum and Thonn). The treatment consisted of three Intra-row spacing (10, 15 and 20cm) laid out in a randomized complete block design (RCBD) with four replications. The variable measured were plant height, number of branches, stem girth, leaf length/width and Fresh leaf yield. Data collected were subjected to analysis of variance (ANOVA) and means separation were done using least significant difference (LSD). The result obtained showed that the Intra-row spacing of 2ocm significantly ($P \leq 0.05$) produced tallest plant (81.8cm), highest number of branches (13.8) and highest fresh leaf yield (5.8t/ha). It was concluded that the Intra-row spacing of 20cm produced optimum growth and fresh leaf yield. Farmers in Kashere and its environs could adopt this spacing to ensure optimum growth, performance and leaf yield of *Sesamum radiatum* (Schum and Thonn).

Keywords: Agronomic characterization, Intra-row spacing, *Sesamum radiatum*, Kashere Nigera.

INTRODUCTION

Sesamum radiatum (Schun and Thonn) also called Black benniseed (English) and Karkaci (Hausa) is a traditional leafy vegetable of national important found in a wide range of habital and in moist places in open savannah and belong to the family *Pedaliaceae* (Grubben and Denton, 2004; Garjila, 2016). *Sesamum* comprises about 20 species, most of which are indigenous to tropical Africa. Sometimes small horns can be present on fruit of *Sesamum radiatum* and in that case confusion is possible with *Ceratotheca desmoids. Sesamum radiatum* and other *Pedaliaceae* are covered with mucilage glands. The gland may enable the plant to withstand severe desiccation without tissue death, after contact with water, the outer cells wall of the head cells dissolve, producing an enormous amount of mucilage (Adeoti *et al*.,2012; Garjila *et al*.,2020).

Sesamum radiatum are only grown on a small scale, mainly for home consumption. In Nigeria a leaf yield of 5-6 tonnes/ha can be expected. For leaf production, the plant is topped to promote the growth of new basal shoots from which large leaves can be harvested. The plant is a popular vegetable in Africa in which the edible leaves are used and shots cooked and eaten as vegetable. The plant also yields an oil and has local medicinal uses. It is cultivated in Africa, India, Srin lanka and South America (Guyana), mainly for its edible leaves, also for its high quality seed oil which is traded in mixture with the vegetable oil of *Sesamum indicum* (Garjila et al, 2020; TPD, 2020). The leaves are also used for treating various sickness including stomach oilments, catarrh, eye pains, bruises and erupted skin (Ogunlesi et al, 2010). A paste made from the pounded seeds combined with shea butter (*Vitellaria paradoxa*) and other ingredients, is applied as a treatment for rectal prolapsed. A leaf infusion is used as a shampoo and to kill head lice (Dansi *et al*., 2012; Garjila, 2016; TPD, 2020).

There are a number of constraints that limits the production of *Sesame*. One of them is lack of optimum plant population and row spacing recommendations. Farmers in the arid and semi-arid areas usually use high population and broadcast method for all crops grown for various

ISSN: 2814-0508

reason. This practice mostly resulted in poor seedlings growth and development, because of severe competition at the seedlings stage that leads to lower yield (Lakew *et al*.,2018). Yield responses to plant population and row spacing need to be known for practical purpose, as plant density is a major management variable used in matching crops requirement to the environmental offer of resources (Smith and Hamal, 2012). Despite the nutrition, medicinal and economic value of the plant, it is still unfortunately neglected by scientific research (Adeoti *et al*.,2012), and poorly investigated and is currently classified among the natural underutilized species of crops (Dansi *et al*.,2012). In view of that there is need to determine the spacing for the optimum production of *Sesamum radiatum* (Schum and Thonn) in the study area.

MATERIALS AND METHODS

The field experiment was carried out under irrigation in 2020 at the Teaching and Research Farm of the Faculty of Agriculture, Federal University of Kashere (Latitude 9^0, 54' 46" N and longitude 11^0, O' 27" E), at an altitude of 349m above sea level.

The treatment consisted of three intra-row spacings (10, 15 and 20cm) laid out in a randomized complete block design (RCBD) with four replications. Clearing and sloughing of the trial field was carried out manually using cutlass and hoes. Sunken seed beds were constructed and each measured 2m x 3m ($6m^2$). Prior to seedbed preparation, representative soil samples were collected at 0-15cm depth using a soil auger and bukked to form a composite sample. The soil was air dried in the laboratory and grounded to fineness and sieved through 2-mm mesh before using for routine analysis following the prescribed standard analytical procedure (IITA, 1982).

The *Sesamum radiatum* seeds sourced from local seed banks in the area were mixed with sand and then drilled in an inter-row of 50cm apart after thorough watering of the seedbeds. At 2 weeks after emergence, the seedlings were thinned to one plant per stand at 10, 15 and 20cm intra-row spacings. All normal agronomic management practices such as land preparation, weeding, manure application, pest and disease control, erosion control, etc. were followed to ensure good crop growth.

Harvesting of the fresh shoots was carried out at 2 weeks' intervals commencing from 8 weeks after sowing (WAS) and terminated at 16 WAS. Parameters measured were plant height (cm), number of branches, stem girth (cm), leaf length/width (cm) and fresh leaf yield (t/ha) was determined from the summation of leaf yield at the end of harvest. Data collected were subjected to analysis of variance (ANOVA) using SAS 9.4 version and means separation was done using the least significant difference (LSD) at $P \leq 0.05$.

RESULTS AND DISCUSSION

Analysis of the physic-chemical characteristics of the surface soil samples at the site during the period of the experiment showed higher proportion of sand, low silt and clay contents respectively indicating a sandy loam texture (Table 1). The sandy nature of the soil indicated its limited ability to retain water and nutrients unlike soils with large amount of clay or organic matter which tend to have higher tenacity to retain nutrients against leaching. The low silt content of the soil suggests that its agricultural potential could be improved by adoption of appropriate soil management and cropping practice (Uchida, 2000).

The effect of different intra-row spacings on plant height, numbers of branches and stem girth were significant at $P \leq 0.05$ as shown on Table 2. Plant height increased as intra-row spacing were increased with the tallest plants (39.3/81.8cm) at 4 and 6WAS with the highest intra-row spacing (20cm), while plants in 10 cm intra-row spacing were shortest (28.2/42.8cm) at 4 and 6WAS respectively. The tallest plants produced the highest number of branches (13.8) with largest stem girth (1.2cm) and plant in the 10cm intra-row spacing had fewest branches (5.6) which also had smallest stem girth (1.0cm) during the same period. The results is in agreement with the findings of Garjila *et al*., (2020) and Thompson (2021) who reported that the ideal spacing between the rows in your garden provides ample room for your plants to grow for you to work in and encourage large and healthier plants.

Plant leaf growth and expansion increased significantly ($P \leq 0.05$) from plants in 10cm intra-row spacing plots and maximized in plants in plots with the highest intra-row spacing (20cm). Plants in 20cm intra-row spacing produced the longest leaves (4.3cm) and widest leaves (1.3cm) than plants in 10cm intra-row spacing with shortest leaves (1.4cm) and smallest leaves (0.8cm) respectively. This results are also similar to the findings of Idoko *et al*., (2018), Lakew *et al*., (2018) and Garjila *et al*., (2020) who reported increased in intra-row spacing.

ISSN: 2814-0508

Fresh leaf yield was also influenced by intra-row spacing and like other parameters. It also increased significantly (P≤0.05) with each incremental spacing and maximize at the maximum intra-row spacing. While plants in shorter spacing had the least values for parameter spacing had the least values for the parameter (Table 2). The highest fresh leaf was produced in plots with an intra-row spacing of 20cm (5.8t/ha) followed by 15cm (4.8t/ha) and 10cm with the lowest fresh leaf yield of 3.8 e/ha. This result is in agreement with the findings of Haruna and Abimiku (2012), Eifediyi *et al*. (2018), Lakew *et al*. (2018), Raymond *et al*. (2020) and Garjila *et al*. (2020) who reported highest yield with increased in plant spacing and organic manure.

Table 1: Pre-planting Physico-chemical properties of soil at the experimental site.

Parameter	Soil depth 0 – 15cm
Sand (%)	83.44
Silt (%)	7.35
Clay (%)	11.42
Texture	
pH 1:2.5 (Hz0)	6.32
pH 1:2.5(CaC12)	5.2
Organic carbon (gkg^{-1})	5.41
Total N (gkg^{-1})	3.62
C/N ratio	4.31
Available P (mgkg^{-1})	2.24
Exchangeable Calcium (cmol kg^{-1})	0.53
Exchangeable magnesium (cmol kg^{-1})	1.36
Exchangeable potassium (cmol kg^{-1})	1.53
Exchangeable Sodium (cmol kg^{-1})	0.55
Effective cation exchange capacity (cmol kg^{-1})	5.26

CONCLUSION

Sesamum radiatum (Schum and Thonn) responded differently to intra-row spacing with the highest fresh leaf yield obtained in plots with widest intra-row spacing (20cm) which could be an indication that higher yields may still be possible at wider intra-row spacing than 20cm.

ABSTRACT

Growth and yield responses of bitter leaf to pinching and planting positions were studied at the Teaching and Research Farm of the Department of Crop Science and Horticulture, Nnamdi Azikiwe University, Awka, Nigeria. The planting positions were horizontal (180˚ to the soil surface), slanting (45˚ to the soil surface) and vertical (90˚ to the soil surface) while pinching levels were pinching and no pinching. The pot experiment was laid out as a 2 x 3 factorial experiment in completely randomized design, replicated eight times. Data on number of leaves, plant height, number of primary branches, fresh and dry leaf yield were collected. Results showed that planting positions and pinching significantly (P<0.05) influenced the growth and yield of bitter leaf. Horizontal planting position enhanced production of tallest plants, widest stems, highest number of leaves and highest fresh leaf yield (2.35 t/ha) whereas the slanting method resulted in lowest fresh leaf yield (1.55 t/ha). Expectedly, shorter plants were observed in pinched plants but the pinching significantly (P<0.05) promoted production of higher number of leaves and fresh leaf yield (2.43 t/ha) than the unpinched plants (2.20 t/ha) particularly when horizontal planting position was used. Horizontal planting position and pinching of bitter leaf was therefore recommended to be adopted by bitter leaf farmers in the study area for higher fresh leaf yield.

Key words: *Vernonia amygdalina*, planting orientation, pinching, tipping, leaves, yield.

INTRODUCTION

Vernonia amygdalina, commonly known as bitter leaf, because of the bitter taste of the leaves, have valuable nutritional and medicinal qualities owing to many phytochemicals found in the plant. It contains significant quantities of lipids (Ejoh *et al*., 2007), proteins with essential amino acids (Igile *et al*., 1994). It also contains carbohydrates (Eleyinmi *et al*., 2008) and carotenoids, though not in large quantities (Udensi *et al*., 2002). The leaves also contain essential elements such as calcium, iron, protein, potassium, phosphorus, manganese, copper and cobalt (Bonsi *et al*., 1995). The plant leaves can be used for flavouring, seasoning and garnishing of foods (Fayemi, 1999). The plant has been shown to be anti-helminths, blood purifier, anti-laxative and anti-malarial. It is also used by scientists in curing joint pains associated with diabetes, persistent headache, fever reduction and a host of others (Momoh *et al.,* 2010). The roots are used for treatment of gastro-intestinal problems, malaria, toothache, and fertility problems. The aqueous leaf extract in combination with *Azadirachta indica* leaf extract was reported to be the best cure for type 2 diabetes in Nigeria (Eyong *et al*., 2011).

In Nigeria, the leaves of bitter leaf are squeezed severally to remove the bitter taste and thereafter utilized to prepare bitter leaf soup. Bitter leaf soup is a common soup in Nigeria and a special delicacy in Anambra state, Nigeria hence, the plant is found virtually in all households in the state. The major commercial bitter leaf farmers exist within Nimo and Oraukwu communities in Njikoka Local Government Area of Anambra state. The commonest planting material for bitter leaf is the stem cuttings which are planted at different orientations namely slanting (at an angle to the soil surface) and vertical (upright in vertical position). Despite the economic importance of bitter leaf, there is lack of documented information on the appropriate planting position for optimum productivity of bitter leaf. According to Legese *et al*. (2011), the root yield of cassava was significantly influenced by planting position of the stem cuttings. In another study, Amponsah *et al*. (2017) reported significant variation in yield and root tuber breakage of cassava as well as field capacity of improved manual cassava harvesting tool. Research on planting position of bitter leaf stem cutting could give relevant information to the farmers as regards the best planting position for optimum growth and productivity of bitter leaf.

On the other hand, Ndukwe and Baiyeri (2018) had opined that pinching is one of the methods for re-direction of photo-assimilate to the needed part of the plant since manipulation of source-sink relationship serves as one of the sustainable strategies to increase crop yield. Pinching, a horticultural operation, is the removal of the terminal growing end of a plant resulting in the promotion of branching and more leaf production by counteracting the effect of apical dominance. Since bitter leaf is a leafy vegetable, more leaf production and yield may be improved with pinching. Hence, the aim of this study was to determine influence of planting position and pinching on growth and leaf yield of bitter leaf.

MATERIALS AND METHODS

Experimental Site

The study was conducted at the Teaching and Research Farm of the Department of Crop Science and Horticulture, Nnamdi Azikiwe University, Awka, Nigeria. Awka is a tropical rain forest with an average temperature of 27^0C - 30^0C. The area is located between latitude 06^0 15'N and longitude 07^0 08'E, with an average rainfall of 1810.3 mm per annum and a relative humidity of 75-80%.

Composition, Composting and Potting of Growing Media

The media comprised top soil and poultry manure (3:1 volume/ volume) which was mixed and composted for 6 weeks. Thereafter, the media was potted in perforated 7 liter growing pots. The average weight of the media in the pots was 10kg. The pots were placed 1m x 1m apart.

Source of Planting Material and Treatments

The planting material was stem cuttings of bitter leaf which were collected from bitter leaf plants growing at the teaching and research farm of the Department of Crop Science and Horticulture, Nnamdi Azikiwe University, Awka. The stem cuttings were cut at 15 cm long consisting of about 7-10 nodes.

Treatments and Experimental Design

During planting, three planting positions were used namely horizontal, vertical and slanting. In horizontal planting, the stem cuttings were totally buried at the depth of 5 cm while in vertical planting, stem cuttings were inserted into the media vertically (90°) with 2-3 nodes of the cuttings underground while the remaining nodes were above ground. But in slant planting, the cuttings were inserted into the media in a slanting position (45° to the top of the media) with 3-4 nodes remaining underground while the rest of the nodes were above the media surface. On the other hand, some plants were pinched at one month after planting while none pinched plant represented the control. These factors were combined and laid as 3 x 2 factorial experiment in a complete randomized design (CRD) with eight replications.

Cultural practices

Weeding was done manually with hand and hoe. Irrigation water (1.5 litres) was daily applied during the dry season. At the establishment of rain, the pots were left for rain fed.

Data collection

Data collected during the experiment were growth and leaf yield of *Vernonia amygdalina*. Data on growth included, number of branches and height of tallest branch (measured from the soil level to the point of attachment of the last leaf on the shoot obtained with the aid of flexible meter tape in centimeter), stem girth of tallest branch (measured with the aid of a digital center caliper at 10cm above soil level) and number of leaves obtained from counting. Fresh leaves were harvested at monthly interval and weighed. The fresh leaves harvested were oven-dried in a laboratory oven at 70°C until a constant weight was obtain as the leaf dry weight.

Data analysis

The data collected were subjected to statistically analysis using analysis of variance for factorial experiment in completely randomized design with the aid of GENSTAT software package (GENSTAT, 2012). Least significant difference at 5% level of significance was used to detect significant treatment means.

RESULTS

Effect of planting position on plant height and number of leaves of bitter leaf before pinching

Planting position significantly ($P<0.05$) influenced growth attributes of bitter leaf at 7 and 9 weeks after planting (WAP), before pruning the plants (Table 1). Tallest plants and highest number of leaves were recorded in shoots emerged from horizontal stem planting. At 7 WAP, planting the stem cuttings in vertical position resulted in producing shortest plants and least number of leaves. But at 9 WAP, shortest plants and least number of leaves were recorded in shoots that emerged from stems planted in slanting position.

Effect of planting position and pinching on plant height of bitter leaf

Plant height after pruning indicated significant ($P<0.05$) variation as a result of planting positions and pinching as well as their interactions (Table 2). Main effects revealed that horizontal planting could produce tallest plants. Expectedly, plants that were not pinched also produced taller plants than pinched plants. The interaction of planting position and pinching showed that planting the stems horizontally without pinching produced tallest plants although the mean values were significantly at par with the values recorded with vertical planting without pinching, in all the sampling periods.

Effect of planting position and pinching on number of leaves of bitter leaf

Number of leaves was significantly ($P<0.05$) influenced by planting positions, pinching and the interaction (Table 3). Highest number of leaves was recorded in shoots that emerged from either horizontal or vertical planting positions. Pinching the plants resulted in higher number of leaves than the no pinched plants especially at 19, 21, 23 and 25 WAP. Similarly, the combined effect of planting position and pinching significantly ($P<0.05$)

recorded highest number of leaves for pinched plants which emerged from horizontal planting.

Effect of planting position and pinching on leaf yield of bitter leaf

Table 4 shows the combined effect of planting position and pinching on fresh and dry leaf weight of bitter leaf. There was significant interaction effect on both fresh and dry leaf yield. Horizontal planting of stem cuttings and pinching of shoots resulted in the production of significantly ($p<0.05$) heaviest fresh and dry leaves at every harvest. However, the mean values obtained were statistically at par with mean values recorded for yields from plants that developed from horizontal stem cuttings without pinching. The lowest leaf yield was produced by plants developed from planting position with or without pinching. Although harvest index was not influenced by planting position or pinching but the value ranged from 55.5 to 72.3%.

Effect of planting position and pinching on shoot and root yield of bitter leaf

Fresh root weight and number of roots were significantly (P<0.05) highest for horizontal planting followed by vertical planting although the mean value was statistical similar with slant planting (Table 5). Pinching resulted in producing heavier secondary branches than no pinching. Interaction of planting position and pinching indicated that fresh weight of secondary branches and number of roots were significantly highest in pinched and unpinched plants developed from horizontal planting of stems, respectively.

DISCUSSION

The result of this study showed that planting position and pinching can influence the growth and yield of bitter leaf. Horizontal planting of the stem cuttings produced tallest plants, highest number of leaves, branches and highest fresh leaf yield compared to other planting positions. More roots must have developed from stem cuttings planted horizontally since they were totally buried in the soil (Abdullahi *et al*., 2014). Covering the entire stem cutting with soil (earth), must have exposed the stem cuttings to having more energy storage for a higher growth and development. However, pinching of the apical part of the stem cuttings also can affect the performance of bitter leaf in terms of branching and subsequently, number of leaves. In this study, it was recorded that no pinching of the apical part of the bitter leaf performed less when compared to pinching. Removing the apical part actually induced or facilitated stem branching which led to subsequent increase in the number of leaves, the primary target of most farmers. Where the farmer intends to plant for the purpose of producing stem cuttings, it showed that pinching can significantly increase the stem yield by producing more branching. According to Singh *et al*. (2017), pinching is commonly undertaken to promote branching and bushy growth of the canopy by counteracting the effects of apical dominance. It was also observed that pinching enhanced spread of the canopy due to branching in contrast to no pinching. Pinching significantly increased branching, number of leaves which automatically created a shade hence can also suppress growth of weed and their comparative competition for nutrient, water, air and light.

CONCLUSION

The study showed the importance of manipulating plants with horticultural strategy for better performance in terms of growth, development and more especially yield. Therefore, horizontal planting position and pinching of plants was recommended to be adopted by bitter leaf farmers in Awka.

ABSTRACT

A field experiment was conducted at National Horticultural Research Institute Research Farm at Kadawa during 2020 dry season, to study effect of spacing and planting pattern on growth and yield of radish (*Raphanus sativus*). Three spacings (10cm, 15cm, and 20cm) and two planting patterns (Direct sowing and transplanting) were investigated. The experiment was conducted in Randomized Complete Block Design (RCBD) with three replicates. The results showed that there was no significant difference for all studied traits among the treatments interactions. However, seeds directly planted in the field at the spacing of 10cm revealed high number of leaves per plant, tall plants, leaf length per plant, thicker tuber and long tuber while heavy tuber weight per plant was recorded for transplanting at spacing 20cm. Based on the results of this study, it suggested that transplanting at the spacing of 20cm provides high tuber yield of radish.

Key words: Radish, Spacing, Growth, Planting Method, Tuber Yield

INTRODUCTION

Radish (*Raphanus sativus*) belongs to the family brassicaceae that was domesticated in Asia in pre-roman times. Radish being mostly eaten raw as crunchy salad and edible root vegetable (Annon, 2007). Radish is very rich in nutrients such as minerals, vitamins, folic acid, antioxidants, antimicrobial, antibacterial and anthocyanin. It also has the capacity to treat skin ailments like dry skin. Drinking radish juice helps to clean the kidneys and also treats urinary health issues, taking radish help to treat cancer; it is good options for those who wish to lose weight to be eaten radish. Some of the factors responsible for reduced growth and lower yield of most vegetable crops including radish are cultural practices such as proper timing of dates of sowing, and appropriate plant population to be used for raising vegetable crops in order to get higher production of good quality vegetables. However, growth and tuber yield of radish depends on good agronomic practices, including spacing and planting method. Lavanya et al. (2014) reported high root yield for 45x10cm, while El-Desuki et al. recorded maximum plant height and root yield of radish at 10x20cm. There is little information regarding spacing and plant methods of radish in Sudan Savannah. Therefore, the experiment was conducted to determine effect of spacing and planting method on growth and yield of radish.

MATERIALS AND METHODS

The research was conducted at National Horticulture Research farm Kadawa. The Experiment was undertaken in a randomized complete block design (RCBD) and replicated three times with an alley of 0.5m between plots. Plot sizes consist of 6 ridges 0. 75m apart of 3m. The treatments consist of planting method (direct sowing and transplanting) and spacing (10cm, 15cm and 20cm) which were randomly allocated to the plots. Weeding was conducted manually using local hoe at 3 and 6 weeks after sowing and later supplemented with earthen up to support the crops rooting. Data were taken on number of leaves, plant height, leaves length, leave width, canopy spread, tuber length, tuber diameter and tuber weight. Harvesting was done manually after the tubers were matured. The data were analyzed using STAR software 2.0.1 (2014).

RESULTS AND DISCUSSION

The results indicate the effect of spacing and planting method on plant height, number of leaves per plant, leaf length per plant, leaf width per plant and canopy spread per plant at Kadawa farm (Table 1). The results revealed non-significant difference for spacing and planting method interaction of the studied traits. Spacing of 10cm sowed directly on the field recorded high number of leaves (24.82) followed by spacing of 15cm (18.71). Minimum number of leaves per plant were observed at 20cm transplanted. Lavanya *et al.* (2014) reported high number of number of leaves per plant at 10cm spacing. This result agreed with the finding of Pervez et al., 2004. The results also revealed that, spacing at 10cm under direct sowing and transplanting recorded taller plants of 26.10 and 25.82cm, respectively, which were significantly higher than 15cm and 20cm spacing. Transplanting at the spacing of 10cm recorded long leaf length (28.47cm) followed by direct planting (19.86cm) at the same spacing, while shorter leaf length (11.92cm) was noticed under transplanting at 20cm spacing. Both 20cm and 10cm spacings at direct sowing showed wide leaf width per plant compared to transplanting with values of 14.85cm and 10.62cm. It observed that at 10cm and 15cm spacings direct sowing and transplanting, recorded wider spread of leaves of 32.76cm and 30.82, respectively; than the other spacings. Spacing of 20cm and 15cm at direct sowing showed thicker tubers with values of 57.22mm and 46.79mm, respectively; which were significantly better compared to the values recorded under transplanting method. Thicker tuber (40.09mm) was also recorded at spacing of 10cm under transplanting method. Direct sowing and transplanting at both 15cm and 20cm revealed longer tuber per plant. These results for thicker and long tubers were due to wide space for the tuber development and minimum competition for nutrients, sunlight and water. The results for tuber weight per plant, showed no significant differences treatments interaction, however, transplanting recorded high yield for tuber per plant for 20cm and 10cm spacings than direct sowing. The results corroborated with findings of Pervez *et al*., 2004, Brintha and Seran, 2009, and Lavanya *et al.* (2014).

CONCLUSIONS

Based on the results of this study, it suggested that transplanting at the spacing of 20cm provides high tuber yield of radish.

ABSTRACT

Pepper production in rainforest agro-ecology of Nigeria is still short of what is demanded due to growing of unknown sources of seeds and for our local pepper farmer in the study area to have a distinct pepper line, there was need to have new varieties or lines with higher yields, superior quality and pest's resistance evaluated. Therefore, this study was designed to evaluate the growth and yield of some selected pepper line during early cropping season. The field trial was conducted during early cropping season of 2020 in rainforest agro-ecology of Nigeria. The trial was laid out as randomized complete block design and replicated thrice. Treatments consisted of 30 pepper lines. Data collected on growth and yield attributes of pepper lines were subjected to analysis of variance and significant means were separated using Least Significant Difference at P≤0.05. General growth and yield characters in the pepper lines varied significantly during the early cropping season. Pepper line SP103 (T2) recorded the highest yield follow by NCHF IRB (T4); SP 103 (T10) and NHCC RD5 (T6). These lines should also be used for further breeding and physiological studies.

Key words: Pepper lines, Yield, Rainforest agro-ecological zone.

INTRODUCTION

Pepper is one of the most important vegetable crops in the world. In 2018 the total cultivated area under pepper in Ethiopia was 8001 hectares with a production quantity of 4889 tons (FAOSTAT, 2018). There are twenty-five wild and five domesticated species of pepper belonging to the genus *Capsicum* (Bosland and Votava, 2000). There is the general believe that Central and South Americas are the original centers of pepper (*Capsicum* spp.). Exclusively, chili and sweet pepper (*Capsicum annum*) are from Mexico while aromatic hot pepper (*Capsicum chinense*) is from the Amazonian region and Bird pepper (*Capsicum frutescens*), the coastal regions of the southern part of tropical South America. *Capsicum annuum*, *Capsicum frutescence* and *Capsicum chinense* in tropical Africa are treated as a single species, *Capsicum annuum* (Purseglove *et al*., 1981; Grubben *et al*., 2004). Grubben *et al*. (2004) classified *Capsicum annum* into four cultivar-groups namely: Sweet pepper, chili, bird pepper and aromatic pepper. Pepper fruits may be used as a vegetable, spice and coloring as well as for medicinal purposes (Sana, 2003). The fruit which is eaten either in the fresh or processed form has high vitamin and mineral contents (Burton and Foster, 1988; Yayock *et al*., 1988).

However, in the study areas farmers used to grow unknown sources of seeds and for our local pepper farmer to have a distinct pepper line, there was the need to have new varieties or lines with higher yields, superior quality and pest's resistance evaluated. Thus, the objective of this study was to evaluate the growth and yield of some selected pepper line during early cropping season.

MATERIAL AND METHODS

The field trial was carried during early cropping season (March - August 2020) at block 3 Vegetable Research Field of the National Horticultural Research Institute (NIHORT), Ibadan (Latitude 7° 22' N and Longitude 3° 50' E at 234m above sea level), located in the forest agro-ecological zone of Nigeria. The experimental site had been under continuous cultivation for many years.

Nursery Preparation: Top soil was collected and sterilized by heating to 100^0C in a metal drum and was allowed to cool. The sterilized soil was filled into nursery trays after which seeds of pepper lines were sown. Regular watering and monitoring was carried out in the nursery for five weeks. Experimental Design and Treatments Application: The trial was laid out as randomized complete block design (RCBD). The treatments consisted of 30 pepper lines namely; T1= HP75, T2= SP103, T3=P_1/9, T4=NCHF IRB, T5= P4/5, T6= NHCC RD5, T7= NHCC RD4, T10= SP 103, T11= P_1/4, T12= NHCC RD6, T13= NHCC RD2, T16= SP 167, T17= SP 103 POLL A13, T20= P3/1, T25=NHCC RD_3.

Field Establishment: The land was ploughed and left for two weeks to allow buried weeds to decay and reploughed followed by harrowing. Pepper seedlings were transplanted at 5 weeks after sowing (WAS) at the spacing of 50 cm x 50 cm. The plot size was 2 m x 2 m, alley of 1.0 m within plots and 1.0 m between replicates.

Cultural Management Practices: At 3 weeks after transplanting, NPK 20-10-10 fertilizer was applied at rate of 5g /plant. Weeds were controlled using hand hoeing at 3weeks interval during the rainy while weeding was carried at 4 weeks' interval during the dry season. Neem biopesticide was applied to control the fungi infection.

Data Collection: The following data were collected from five (5) randomly selected tagged plants within the plot for growth and yield attributes; Plant height, Stem Girth, Number of leaves, Number of branches, number of fruit per plant and average fruit weight ton/ha.

RESULTS AND DISCUSSION

Raining season

Effects of growth parameters on pepper lines are presented in Table 1. The result had no significant effect on the plant growth. The highest plant height of 12.58cm was observed from P4/5 line (T5) while the least plant height of 1.50cm was recorded from SP 167(T16). Pepper line of P4/5(T5) had the highest number of leaves (20 leaves) while the least number of leave (1.67) was gotten from NHCC RD_3 (T25) (Table 1). There were no significant differences among the stem girth of the tagged plants but NHCC RD4 (T7) gave the highest value of 0.73cm at 2WAT while SP 103 POLL A13 (T17) recorded the lowest at 0.00, similar result was obtained at 4WAT where P4/5(T5) had the highest at 2.31cm and SP 167 (T16) gave the lowest at 0.47cm. With regards to relationship between plant height and stem girth, our study agrees with work done by Rudall (1994) which stated that increase in height is often accompanied by a corresponding increase in stem thickness. Furthermore, there were also no significant differences among branches but SP103 (T2) had the highest at 5.33 while there were four pepper lines which gave lowest value at 0.00 and they are NCHF (T4), NHCC RD4 (T7), SP 167(T16) and SP 103 POLL A13 (T17) respectively. The variation in the growth parameters among the pepper lines may be attributed to their genetic potential as well as environmental factors. In table 2, there were significant variation in the yield attributes among the pepper lines. P_1/9(T3) had the highest value for number of fruit/plant at the average of 20.67 while SP 103 POLL A13 (T17) had the lowest average value of 1.33. The highest fruit yield of 5.15 ton/ha, was recorded from SP103 (T2) which was significantly varied among the pepper lines while P3/1 (T20) had the lowest yield of 0.15 ton/ha. The significant differences in fruit yield in the pepper lines as found in this study agrees with the findings of other studies (Izge *et al*., 2007; Hassan Wasiullah *et al*., 2003; Hassan *et al*., 2001; Sana *et al*., 2003; Khoshnazar *et al*., 2000) who reported similar differences in other crops as a result of genetic and environmental factors. In conclusion, growth and yield characters in the pepper lines varied significantly during the early cropping season. Pepper line SP103 (T2) recorded the highest yield follow by NCHF IRB (T4); SP 103 (T10) and NHCC RD5 (T6). These lines should also be used for further breeding and physiological studies.

ABSTRACT

A field experiment was conducted to evaluate the growth and yield of eight accessions of bitter leaf (Abatete, Akpu, Ifite-Awka, Mbaukwu, Nimo, Nkpologu, Oraifite and Ukpo) in Anambra State, Nigeria. The experimental design was Randomized Complete Block Design replicated ten times. Growth data collected were number of branches, number of leaves, plant height, and stem girth and leaf area at two weeks' interval. The yield data were fresh weight of leaves and total leaf yield. Ukpo, Akpu and Oraifite significantly (P<0.05) produced tallest plants (113.7, 113.1 and 107.8cm, respectively), Highest number of leaves (168, 123.2 and 109.7, respectively), widest stems (15.97, 15.90 and 15.05mm respectively), highest number of branches (3.85, 3.73 and 3.71 respectively) and total fresh leaf yield (4.07, 3.36 and 2.08t/ha respectively). Results obtained from the study indicated that Ukpo, Akpu and Oraifite accessions should be given the highest consideration when setting up a bitter leaf farm in Awka. More studies need to be embarked on to determine the genetic variability of these accessions, so as to give more insight on the various nutritional, pharmaceuticals and other potentials of these bitter leaf accessions.

Key words: *Vernonia amygdalina,* accessions, yield, biomass, leaf

INTRODUCTION

Vernonia amygdalina, also known as bitter-leaf, is a tropical African shrub or small tree that is also widely dispersed in Asia (Oseni and Babatunde, 2016). It belongs to the Asteraceae or Compositae family. Bitter leaf is a drought-resistant plant that thrives in humid conditions. It is widely grown in Benin, Nigeria, Cameroon, Gabon, and the Democratic Republic of Congo, as well as to a smaller extent in adjacent countries (Ijeh and Ejike, 2011). Bitter leaf is used for more than just cooking. Malaria, infertility, diabetes, gastrointestinal issues, and sexually transmitted diseases are all traditionally treated with bitter leaf in Africa (Farombi and Owoeye, 2011). According to Eyong *et al*. (2011), the best therapy for type-2 diabetes in Nigeria is aqueous leaf extracts of bitter leaf and *Azadirachhta indica*. In Northern Nigeria, bitter leaf is given to horse feed to make a strengthening or fattening tonic known as "Chusan Dokin" (Hamzah *et al*., 2013). In addition, the roots can be used to treat gastrointestinal issues, malaria, toothaches, and infertility issues (Momoh *et al*., 2010). Although *V. amygdalina* is usually propagated by cutting, the hairy root of *V. amygdalina* can also be grown in vitro using explant cultures and auxin. For its adventitious root induction, IBA (concentrations ranging from 0.25 to 2 mg/l) was determined to be the optimum growth regulator (Khalafalla *et al*., 2009). Accessions can be found in almost every domesticated crop. They are studied in order to pick the highest performing accession to assist a crop thrive. Accessions differ in terms of growth, nutrition, and physiological aspects, indicating variability (Ahiakpa *et al*., 2013). Many morphological variations have been found in bitter leaf identified in Nigeria but there is scarcity of information on morphological differences in bitter leaf even when there are identifiable variations (Field Survey, 2017). Hence, the objective of this study was to evaluate the growth and leaf yield of eight accessions of bitter leaf.

MATERIALS AND METHODS

Experimental Site

The experiment was conducted at the Research Farm of Crop Science and Horticulture, Nnamdi Azikiwe University Awka, Anambra State, Nigeria. The Research Farm is at an altitude of 91m from sea level with latitude and longitude $6^{0}15'$ N and $7^{0}07'$ E respectively. The farm has an average annual rainfall of 1650-2000 mm per annum with a temperature of 27°C-30°C respectively and a relative humidity of 75-80% (GEOMET-NAU, 2019).

Establishment and Planting

The bitter leaf accessions that were evaluated includes Abatete, Ukpo, Akpu, Oraifite, Nkpologu, Ifite, Nimo and Mbaukwu. Stem cuttings of these accessions were collected from plots of farmers in the different communities. Stem cuttings of length 1 meter each were collected from 3 farmers' plots per community. These cuttings were later cut into smaller-sized stem cuttings of 15cm bearing 3-5 nodes. The 15 cm stem cuttings were planted in a 45^0 slanting position with plant spacing of 50 cm x 50 cm.

Cultural Practices

The plot was cleared from the existing vegetation. Ridges of 7 m long and 1 m width were made. Each of the accessions was planted as a single row plot of 10 plants per ridge. The ten plants represented the replications. Weeding was done at intervals, at least once in a month. Application of 10 t/ha poultry manure at a uniform rate was done at 4 weeks after planting to facilitate growth of leaves and improve vigour. The experimental design was randomized complete block design replicated ten times.

Data Collection

Data were collected from the 5 middle-most plants per ridge or accession. Data collection commenced at 4 weeks after planting which continued at 2 weeks' interval. The growth parameters were plant height of tallest branch (taken by measuring with flexible meter rule vertically from the ground level to the point of attachment of the last two opened leaves at the apex, to the nearest 1 cm), number of branches (obtained by counting the total number of primary branches per plant), stem girth of tallest branch (measured with the aid of a digital vernier caliper at 10 cm above the soil level), and number of leaves (obtained by counting the total number of fully opened green leaves per plant). The leaf yield was obtained by harvesting the fresh leaves at 12 weeks after planting. The fresh leaves were weighed with a digital weighing balance. Thereafter, the fresh leaves were dried to a constant weight with the corresponding determination of the dry leaf weights.

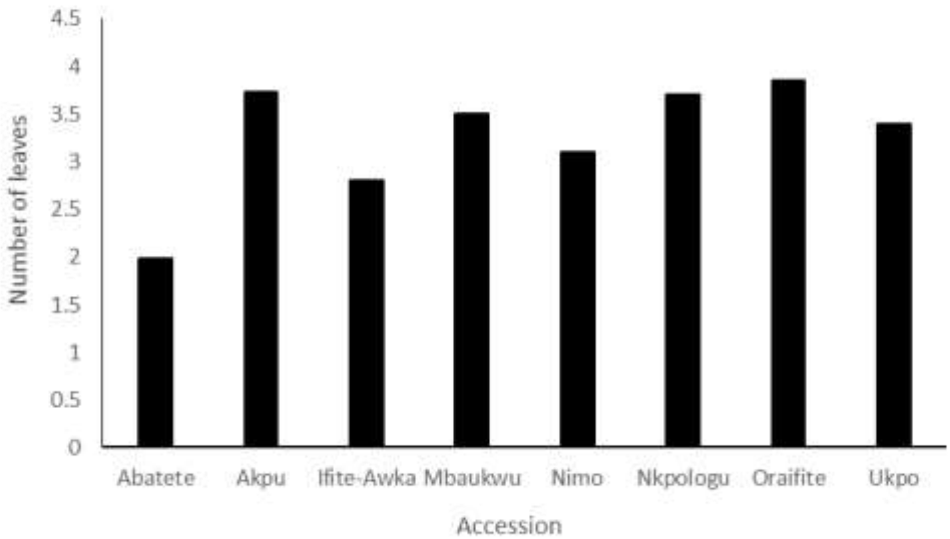
Data Analysis

All the data collected were subjected to analysis of variance following the procedure for randomized complete block design using GENSTAT (2012). Mean separation was done using least significant difference (LSD) at 5% level of probability.

RESULTS

Effect of accession on number of branches of bitter leaf at 4 weeks after planting

Table 1 shows the effect of accession on number of branches of bitter leaf at 4 weeks after planting (WAP). Oraifite accession produced the highest number of branches although the number of branches (3.85) was not significantly ($p > 0.05$) different with the mean number of branches produced by Akpu, Nkpologu, Mbaukwu, Ukpo and Nimo. However, the lowest mean number of branches (1.98) were significantly ($P<0.05$) recorded in Abatete accession.



Effect of accession on plant height (cm) of bitter leaf at 4, 6, 8, 10, 12 weeks after planting

Table 2 shows the effect of accession on the plant height of bitter leaf at 4, 6, 8, 10 and 12 WAP. Tallest plants were significantly ($p>0.05$) recorded in Oraifite, Ukpo and Akpu accessions at 4, 6, 8, 10 and 12 WAP. The shortest plants were significantly produced by Ifite-Awka and Nimo accessions.

There was a remarkable increase in plant height across the accessions at every 2 weeks' interval, although the accessions Ifite-Awka and Nimo showed a slow increase in plant height compared to the other accessions. It was observed that Abatete accession showed a sharp increase in plant height between 8 and 10 weeks after planting.

Table 2: Effect of accession on plant height (cm) of bitter leaf at 4, 6, 8, 10, 12 weeks after planting (WAP)

Accessions	4WAP	6WAP	8WAP	10WAP	12WAP
Abatete	17.3	35.5	42.0	90.8	97.8
Akpu	32.7	69.2	80.4	100.9	107.8
Ifite-Awka	6.7	9.0	10.9	23.7	31.3
Mbaukwu	16.2	36.8	38.9	66.6	74.1
Nimo	9.7	14.5	17.1	36.5	44.6
Nkpologu	16.7	50.5	52.0	84.2	92.4
Oraifite	34.0	72.7	75.0	112.0	113.1
Ukpo	29.3	68.8	72.5	107.9	113.7
$LSD_{0.05}$	7.7	14.8	14.3	18.0	18.0

Effect of accession on stem girth (mm) of bitter leaf at 4. 6, 8, 10 and 12 weeks after planting

Table 3 revealed that the Ukpo accession had widest stems (4.95) at the 4WAP but there was no significance ($p>0.05$) difference from Akpu, Oraifite and Mbaukwu at 4 WAP. Data collected at 6 WAP also showed that Oraifite accession produced the widest stems (10.89). However, the mean values did not significantly ($p>0.05$) vary between Ukpo and Akpu. At 10 and 12 WAP, widest stems were significantly produced by Oraifite, Ukpo, Abatete, Akpu and Nkpologu accessions. At 8 WAP, Akpu accession produced widest stems although the mean value (11.17) did not significantly differ with the mean values (10.99 and 10.41) recorded for Oraifite and Ukpo accessions.

Table 3: Effect of accession on stem girth (mm) of bitter leaf at 4, 6, 8, 10, 12 weeks after planting (WAP)

Accessions	4WAP	6WAP	8WAP	10WAP	12WAP
Abatete	3.20	8.04	8.70	14.07	15.10
Akpu	4.91	10.05	11.17	14.21	15.05
Ifite-Awka	2.50	3.15	3.31	6.37	7.27
Mbaukwu	3.84	8.06	8.12	11.07	12.02
Nimo	2.35	3.95	4.04	7.39	8.27
Nkpologu	2.85	8.88	8.81	13.37	14.22
Oraifite	4.77	10.89	10.99	15.10	15.97
Ukpo	4.95	10.16	10.41	14.96	15.90
$LSD_{0.05}$	1.11	1.94	1.90	2.32	2.30

Effect of accession on number of leaves on the tallest branch of bitter leaf at 4, 6, 8, 10 and 12 weeks after planting

Table 4 shows that the Oraifite accession produced the highest number of (16.38) at 4 WAP which was not significantly different from Akpu and Ukpo accessions. At 6 WAP, the Nkpologu accession produced the highest number of leaves (35.4) but the mean values was not significantly different ($p>0.05$) from Oraifite, Ukpo and Akpu accessions. At 8 WAP Akpu accession recorded highest number of leaves (42.3), although the mean number of leaves was not significantly (p>0.05) different with Ukpo, Nkpologu and Oraifite accessions. At 10 and 12 WAP, Ukpo and Abatete significantly (p<0.05) produced the highest number of leaves (95.7 and 101.0 respectively) while Nimo and Ifite-Awka accessions consistently produced fewer numbers of leaves at 4, 6, 8, 10 and 12 WAP.

Table 4: Effect of accession on number of leaves on the tallest branch of bitter leaf at 4, 6, 8, 10 and 12 weeks after planting(WAP)

Accessions	4WAP	6WAP	8WAP	10WAP	12WAP
Abatete	12.31	21.4	26.5	86.3	90.1
Akpu	15.75	33.9	42.3	64.9	71.9
Ifite-Awka	7.40	8.7	10.9	17.0	24.0
Mbaukwu	13.38	18.9	21.5	40.3	51.5
Nimo	7.60	10.3	13.0	22.1	28.9
Nkpologu	10.60	35.4	38.6	46.3	52.2
Oraifite	16.38	34.3	38.1	71.2	77.9
Ukpo	14.38	35.2	40.3	95.7	101.0
$LSD_{0.05}$	3.265	11.92	13.89	16.57	15.57

Effect of accession on total number of leaves of bitter leaf at 4, 6, 8, 10 and 12 weeks after planting

The total number of leaves significantly (p>0.05) varied among the accessions at 4, 6, 8, 10 and 12 WAP (Table 4.5). At 4 WAP Oraifite and Akpu accessions produced the highest number of leaves (46.3 and 45.6, respectively). At 6 and 8 WAP, Ukpo and Akpu accession recorded highest number of total leaves (62.8 and 71.5, respectively at 6 and 8 WAP). However, these mean total numbers of leaves did not significantly (p>0.05) vary with the mean total number of leaves obtained from Akpu, Oraifite and Nkpologu accessions. Similary, at 10 and 12 WAP, Ukpo accession produced the highest number of total leaves. This was followed by Abatete, Akpu and Oraifite accessions. Nimo and Ifite-Awka accessions consistently recorded least number of total leaves across the period of data collection.

Effects of accession on measured leaf area, total leaf fresh weight and yield of bitter leaf

Measured leaf area was broadest in Ukpo accession (Table 6). However, the mean leaf area (100.7cm^2) for Ukpo accession was not significantly different with the mean measured leaf area recorded for Abatete (95.3cm^2), Mbaukwu (94.7cm^2), Oraifite (96.4cm^2), and Akpu (93.3cm^2). Ifite-Awka and Nimo accessions had narrower leaves than other accessions.

Table 5: Effect of accession on total number of leaves of bitter leaf at 4, 6, 8, 10 and 12 weeks after planting(WAP)

Accessions	4WAP	6WAP	8WAP	10WAP	12WAP
Abatete	20.2	31.6	38.2	115.4	120.5
Akpu	45.6	62.2	77.8	112.5	123.2
Ifite-Awka	15.9	14.3	18.0	28.5	40.8
Mbaukwu	34.3	33.4	38.2	64.7	82.2
Nimo	18.7	17.5	21.7	33.0	45.1
Nkpologu	28.8	52.0	57.2	27.0	31.7
Oraifite	46.3	60.4	66.8	100.1	109.7
Ukpo	33.1	62.8	71.5	157.5	168.0
$LSD_{0.05}$	11.54	18.95	21.28	38.52	39.67

It was observed that the accession Ukpo produced the highest total weight of leaves followed by Oraifite and Akpu (203.4, 173.9 and 167.8 respectively). But total leaf fresh weight was significantly lowest in Ifite-Awka and Nimo accessions. On the other hand, Ukpo and Akpu accessions significantly ($P<0.05$) produced highest fresh leaf yield compared to other accessions while the lowest fresh leaf yield was recorded in Ifite-Awka and Nimo accessions.

Table 7: Effects of accession on measured leaf area, total leaf fresh weight and yield of bitter leaf

Accessions	Measured leaf area (cm^2)	Total leaf fresh weight (g)	Total leaf fresh yield (t/ha)
Abatete	95.3	101.9	2.04
Akpu	95.3	167.8	3.36
Ifite-Awka	46.9	52.8	1.06
Mbaukwu	94.7	136.0	2.72
Nimo	40.0	69.4	1.39
Nkpologu	84.8	99.9	2.00
Oraifite	96.4	173.9	2.08
Ukpo	100.7	203.4	4.07
$LSD_{0.05}$	9.95	48.3	0.97

DISCUSSION

The results of this evaluation demonstrated that the growth and biomass variations in the accessions could be as a result of intrinsic genetic variability. The report of Amoatey *et al*. (2015) indicated genetic variability in 29 okra accessions. Oraifite, Akpu, and Ukpo accessions exhibited high vigour and can quickly adapt to a new habitat. Although agronomic characterization and evaluation are the primary steps in determining genetic diversity, but to assess the real extent diversity of the bitter leaf accessions in Anambra state, agronomic, physiological, biochemical and molecular evaluation and characterization must be done as information on them are not available.

CONCLUSION

From the study, Ukpo, Akpu and Oraifite accessions should be given the highest consideration when setting up a bitter leaf farm within the study area. More studies need to be embarked on to determine the genetic variability of these accessions, so as to give more insight on the various nutritional, pharmaceuticals and other potentials of these bitter leaf accessions.

ABSTRACT

An arable land under long term cassava cultivation was assessed for its suitability for Coffee cultivation at Iwaraja in Osun State, Nigeria. The soil samples at both the top and sub-soil levels were analysed for the physical and chemical attributes and it indicated that the site soils had mean gravel content of 38.96% at the top soil and 44.53% at the sub-soil which indicates that the gravel content increased with soil depth. Thus, the site soil is characterized with stones, boulders, pebbles and gravels. The soils were sandy loam with the soil silt + clay contents lower than 32% which indicates need for irrigation during dry spells to support planted coffee seedlings. The soil pH 5.00-7.50 was suitable for coffee cultivation while the organic C of 0.65-2.09 g/kg soil was very low Total Soil N content of 0.06% is low compared with the critical level of 0.1% for coffee. The soil available P of 22.29 mg/kg soil was higher than critical value of 9mg/kg soil. The soils are lower in K and Ca contents but sufficient in Mg content, however, K/Mg ratio of 0.27-0.49 is lower than 2.0 expected. Generally, the soil Mn, Fe, Cu and Zn contents were optimal. The site soil was generally very low in macro-nutrients and most importantly N, which must be outsourced through fertilizer application and majorly, by way of organic manure application in order to build up the soil organic matter content and to achieve optimum growth and establishment of coffee plants.

Key words: Coffee production, fertilizer scarcity, optimal yield, soil management, water supply

INTRODUCTION

Coffee spp. is a crop of economic importance that contributes substantially to the foreign exchange earnings of the producing nations (Tijani *et al.*, 2001; Famaye, *et al.,* 2012). In Nigeria, Coffee is among the vital tree crops of high economic importance with more than 350,000Mt year^{-1} in the 1990's but dropped to less than 200,000Mt year^{-1} in 2006 (Ipinmorot and Ogeh, 2014). Though, coffee remains a big revenue spinner in the world market but Nigeria's production has fallen to less than 60,000 metric tonnes in 2020 (The Nation, 2021) and stakeholders are calling for repositioning of the coffee industry to enable the Nigeria earn more foreign exchange from coffee production. Presently, the Nigerian government is on diversifying the economy from sole dependence on petroleum into agriculture as a business. To this effect, more people are attracted to plantation agriculture, with more new plantations of tree crops and most importantly, coffee, being established. Virgin forests are the most ideal for opening up of tree crop plantations such as coffee. However, due to scarcity of virgin lands or forests and the huge cost of land acquisition, most people are left with the option of establishing their plantation crops on fallowed lands, arable cropped lands and lands supporting old unproductive or moribund plantations (Ipinmoroti, *et al.*, 2005). It is pertinent to note that such lands require being evaluated to know their suitability for sustainable coffee plantation management. This study was carried out to evaluate soils on land under long time cassava production for suitability for coffee cultivation at Iwaraja area, Osun State, Nigeria.

MATERIALS AND METHODS

The site is approximately 4ha and is on a hilly land that is sloppy down to the northeast direction with some shrub tress, scattered oil palms and rock outcrops as common features. Some portion of the site is currently cultivated to cassava on heaps while others were under fallow condition after several years of being used for cassava cultivation, which is an indication of human activities on the land. Soil samples were collected at approximately 25 meters apart along two traverse lines with first traverse at the upper slope and the second traverse at the lower slope. On each traverse line, 4 sampling points were made and at each point, 2 sampling depths, 0-30 and 30-60 cm depths were made, for a total of 16 samples. The collected soil samples were labelled and taken for laboratory processing and analysis. Soil samples were analysed for some physical, chemical and nutrient contents that are relevant to coffee production.

The soil samples were each air dried, sieved through 2 mm sieve and routine physical and chemical analysis carried out. Soil particle size distribution was by hydrometer method, while the soil pH was in soil/water ratio of 1:2.5 and read with pH- electrode Soil Total N was determined by micro-kjeldah method (Bremmer, 1996) and available P was measured by Bray 1 method (Bray and Kurtz, 1949). The organic carbon (OC) was determined by wet dichromate oxidation method (Nelson and Sommers, 1982). The exchangeable bases were extracted by 1N NH_4OAC at pH=7 and the K, Ca and Mg contents were read using atomic absorption spectrophotometer (Tel and Rao, 1982). The soil Zn, Fe, Mn and Cu were determined after extracting the soils with 0.1N HCl and the filtrate read on a Perkin-Elmer AAS (A.O.A.C., 1990).

RESULTS AND DISCUSSION

Soil physical attribute

The site soil samples showed that at 0-30 cm soil depth, gravel content ranged from 27.9-68.9% with mean value of 38.96%, while at depth of 30-60 cm, gravel content ranged from 26.97 – 83.8% with mean value of 44.53% (Table 1). The gravel content therefore increased with soil depth. Thus, the site soil is characterized with stones, pebbles and gravels. The soil textural analysis (Table 2) indicated that the soils of the site were generally sandy loam with more sand compared to the silt and clay contents. Though the clay content increased with soil depth, the soil Silt + clay contents were lower than 32% at the top soil (Table 2). This indicated that the soils will not be able to hold sufficient water for sustainable coffee cropping, especially, during the dry season (Ipinmoroti and Ogeh, 2014). There would be need for irrigation during the dry season. Due to the sloppy nature of the land, there is need for introduction of cover crops to fill the gaps between stands of coffee seedlings to protect the land against agents of erosion. Arable crops like melon, maze, rice, cocoyam and the use of plantain are common on plantation crops under a mixed-cropping system when the main crops are still in the juvenile stage of establishment (Famaye *et. al.*, 2012; Ipinmoroti *et al.*, 2007)

Soil chemical properties and macronutrient contents

The level of the site soil pH, organic C and major nutrient contents are indicated in Table 3. The values varied from point to point along the land transverse and across the slopes of the land as well as down the soil profile. The trend for each attribute showed that the soil pH ranged from 6.17-7.20 at the 0-30cm depth while it was 6.40-7.40 at 30-60cm depth (Table 3). These values were within the range of pH 5.00-7.50 that is considered suitable for coffee cultivation. However, there is need for caution to checkmate farming activities that may lead to any further increase in the soil pH in the long run. The soil organic C was 0.59-2.09 g/kg soil at the 0-30cm depth and 0.30-0.9 g/kg soil. The value was higher at the top soil level compared with the subsoil, which indicates that the soil organic C decreases down the soil profile. The very low amount of the soil organic C shows that the soil is very low in organic matter content. A good soil that will adequately support the establishment and sustainable production of coffee must have at least 3.3% soil organic C. this thus indicates the need to involve use of cultural practices that will contribute to the build-up of the soil organic C. This may be by the use of cover crops, organic fertilizers, mulching and pruning of alley crops on the field (Ipinmoroti and Ogeh, 2014; Famaye *et al.*, 2012).

Table 3: Soil chemical properties and macronutrient contents of the site soils

	D_4 = 30-60	7.40	0.76	0.09	25.07	0.32	3.50	0.63	0.30	0.05	4.80	98.96

A – D = Representative composite soil samples on the plot

The total soil N ranged from 0.01-0.14 % with mean value 0f 0.06 % at the 0-30cm depth while it is 0.05-0.11 with mean value of 0.05% at the 30-60cm depth. The amount of soil N was higher at the lower slope with mean of 0.12 % compared to the upper slope with mean of 0.06%. This indicates that certain amount of the soil N at the upper slope had been washed down the lower slope. The mean total soil N content of 0.06% is very low when compared with the critical level of 0.1% for sustainable coffee cultivation on the soil, there would be need to apply N supplying fertilizers in order to meet the N needs of the coffee plants for vigorous and healthy growth (Adeoye, *et al*., 2001; Ipinmoroti, *et al*., 2007). The soil available P was 18-24.24 mg/kg soil with mean value of 22.29 mg/kg soil at 0-30cm depth and it was 21.50-30.19 mg/kg soil with mean value of 25.18 mg/kg soil at 30-60cm depth. However, the soil available P was higher at the upper slope compared to the lower slope. In overall, the amount of the soil available P is higher than the critical value of 9mg/kg soil, which implies that, there would be no need for application of P supplying fertilizer, especially at the juvenile stage. However, for good soil health and sustainable soil P level, soil fertility management on the farm after 3 years of establishment should involve P fertilizer application based on crop removal on annual basis that should be in two split applications in June and September of the year.

The soil K content had a mean value of 0.31cmol/kg soil at the 0-30cm depth and 0.25cmolkg soil at the 30-60 cm depth. The soil K was higher at the lower slope compared to the upper slope. The mean values were lower than the soil critical level of 0.35cmol.kg soil for soils suitable for coffee cultivation. This suggests the need for application of K supplying fertilizer(s) for optimum coffee cultivation. The soil Ca content was 3.73-4.40cmol.kg soil at 0-30 cm level and 3.29-4.10cmol.kg soil at 30-60cm level, which shows that it decreased with soil depth. Irrespective of the soil depth, the soil Ca content was lower than the critical value of 8.0cmol.kg soil. Hence, there is need for Ca supplying fertilizer in order to meet the needs of coffee plants on the plot.

The soil contains 0.76-0.97cmol/kg soil of Mg at the 0-30cm depth and 0.26-0.33cmol.kg soil at the 30-60cm depth. This showed that there was a higher Mg content at the lower slope compared to the upper slope, which was in trend with the soil Ca content. It is higher in the top soil compared to the subsoil. The soil is however sufficient in Mg content and hence, the soil will not need Mg supplying fertilizer as part of the soil fertility management. However, the soil K/Mg ratio ranged from 0.27-0.49 which is lower than 2.0 expected for K and Mg nutrient balance. Hence, there is need for great amount of K fertilizer to bring the soil K/Mg to 2.0 level so that the soil will have a balance nutrient for the coffee plants. The soil Na content was 0.30-0.43 cmol/kg soil at 0-30cm level and 0.26-0.33 cmol/kg at 30-60cm depth. It was higher at the lower slope compared with the upper slope, however, the range was not high to the extent of causing any deleterious effect on coffee plants.

The soil exchangeable acidity (H^{-+} Al^{+3}) was 0.05-0.10cmol/kg soil at 0-30cm and 0.06-0.09cmol/kg soil at 30-60cm depth. The values were highly negligible and could not lead to any serious acidity threat on the field crops. Hence there is no need for any acidity control measure on the field. However, activities that can escalate acidity threat must be avoided since the soil organic C content was generally very low. The soil ECEC values decreased with soil depth but higher at the lower slope compared to the upper slope (Table 3). The values were too low when compared to 30cmol/kg soil common in tropical soils (Ayoola and Agbola, 2002). This shows that the soil organic matter must be built upon in order to increase the cation exchange sites of the soil. This will make the soil to be able to hold nutrients against leaching losses and also able to make same available to crops for optimum production on a sustainable manner.

Soil micro-nutrient contents

The soil micro-nutrient content (Table 4) showed that the lower slope had higher Mn content compared to the upper slope. On the other hand, the Fe content increased with soil depth and it was higher at the upper slope than at the lower slope. This trend was observed for the soil Cu content. The soil Zn content was 44.07-52.90 mg/kg soil at the 0-30cm level compared to 26.60-53.47 at the 30-60cm level. In all, the amount of the soil Mn, Fe, Cu and Zn contents were optimal for coffee production without any detrimental effect.

Table 4: Site soil micronutrient contents

S/N	Soil depth	Mn	Fe	Cu	Zn
		←	mg.kg		→
Upper slope					
	A_1 = 0-30	55.05	5.40	0.50	44.07
	A_1 = 30-60	117.65	11.70	0.70	53.07

B_2 = 0-30	65.10	4.30	0.49	49.02
B_2 = 30-60	42.75	18.00	0.47	30.15
Lower slope				
C_3 = 0-30	97.15	2.40	0.40	46.55
C_3 = 30-60	83.80	11.10	0.63	43.05
D_4 = 0-30	112.20	8.20	0.66	52.90
D_4 = 30-60	74.15	9.30	0.58	26.60

A – D = Representative composite soil samples on the plot

CONCLUSION

The site soil is very low in macro-nutrients that are vital for sustainable coffee production. The nutrients must be outsourced through the use of fertilizers application in order to achieve optimum growth and establishment of the coffee plants. This must majorly be by way of organic manure application and most importantly with the use of poultry manure, which is the most common and cheapest and richest source of those nutrients and organic matter to the field. It is recommended that the application of this manure could be done at 1.5 t/ha. However, the manure must be maturely cured before usage in order not to cause any injury to the coffee or any other companion crop(s).

ABSTRACT

Cashew is an important nut crop which has been generating substantial foreign exchange earnings for the country. However, its production has diminished in recent years due to lack of assessment of the soils. The objective of this study is to assess the soils formed in granite and gneiss in humid area of southwestern Nigeria for cashew production. Five profile pits were established at different physiographic positions along the toposequence in Ife Area, Osun state, Nigeria and described following the FAO/UNESCO guidelines for soil profile description. In order to examine the attribute of the soils, samples were collected, subjected to routine analysis and evaluated its potential for cashew production. The morphological, physical and chemical characteristics of the soils were determined. Suitability of the soils for cashew production was carried out using parametric approach. The result showed that the soils were very deep (127-200cm) and well drained. Soil surface textures were sandy loam underlain by sandy clay loam. The clay contents were low and increased with soil depth while sand content were high at the surface level and decrease with soil depth. The soils were acidic in nature and soil organic carbon content varied from low to high value ranging from 0.04 to 1.64%. Available phosphorus and Exchangeable bases were above the critical values needed for ideal cashew production. Suitability evaluation result showed that pedons 1, 2, 4 and 5 are presently highly suitable for cashew production while pedon 3 is moderately suitable. Potentially, all the pedons are highly suitable for cashew production.

Key words: Suitability assessment, granite, gneiss, cashew

INTRODUCTION

Cashew (*Anarcadium occidentale L.*) is one of the essential cash crops next to cocoa as export crop. It requires less intensive maintenance compare to other crops. Its various parts are of economic value such as source of food, income and medicine. Also, a source of raw materials to beverage, food and confectioneries industries (Oni, 2015). Cashew industry plays an important socio-economic role as it provides employment to people such as harvesters, transporters, processors among others. Cashew has been stated to be grown and marketed for its raw nuts, apple, processed kernel and wood. Cashew is one of the most popular nuts that have low levels of soluble and saturated fats, also contains high percentage of proteins and polyunsaturated fatty acids to reduce cholesterol levels in the blood; and high level of mineral salt (Chemonics International, 2002). Nambiar et al., (1990) reported that cashew nuts proteins are whole, each kilogram of the nut yields about 6000 calories compared to 3600 calories from cereals, 1800 calories from meat and 650 calories from fresh citrus fruits. It also has all the necessary amino acid. Low soluble sugar content (<1%) in the kernel make cashew consumers not to be vulnerable to excess calories (SasiVarma, 2002).

Researchers have developed several products from cashew nuts and these include kernel oil, roasted kernel sacks, cashew nut shell liquid; from the apple: syrup/juice, jams, wine, alcohol; from wood: firewood, charcoal, furniture and it is also use for boats building. Chemonics International, (2002) reported that the stability of cashew kernel oil is higher than that of commercial like cocoa butter, palm oil, groundnut oil. Cashew apple is highly rich in vitamin C, its content is several times higher than citrus orange. Presently, Nigeria is ranked third and fifth highest cashew-producing country in Africa and world respectively with 155,000 metric tons' production in the year 2015 (ACMR, 2015).

Cashew production currently in Nigeria is constrained by lack of adequate land evaluation system, lack of access to good quality planting material which leads to low quality, small nuts and kernel size; and high susceptibility to pest and diseases. Land suitability assessment (LSA) is the examination of a piece of land for its capability to sustain a specific agricultural use (Littleboy *et al.*, 1996). Generally, LSA for agricultural purposes includes characterization of the biophysical and ecological characteristics of a location according to the agricultural potentials of the land. It encompasses evaluating the relative edaphic-ecological requirements of the crops with the spatial edaphic-ecological conditions of a particular location. The locations where the edaphic-ecological conditions amalgamate with the crop requirements will be acknowledged as suitable. Thus, LSA consists of analysis of soil, topography, climatic and vegetation data with the intention of matching land physiognomies with crop requirements (Wang *et al*., 2006).

Inadequate information is obtainable on suitability evaluation of cashew production in spite of its high economic value, significance to populace and the economy. When adequate information is available on its land evaluation, this will ascertain optimal and sustainable production. So, the country would become the World's number one cashew nuts producer. The numerous significance of cashew tree and its long-lived perennial nature thus necessitate land suitability evaluation of its production, hence this research is imperative. The objective of this research is to evaluate the soils of Ife area and assess their suitability for cashew production.

MATERIALS AND METHODS

The study area

The study was conducted in Ife Central Local Government area of Osun State, at the Teaching and Research Farm (T&RF), ObafemiAwolowo University (OAU). The T&RF is located between latitudes 7° 32' and 7° 33'N and longitudes 4° 32' and 4° 40'E, at about 200 m above sea level. The total annual rainfall is about 1502.23 mm, predominant annual wind direction is 221.87° while the mean annual temperature is 29.42°C (NASA, 2019). The soil temperature regime in the study area is considered isohyperthermic (Amusan and Ashaye, 1991). The climate of the area is tropical with wet and dry seasons.

Field study

Five profile pits were established and geographical location of each pedon was recorded using GPS as follow: pedon 1 (latitude 7° 32' 50.8''N and longitude 7° 32' 57.3''E), pedon 2 (latitude 7° 32' 50.6''N and longitude 7° 32' 56.0''), pedon 3 (latitude 7° 32' 49.0''N and longitude 7° 32' 56.5''E) pedon 4 (latitude 7° 32' 47.2''N and longitude 7° 32' 57.5''E) pedon 5 (latitude 7° 32' 45.4''N and longitude 7° 32' 58.1''E). The five profile pits established were described according to the FAO/UNESCO (2006) procedures for soil profile description. The profile pits were described horizon by horizon for horizon depth/thickness, with the aid of a measuring tape, colour (moist) using Munsel colour Chart, texture using hand feel method while the nature of the soil structure, consistence, mottles, presence or absence of inclusions (nodules and concretions) roots and horizon boundaries were carefully documented on the field. Soil samples for bulk density determination were collected from each horizon. Multiple sub-sampling method was employed to guarantee representativeness of the samples collected from a given horizon. The soil samples collected were bagged, labeled and taken to the laboratory for physical and chemical analyses.

Laboratory analyses

Soil samples collected were air-dried, pulverized and sieved through a 2mm sieve. The less than 2 mm fraction was retained for analyses in the laboratory except bulk density determination. The following physical and chemical analyses were carried out: Particle size distribution using the Bouyoucos hydrometer method (1965) as reported by (Gee and Or, 2002).The soil pH both in distilled water and 1.0 N KCl (Thomas, 1996).Soil organic carbon by the Walkley-Black (1934) method using the chromic acid digestion as reported by (Darrell *et al*., 1994).Available phosphorus (Bray and Kurtz, 1945 as reported by Kuo,1996).Total nitrogen using the micro-Kjeldahl digestion method (Bremner, 1996).Exchangeable cations were extracted with 1.0 N NH_4OAc solution at pH 7, Mg and Ca were determined by AAS and K and Na by flame photometer (Thomas, 1982) modified by Jones (1998).Cation exchange capacity by 1.0 N ammonium acetate (NH_4OAc) at pH 7 (Sumner and Miller, 1996).Exchangeable acidity was determined by 1.0 N KCl and titrated with 0.05 N NaOH and HCL solutions to measure total acidity ($Al^{3+}$and H^+) concentrations respectively (Mclean, 1965) while effective cation exchange capacity (ECEC) was computed by the summation of exchangeable cations and exchangeable aluminium.

Land evaluation

Following the method of Sys *et al*., 1993 suitability of the soils for cashew production were assessed using parametric approach. Each pedon was assigned to suitability classes by matching their characteristics with the requirements for cashew production (Table 1). Each feature was ranked using Square root method equation:

IP = A x √ ((B/100) x (C/100) x … x (F/100)). where; IP is the index of productivity, A is the overall lowest

ISSN: 2814-0508

characteristic rating and B, C…F are the lowest characteristic ratings for each land quality group (Udoh *et al*., 2006). Current and potential index of production for each pedon was calculated. In each pedon, only one member of each of the five land quality groups (climate(c), topography (t), wetness (w), soil physical characteristics(s) and fertility (f)) were used in the calculation because there were strong correlations among members of the same group (Ogunkunle 1993).

RESULTS AND DISCUSSION

Morphological and physical properties:

Pedon 1: It occupies the upper slope position of the landscape. The soils were deep and well drained. The colour varies from brown (10YR 5/3) with silt loam texture, coming down to strong brown (7.5 YR 4/6) gravelly sandy clay loam (SCL) texture; to red (2.5 YR 5/8) with SCL texture and reddish yellow (5 YR 6/8) with silty clay loam texture in the subsoil. Duncan, (2001) reported that soil texture is critical for cashew production, its production relates to well-drained soil with a sandy loam texture. Widiatmaka *et al*. (2014) also stated that cashew seems to flourish in a free-draining and light-textured soil. The soils have moderate medium crumb on the surface coming down to moderate medium sub-angular blocky structure in the subsoil with diffuse and wavy horizon boundary. Bulk density values ranged from 1.33 on top to 1.71 g/cm^3 in the subsoil. These bulk values are ranked low and will not harm crop production. Bulk density is a reflection of texture and structure. Aubertin and Kardos (1965) reported that a normal range for sand is 1.2 to 1.8 mg/m^3; clay is 1.0 to 1.6 mg/m^3 with potential root restriction occurring at ≥ 1.4 mg/m^3 for clay and ≥1.6 mg/m^3 for sand. Generally, the studied soils are not expected to cause any obstacle to seedling emergence and root activity (water and nutrient uptake).

Table 1: Land use requirements for cashew cultivation

Land, soil and climatic characteristics	S11 (100%)	S12 (95%)	S2 (85%)	S3 (60%)	N1 (40%)	N2 (25%)

Source: Modified from Sys (1985).

Pedon 2: It occupies upper slope to middle position on the landscape. It is the deepest and well drained. On the soil surface, the texture is sandy loam, structural aggregate is moderate; moist consistence is loose while wet consistence of the soils is not sticky, not plastic with common fine, very fine root distribution. Soil colour range from dark brown (7.5 YR 3/2) at the surface to reddish yellow (7.5 YR 6/8) at sub soil. Bulk density values ranged from 1.13 g/cm^3 at the surface to 1.62 g/cm^3 at subsoil. These values are rated low as reported by Soil Survey Staff (2006) that a value of 1.85 g/cm3 could hinder penetration of plant roots.

Pedon 3: It occupies the middle slope on the landscape, mostly deep and well drained. The soils have a very dark grey colour (7.5 YR 3/1) with gravelly sandy loam texture on top coming down to yellowish red (5 YR 5/6) with gravelly sandy clay loam to red (2.5 YR 4/6) with slightly gravelly, sandy clay loam to red (2.5 YR 5/6) with slightly gravelly clay. The soil has a weak fine crumb on the surface coming down to moderate medium sub-angular blocky structure in the subsoil. Very few very fine and coarse roots occurred frequently in the pedon. Bulk density values ranged from 1.46 g/cm^3 at the surface to 1.75 g/cm^3 at subsoil.

Pedon 4: The soils were moderately deep and well drained. The soils have sandy loam texture with dark brown (7.5 YR 3/2) at the surface coming down to reddish brown (5 YR 4/4) gravelly sandy clay to strong brown (7.5 YR 5/8) gravelly sandy clay and red (2.5 YR 5/8) slightly gravelly clay at subsoil. The soils have a fine weak crumb on the surface coming down to moderate medium crumb at subsurface, very fine, few medium roots are common. Bulk density values ranged from 1.39 g/cm^3 at the surface to 1.61 g/cm^3 at subsoil.

Pedon 5: It occupies the lower slope portion on the landscape. The soil is poorly drained but very deep. The colour varies from dark brown (7.5 YR 3/2) with gravelly sandy clay loam to brown (7.5 YR 5/4) gravelly sandy loam; to strong brown (7.5 YR 5/8) slightly gravelly clay loam; to reddish yellow (5 YR 6/8) gravelly sandy clay and reddish yellow (7.5 YR 6/6) slightly gravelly sandy clay at subsoil. Structural aggregate is moderate, very few fine roots are common. On the soil surface moist consistence is very friable while wet consistence is non sticky, non-plastic. At subsoil, they are friable, sticky and plastic respectively. Bulk density values ranged from 1.55 g/cm^3 at the surface to 1.86 g/cm^3 at subsoil.

The soil's chemical properties

The soil pH ranged from extremely acid to moderately acid in water (4.4 to 5.6) and from extremely acid to strongly acid (3.6 to 5.1) in 1N KCl solution. The values fluctuate irregularly with depth. Aliyu, (2007) stated that cashew can grow best in well drained sandy soils with pH ranging from 4.5 to 6.5. Factors suggested to be responsible for the acidic nature of the soil could be nature of the parent rock, high rainfall which made the soil to be fragile and vulnerable to leaching of exchangeable bases from the soils.

The percent organic carbon was low to high ranging from 0.04 to 1.64%. The low values might be connected with the decomposition of organic matter due to high temperature, continuous removal of crop residues and bush burning in the study area. Lal (1991) reported that the high OM content at the surface horizon of most of the pedons could be ascribed to more decomposable organic materials in the surface soils. This high content of OM at the surface soil was not unexpected since it is at the soil surface that litters accumulate which subsequently decayed and mineralized to yield OM (Olayinka, 2009).

Phosphorus is a fundamental part of the genetic material of the cell nucleus in cashew. Its deficiency causes stunting, delayed maturity and shriveled seeds (Aikpopodion *et al.,* 2009). Available phosphorus content of the soils was above the critical value of 10 ppm recommended for most cultivated crops in the area as stated by Obigbesan, (2009). The values ranged from 12.34 to 34.50 ppm.

The calcium content of the soils ranged from 0.91 to 3.17 cmol/kg. All the pedons examined had their exchangeable Ca^{2+} content greater than 0.8 cmol/kg which is the critical value for Ca^{2+} in cashew production (Egbe *et al.,* 1989). Magnesium content of the soils varied from 0.34 to 1.04 cmol/kg soil. The soil Mg^{2+} values for each pedon were above the critical value of 0.08 cmol/kg for ideal soils of cashew. Exchangeable potassium (K) contents ranged between 0.06 and 0.22 cmol/kg. Potassium contents of the studied soils were adequate for cashew since most of the values were higher than the critical level (0.12 cmol/kg) of potassium for cashew production as reported by Egbe *et al.* (1989). Exchangeable Na remained almost constant in all the pedons. The values were less than 1 cmol/kg, this indicates that the studied soils were not sodic (EUROCONSULT, 1989). In general, the result of the chemical analysis of the studied soils revealed that the soils were not deficient in essential macronutrients elements needed by cashew for ideal production.

Land suitability evaluation

Land evaluation was carried out using parametric method (Sys *et al.,*1993). Table 1 shows the factor rating of land use requirements for cashew indicating S1 (highly suitable) rated 100%, S2 (moderately suitable rated 85%, S3 (marginally suitable) rated 60%, N1 (presently not suitable) rated 40% and N2 rated 25% (permanently not suitable). The suitability class of a soil is that indicated by its most limiting characteristics. Table 2 shows the summary of land suitability classes for actual/current suitability class and potential suitability class (i.e after soil fertility improvement). The assessment of the soils for crop production encompassed the use of properties that are permanent in nature and that cannot be altered or modified without excessive cost. Such properties include soil depth, slope, drainage, texture and amount of coarse fragments. These properties are known to generate some kind of hindrance to crop production. Chemical properties that are usually considered (e.g. fertility) can be changed by minor improvement (Sys, 1985).

The annual rainfall of the study area approximately 1502 mm for all the pedons made the soil fall into suitability class S1 and rated 100% due to sufficient rainfall requirement for cashew production (1600-2000 mm) as detailed in Table 1. The mean annual temperature (29.42^{o}C) was within the class S1, rated 100% and therefore highly suitable for cashew production. All the pedons are well drained. Therefore, with reference to flooding and drainage, the soils fall within S1 suitability class, rated 100 and highly suitable for optimal yield of cashew. Similarly, in term of coarse fragment, all the pedons were considered as S1 because there were no stones and gravels which can pose an impediment to root development and movement. Average soil rooting depth and textural class in all the pedons fall within high suitability class S1 and was scored 100. When organic matter was used as an evaluation criterion, all the soils are highly suitable (S1). With reference to base saturation, all the pedons fall into S1 class.

In summary, the result for the actual suitability showed that pedons 1, 2, 4 and 5 were highly suitable while pedon 3 was moderately suitable for cashew production. The potential suitability which is a reflection of what is expected after effective soil fertility management is highly suitable (S1) for all the pedons. This implies that little fertility management practices are required to achieve optimum cashew production on the studied soil. Therefore, the soil is recommended for cashew production.

CONCLUSION

Considering the result of the studied soils, the study revealed that there is need for little fertilizer supplement for optimal productivity of cashew. The soils were highly suitable. Fertility was not a major limitation likewise climate, topography, physical soil characteristics and wetness.

ABSTRACT

The soil quality index (SQI) for Mango orchard was developed to meet the nutritional criteria of the crop, the increasing demand for the production and quality of mango using a range of soil indicators. The objective of this study was to develop SQI for assessing the effects of current arable management practices on soil quality for tropical soils. Soil samples were randomly collected and analysed for physical, chemical and microbial properties. Principal component analysis was used to determine a minimum data set (MDS). Soil pH, microbial biomass carbon, bulk density, available phosphorus, extractable copper, and cation exchange capacity were identified as the MDS. The SQI was rated low, this implies that mango orchard has a negative influence on soil quality. The method developed in this study can be used to provide a practical, quantitative tool for assessing soil quality under any agricultural management systems.

Key words: Principal component, Data set, Indicator, Samaru

INTRODUCTION

Soil quality is an account of the ability of soil to provide ecosystem and social service through its capacities to perform its function and respond to external influences. Karlen et al. (2001) define soil quality as the capacity of soil to function within the ecosystem and land-use boundaries, to sustain productivity, maintain environmental quality, and promote plant growth as well as animal health. Soil quality is a complex functional concept and cannot be measured directly in the field or laboratory but can be inferred from soil characteristics (Demessie *et al*., 2012). A range of soil parameters or indicators has been identified to estimate soil quality. However, soil quality is often related to management goals and practices. Soil quality may be affected by land-use type and agricultural management practices because these may cause alterations in soil's physical, chemical and biological properties, which in turn results in a change in land productivity (Gelaw *et al*., 2015). Soil quality assessment uses tools to quantify and evaluate the effects of soil management practices (Armenise *et al*., 2013), land use type (Rahmanipour *et al*., 2014) and cover crop (Navas *et al*., 2011) on soil function.

MATERIALS AND METHODS

Location of Study of Area

The IAR experimental farm is located between latitude 11°10'30''N and 11°11'40''N and longitudes 007°36'30''E and 007°38'6'' E, within Sabon gari Local Government Area of Kaduna State The study area has an altitude of 686 meters above sea level. The geological Survey indicated that the study area is located within the undifferentiated Basement complex parent material. (Wright and McCurry, 1970).

Fieldwork

To achieve the objectives of the study, surface soil from 0-20cm were collected from the mango orchard and a natural grass land considered as control in this experiment.

Laboratory Analysis

Soil samples collected were air-dried in the laboratory, crushed with porcelain pestle and mortar and sieved to remove material greater than 2mm (gravel). Percent gravel to total soil was calculated. The less than 2mm fractions were subjected to physical and chemical using procedure described in IITA Manual (1979). Microbial Biomass Carbon and Nitrogen were determined by the chloroform-fumigation method (Okalebo *et al*., 2001).

Soil quality determination

Soil quality was determined following three steps listed below: (1) most critical soil quality indicators, i.e., minimum data set (MDS) of indicators that best-represented soil functions were selected; (2) the indicators were scored; and (3) the scores were integrated into final Soil Quality Index (SQI) (Andrews *et al*., 2002).

Statistical Analysis

Data analysis was carried out using SAS software (SAS Institute, 1990). Principal component analysis (PCA) was carried out from a subset of variables using the PRINCOMP procedure. Lastly, the indicators retained within the principal component (PC) were then subjected to correlation analysis using CORR procedure.

RESULTS AND DISCUSSIONS

The result obtained from Principal components analysis (PCA) (Table 1) indicated that five (5) components of principal component (PC) had an eigenvalue >1, thus, explained 100% of the variability of the data. Soil pH and extractable Cu, had the greatest loading variables under PC 1 and exchangeable Mg, K, exchangeable acidity, cation exchange capacity (CEC), total porosity, moisture at field capacity and sand had a loading value within 10% of the greatest value, but pH and Cu were selected because their correlation coefficient < 7 (Table 2). In PC 2, CEC had the highest loading value and only aggregate stability (MWD) had a loading value within 10% of the greatest value. All the variables selected when correlated had a coefficient of correlation greater than 7 thus, were considered redundant hence, CEC was selected. In PC 3 Ca had the highest loading value and only available phosphorus (AvP) had a loading value within 10% of the greatest. exchangeable Ca and AvP had a correlation coefficient >0.7 (Table 2) thus, exchangeable Ca was retained as valuable indicators for PC 3. Microbial biomass carbon (MBC) was identified from PC 4 on the same bases. In PC 5, Bulk density has the highest loading value and soil pH and Extractable manganese had a loading value within 10% of the greatest value. Bulk density, soil pH and Extractable manganese had a correlation coefficient >0.7 (Table 2) thus, bulk density was retained as valuable indicators. Therefore, pH, Cu, CEC, Ca, MBC and bulk density were selected as the MDS. The contribution of the indicators selected in Table 1 in forming the soil quality indicator (SQI) was NG 42.37

The result obtained from principal component analysis (Table 1) shows pH, MBC, bulk density, AvP, extractable Cu, and cation exchange capacity were most important parameters for the evaluation of soil quality in the area. The concentration of the above mention parameters was controlled by the presence of soil organic carbon (SOC). SOC had been reported by many authors (Oluwatosin *et al*., 2003, Singh *et al*., 2014) to improve the levels of some of the soil quality indicators such as aggregate stability, pH, microbial biomass carbon, compaction and reduce erosion. soil organic matter also influences soil function, determining soil nutrient status, water holding capacity and susceptibility of soil to degradation (Oluwatosin *et al*., 2003). The soil quality index the orchard was rated "low" category (SQI < 50%). Low soil quality in mango orchard (47.69), could be attributed to land management practices.

CONCLUSION

Quantifying the effect of mango cultivation on soil quality is essential to better understand the role of mango cultivation in land degradation. Soil quality of a mango orchard in IAR farm at Samaru was evaluated using soil quality index (SQI) methods. The SQI was calculated using a MDS selected using PCA and norm values of six indicators which gave 100% of the variance of the total data set. The value of the SQI indicated that the soils were of low quality

DYNAMICS OF PHOSPHORUS FIXATION IN SELECTED TEA CROPPED SOILS ON THE MAMBILLA PLATEAU IN TARABA STATE, NIGERIA

Aikpokpodion, P.E.

Soils and Plant Nutrition, Cocoa Research Institute of Nigeria, P.M.B. 5244, Ibadan, Nigeria,

Corresponding author's e-mail: paulaikpokpodion2@yahoo.com

ABSTRACT

Phosphorus has been found to be the most limiting macronutrient in tea cropped soils of the Mambilla Plateau. For appropriate fertilizer recommendation and adequate application to be achieved, the fate and chemistry of phosphorus in the acidic tea soils of the plateau must be understood. Top soil at 0-20cm depth was collected in selected tea farms in Kusuku and Nguroje. The samples were processed and incubated with phosphorus solution of 35, 70, 140, 280 and 560mg P kg^{-1} soil for a period of 3, 15, 30, 45 and 60 days. Result showed a progressive P fixation in both soils from the beginning of the experiment to the end. However, desorption of the adsorbed phosphorus was noticed in both soils within the period of incubation suggesting physisorption controlled mechanism. At the expiration of the experiment, more than 90% of the applied phosphorus was fixed in both soils. P fixation was negatively correlated with soil pH and positively correlated with Fe, Mn, Zn, Cu, Silt and clay at significant level. Kusuku soil with higher values of Clay, Mn, Fe and Zn exhibited higher P fixation capacity than Nguroje soil. The high P fixation capacity of Kusuku and Nguroje soils will reduce the amount of phosphorus readily available for tea uptake after fertilizer application. Though the adsorbed P will eventually become bioavailable, provision for the fixed P should be made at the time of fertilizer recommendation.

Key words: Tea, Phosphorus, fixation, fractional recovery

INTRODUCTION

Tea (*Camellia sinensis*) is the most widely consumed beverage in the world and ranked second to water as the most consumed drink worldwide (Ho *et al,* 2009). Production of tea is steadily on the increase globally. Tea has a significant role as a health drink. It is cultivated in fifty countries with major producers being India, China, Kenya, Sri Lankar, Vietnam, Turkey, Indonesia and Iran (FAO, 2014). Nigeria is one of the countries in Africa that produce tea. Tea cultivation in Nigeria is mainly done on the Mambilla Plateau in Sardauna Local government area of Taraba State in the Northern part of the country. Report of Food and Agriculture organization (FAO) showed that the world production of tea stands at 5.56 million tons with plantation hectarage of 3.80 million (FAO, 2014). In spite of the fact that tea's nativity is traceable to the humid tropics and subtropics, it has been found to have a very wide adaptability and thus can be cultivated in a wide range of climatic conditions and soils. It is also grown across a range of altitude from sea levels up to about 2,200 meters above sea level. Tea cultivation requires a minimum rainfall of 1,200mm per year but thrives optimally with annual rainfall of 2,500 – 3,000Mm.

Currently in Nigeria, tea cultivation for commercial purpose is only on the Mambilla Plateau in Sardauna local government area of Taraba State. This is due to the favorable climatic and soil conditions for tea cultivation on the plateau. The climate of the plateau is semi temperate in nature. Outdoor temperature taken by 7.00 am hardly exceeds 19°C. It can be as low as 13°C during winter. At noon, temperature ranges between 14 and 30°C depending on the period of the year (Aikpokpodion, 2020). Mambilla Plateau has elevation of 1500-2000 meters above sea level with an annual rainfall of 2000-3000mm.

In recent time, the yield of tea crop on the Mambilla Plateau has been on a decline. This might in part be a consequence of the low level of some macro nutrients in the soil. The report of Obatolu (1984) showed that phosphorus was the most limiting macronutrient in kusuku tea grown soil. A recent nutrient auditing carried out by the author on the various tea plantations on the Mambilla plateau showed that all the sampled tea farms had available P lower than 15mg/kg which is the critical level of P required for tea cultivation. The low available P content of the soils could be due to inherent acidic nature of the soils which promotes P fixation in soil and makes it unavailable for tea plant uptake. Information obtained from the farmers indicates that, none of the small scale tea farmers applies fertilizer in replenishing the soil. Rather, they solely depend on the inherent nutrients in the soils for tea sustainability. On the other hand, the Mambila Beverage Company Kakara, the producer of

Highland tea applies N:P:K 15:15:15 fertilizer occasionally on its tea plantations. The fertilizer application however, shows little or no difference on tea yield probably as a result of nutrients fixation in soil.

For adequate phosphorus fertilizer application to be obtained in acidic soils with high potential for P fixation, it becomes necessary to understand the chemistry and fate of applied phosphorus in such soils in order to avoid inappropriate fertilizer recommendation and application.

In order to achieve this, the study was carried out to examine the dynamics of applied Phosphorus fertilizer with respect to its fixation and bioavailability in tea cropped soils.

MATERIALS AND METHODS

Soil Sample Collection

Top soil samples were collected with soil auger at the depth of 0-20cm from selected tea farms at Kusuku and Nguroje in May, 2019. The soil samples were air-dried and sieved with 2mm sieve in the Analytical laboratory of the Mambilla Substation, Cocoa Research Institute of Nigeria, Kusuku, Taraba State.

Fractional recovery

Liquid phosphorus fertilizer was prepared in the analytical laboratory of Mambilla Substation in accordance with a modification of Hunter, (1975) method. To obtain 700ml mg PL^{-1}, 1.54g of KH_3PO_4 was prepared in 500ml of distilled water as stock solution. Five (5) sorption treatment solutions were prepared by diluting 10, 20, 40, 80 and 100ml of the stock solution to 100ml. A 6.0g of each soil sample was weighed into 80ml plastic cups in tray racks and 3ml of each of the five sorption solutions was added to the soil samples to arrive at 35, 70, 140, 280 and 560mg P kg^{-1}soil accordingly. Distilled water was thereafter added to the soil samples to keep the soil moisture at field capacity. The experimental set up was made in triplicate.

The treated soil and the control samples were incubated for a period of 3, 15, 30, 45 and 60 days under moist condition by adding distilled water when necessary. At the end of each incubation period, the treated samples and the counterpart control samples were air-dried and 3g of each subsample extracted with 18ml of Mehlich 3 solution for phosphorus determination. Colorimeter was thereafter used to quantify the recovered phosphorus after soil incubation. Fractional recovery and P fixation were calculated from the data obtained from P extraction. Obtained data were subjected to statistical analysis to evaluate the parameters that control P fixation in the studied soils.

RESULTS AND DISCUSSION

Fractional recovery and P fixation

Fractional recovery of P in Nguroje soil treated with 35mg Pkg^{-1} soil decreased from 0.038 at 3 days after incubation to 0.0013 at 60 days after incubation (Table 1). Result showed a progressive reduction in phosphorus recovery as incubation period increased. It implies that, as the incubation period increased, phosphorus fixation also increased. Similarly, the fractional recovery of P in Kusuku soil treated with 35mgPkg^{-1} soil also decreased from 0.0191 at 3 days after incubation to 0.0006 after 30 days of incubation. Result showed an increase in P recovery in Kusuku soil at 45 days after incubation. It suggests a desorption of certain fraction of initially fixed P in the soil matrix.

Table 1: Fractional recovery of P in investigated soil samples

Mg P/kg soil	Fractional recovery Nguroje 3 days	Kusuku	Nguroje 15days	Kusuku	Nguroje 30days	Kusuku	Nguroje 45days	Kusuku	Nguroje 60days	Kusuku

140	0.0238	0.0047	0.0026	0.0019	0.0035	0.0073	0.0034	0.0021	0.0024	0.0010
280	0.0202	0.0060	0.0052	0.0013	0.0046	0.0096	0.0040	0.0036	0.0038	0.0028
560	0.0048	0.0024	0.0026	0.0060	0.0032	0.0054	0.0023	0.0020	0.0031	0.0018

The observed progressive reduction in P fractional recovery with incubation time is in consonance with the report of Ogunlade *et al*. (2011) and Mallikarjuna *et al.* (2003). The decline in phosphorus recovery was indicative of fixation of a proportion of applied phosphorus in soil solution. A progressive decrease in P fractional recovery from 0.0286 to 0.0016 during 3 and 60 days after incubation respectively was also observed in Nguroje soil treated with 70 mg P kg^{-1} soil. The scenario was however different in Kusuku soil in which progressive decline in P recovery was only sustained in the first 15 days after incubation. Phosphorus fractional recovery declined from 0.014 at 3 days after incubation to 0.0030 at 15 days after incubation. The rate at which P fixation proceeds in soils is an important factor to be considered when assessing P availability to the growing plants. The observed increase in P fixation with reaction time is in agreement with the report of Ghani and Islam (1946) in which P fixation increased from 45% and 85% at 6 hours after incubation to 70 and 95% respectively 6 weeks after incubation in soils of Dacca (pH 5.2) and Berhampur (pH 4.6). Evaluation of phosphorus fixation with reaction time shows a rapid adsorption 96.20 and 98.09% in Nguroje and Kusuku soils respectively at three days after incubation. According to the report of Gupta, (1965) most of the applied soluble P was fixed up in 24 hours but gradually increased up to 30 to 45 days in soils depending upon the type of soil and thereafter remains constant. Desorption of adsorbed P was observed at 30 days after incubation which resulted to increase in P fractional recovery (Table 1). The redistribution of P in terms of desorption that took place at 30 days of P treatment indicates that, a proportion of phosphorus that was adsorbed between 3 and 15 days of treatment was released back into soil solution for tea uptake. This suggests that, phosphorus chemistry in soil is dynamic and not static. As the concentration of P in solution increased beyond70 $mgkg^{-1}$, a progressive decline in P recovery with time reached a climax at 15 days after incubation in both Nguroje and Kusuku soils. The decline in P adsorption in both soils at solution P concentration of 70 $mgPkg^{-1}$ soil suggests saturation of sorption sites on the soil surfaces. Phosphorus fractional recovery was lower in Kusuku soil compared with Nguroje soil. This implies higher phosphorus fixation in Kusuku soil.

In acidic soils of Baruijpur in West Bengal, Basu and Mukerjee (1972) reported a gradual adsorption of phosphorus up to 5 days before reaching a steady state at 18 days after incubation. In alluvial soils of Madhaya Pradesh, P fixation increased with time up to 60 days before reaching a steady state (Dravid and Apte, 1975). The first stage where P fixation is rapid is attributed mainly to exchangeable Al and Ca ions while the second stage of slow P fixation is attributed to the non exchangeable Al presumably dissociated from the non exchangeable sites (Kanwar and Grewal, 1990).

Clay and clay minerals factor in P fixation

Clay fraction of soil is the main site of phosphorus fixation. The nature of clay minerals is also a factor that determines the capacity and intensity of phosphorus fixation in any soil. Phosphorus fixing capacity of the clay minerals is mainly due to the replacement of OH ions from the clay minerals surface and reaction with soluble Al originating from the exchange sites and from the lattice dissociation of clay minerals to form insoluble P compounds. Phosphorus is retained in soil to a greater extent by clays of the 1:1 type (Kaolinite) than the 2:1 type clays (montmorillonite, illite, vermiculite) (Idris and Ahmed, 2012). According to Dean (1949), Fe and Al appear to be the most likely soil constituents that fix P by chemical precipitation in acid soils. Hydrous oxides of Fe and Al have the ability to fix phosphate through adsorption on their surfaces. They occur in soils as discrete particles or films on other soil particles. They occur in the form of amorphous and crystalline hydroxyl compounds in soil. However, when aluminum and iron oxides in soil are less crystalline, the phosphate fixing capacity of the soil increases due to greater surface area available for adsorption. On the other hand, crystalline hydrous oxides fix more phosphate in soil than layer silicates.

Fixation of nutrients in soil is hardly ascribed to a single mechanism or a single soil constituent due to the complex and multi-components nature of soil matrix. However, the higher P fixation in Kusuku soil compared with Nguroje soil may not be unconnected with the higher clay content of Kusuku soil compared with Nguroje soil. Result (Table not shown) showed that Kusuku soil had 340g of clay per kg soil while Nguroje soil had 160mg clay per kg soil. In addition to higher clay content of Kusuku, the soil was also higher in Fe (17$mgkg^{-1}$) than Nguroje soil (14.65$mgkg^{-1}$). Phosphate ions are chemically unstable in soil solution and readily react with oxides and hydroxides of Al and Fe found on clay surfaces of acidic soils (Bolland *et al.,* 2003).

ISSN: 2814-0508

Correlation of soil physicochemical properties of the investigated soils with fractional recovery showed that P fixation increased significantly with clay, Fe, Zn and Mn. In a similar study conducted by Ogunlade *et al*., (2011), it was reported that P fixation increased with clay, organic carbon, Fe and Mn in selected cocoa soils in Nigeria. Thomazi *et al*., (1990) reported that Fe oxides and clay were the main factors contributing to P fixation in soils. Owusu-Bennoah and Acquaye (1989) report showed that phosphate sorption was highly correlated with clay and free Fe_2O_3.

The sesquioxides present in the free and hydrated state also determine P fixation in acid soils. Certain reports have validated the influence of sesquioxides on P fixation. Raychaudhuri and Mukerjee, (1941) reported an increase in P fixation with increase in HCL extracted sesquioxides in red soils. Ghani (1943) reported a considerable reduction in P fixing power of an acidic soil through de-activation of Fe and Al by means of 8-hydroxyquinoline. In addition, an account of Ghani and Islam, (1946) showed that 90% of fixed phosphate in soil was recovered as Fe and Al phosphate.

Other chemical constituents of the soil that might have enhanced higher P fixation in Kusuku soil compared with Nguroje soil is the Ca and Mg contents of the soil. Pearson correlation showed that phosphorus fixation increased with Ca and Mg in Kusuku and Nguroje soils significantly (P = 0.01). Calcium content of Kusuku soil was thrice the value of Ca in Nguroje soil while the value of Mg in Kusuku soil was twice that of Nguroje soil. The nature of the exchangeable Cations present on the colloidal complex of the soils plays an important role in P fixation. Patel and Viswanath, (1946) reported an increase in P fixation capacity with the increase in exchangeable Ca, exchangeable bases and total Cation Exchange Capacity. The exchangeable Ca ions act as bridge between phosphate ions and clay surfaces. According to Kanwar and Grewal, (1990), about 30% of P fixation in acidic soils of Himachal Pradesh was due to exchangeable Ca and Mg.

ABSTRACT

Conventional soil sampling methods currently treat cocoa plantation homogeneously ignoring the natural inherent variability of soils and crop conditions. Site-specific crop management or precision agriculture has been proposed as a means of coping with spatially variable soil properties that affect crop yield. Soil electrical resistivity (ER) method to determine soil properties under cacao plantation was evaluated at Cocoa Research Institute of Nigeria. Omega resistivity meter was used to generate soil apparent resistivity of 120 cocoa trees in-situ using the Wenner configuration and PMS714 moisture meter was used to determine moisture in-situ. Soil samples were collected for baseline laboratory analysis. Data collected was subjected to correlation, non – linear and linear multiple regression analysis using Origin PRO V.8.1 statistical software. It was observed that soil electrical resistivity (ER) significantly correlated with some soil properties such as; bulk density, moisture content, soil organic matter, P, K, Ca with a correlation coefficient (r) of 0.65(P<0.01), -0.61(P<0.05), -0.69(P<0.01), -0,72(P<0.01), -0.61(P<0.05), and -0.67(P<0.01) respectively. Therefore, monitoring soil productivity and management of large agricultural field with soil resistivity methods rather than the conventional methods which is expensive, time consuming, hazardous and tedious.

INTRODUCTION

Cocoa production thrives in tropical environment and a source food and income millions of farmers across Africa, Latin America, the Caribbean and Asia. Cocoa grows well in loamy soils, well deep, well drained and good moisture holding capacity soils with pH range of 5.0-7.5. Cocoa production is mainly impeded by drought, diseases and nutrient status of the soils. Methods of determining soil properties affecting cocoa yield is time-consuming, cumbersome and costly (Asowata *et al*., 2017). Recently, soil electrical resistivity method of predicting soil properties influencing growth and yield of crops has been introduced into precision agriculture. The apparent electrical resistivity (ERa) measurements of soil can be considered as a proxy for the variability of soil physical properties (Banton *et al.,* 1997). The measurement of apparent soil electrical resistivity (ERa) is a technology that has become an invaluable tool for identifying soil physical and chemical properties influencing crop yield (Corwin *et al*., 2003).

The use of precision agriculture that is based on chemical and physical properties of the soils requires dense sampling to determine spatial variability in the field (SILVA et al., 2010). A decreased density of sampling can lead to errors in estimating the spatial variability of soil nutrients and, consequently, errors in recommendations. With the aforementioned modern methods, spatial variability within a field could be documented under various crops (Corwin et al., 2003). Dabas *et al*., 1994 used soil electrical resistance to identify areas of poor crop growth in a field by precise electrical soil mapping. Soil resistivity is the property of the soil that impedes or resists the flow of electric current through the soil. There is little or no information as regard cocoa plantations and soil electrical resistivity technique of identifying soil properties influencing cocoa yield. Thus, the objectives of this research were to determine the correlation between apparent soil electrical resistivity and soil properties under cocoa production system.

MATERIALS AND METHODS

Site description

The study site is about one-acre plot located in the cocoa seed garden field at Cocoa Research Institute of Nigeria, (latitude 7° 13' 0287"N, longitude 3° 51' .685"E) with about 1320 mm annual rainfall and average daily temperature of 30°C. The experimental area is geologically underlain by undifferentiated basement complex rocks in undulating surfaces with sparse rock outcrop. The soils are deep, well drain sandy loam surface soils over gravelly sandy clay loam subsoil. The cocoa plantation experimental set up is a randomized complete block design with eight (8) hybrids cocoa variety's' trees selected as treatments and replicated three times. Soil samples

ISSN: 2814-0508

were collected at a depth of 0 to 30cm for laboratory analysis. Soil Electrical Resistivity survey at electrode spacing of 30cm and a depth of 30cm of investigation based on wenner configuration (Fig.1) was conducted using Omega resistance meter and PMS714 soil moisture meter was used to determine the soil moisture content per tree in-situ as seen in plate 1, and the cocoa trees were also geo-referenced.

In theory, apparent electrical resistivity (ρa) of a material is defined as follows:

$$\rho a = \frac{A\Delta U}{LI} \text{ (ohm m)} \quad 1$$

$$\rho a = \frac{K(\Delta U)}{I} \quad 2$$

$$K = 2\pi a \quad 3$$

Where A is the cross sectional area, I is current, L is the length of wire, K is the geometric factor and ΔU is the potential difference generated within the soil. The potential difference provides information of about the surface and subsurface soil heterogeneity and their electrical properties

Plate 1: A set up of soil electrical resistivity and soil moisture survey under cocoa plantation in-situ

RESULTS AND DISCUSSION

Electrical resistivity (ER) of the soil under cocoa plantation at CRIN

The electrical resistivity (ER) values for soils under various hybrid cocoa varieties are presented in Table 1. The ER values varied across cocoa varieties. Tc-5 gave the lowest ER. Also, soil under Tc-5 plots had the highest soil moisture content as ER strongly depends on soil moisture due to the fact that good moisture content keeps the nutrient in ionic form (soil electrical charge density) responsible for soil electrical resistivity. Soil moisture negatively correlated with soil electrical resistivity, the negative correlation implies that an increase in the value of the soil property leads to a decrease in the measured ER and vice versa. Table 2, also shows a significant negative correlation between soil moisture and soil electrical resistivity.

Table 1: In-situ soil electrical resistivity (ER) under cocoa plantation at CRIN

Correlation between soil properties and electrical resistivity (ER) under cocoa plantation

Multiple linear regressions were carried out to establish models showing relationship between ER and soil properties**.** The soil electrical resistivity values varied across cocoa varieties with some positive and negative correlation with soil properties. Soil properties that significantly correlated with ER under a variety may not be significant with ER under another variety except for soil moisture content which was observed to have a significant negative correlation with the ER under all the varieties. (Corwin *et.al.,* 2003) obtain a significant positive correlation between soil moisture content and soil electrical conductivity ECa, (ECa=1/ER). This current study revealed significant correlation of electrical resistivity measured in-situ with many soil properties-mainly soil moisture content, pH, texture, bulk density, SOM, P, and Ca as seen in Table 3.

Electrical resistivity relates well to texture, salinity and water content (major drivers), organic matter, CEC, Avail. P etc (proxy) and water, temperature and bulk density (temporal effects). Soil electrical resistivity response is dominated by transient soil properties (moisture and temperature) (Sunshine *et al.,* 2014). Soil temperature influences the rate of decomposition of organic matter and consequently affects nutrient availability in soil (Oshunsanya, 2011). The prediction model of soil properties from ER fitted into different equations for all the eight cocoa varieties. Table 4 shows that Quadratic, Cubic and power equations was best for Tc-5, Tc-6 while other varieties fits into one or more equations respectively.

CONCLUSION

Soil electrical resistivity is a measure of several soil properties. Nevertheless, at this particular study site, ER was useful indicators of soil properties. Some properties have positive correlation with soil electrical resistivity while some were negatively correlated. The negative correlation implies that an increase in the value of the soil properties leads to a decrease in the measured ER and vice versa. While the positive correlation means an increase in the soil properties leads to an increase in the ER. Soil properties that significantly correlated with ER under a variety may not be significant with ER under another variety except for soil moisture content which was observed to have a significant negative correlation with the ER under all the varieties and this conformed with significant positive correlation between soil moisture content and soil electrical conductivity (ECa) (Corwin *et.al*., 2003) where ECa has an inverse relationship with ER [i.e. ECa=1/ER). This current study revealed significant correlation of electrical resistivity measured in-situ with many soil properties-mainly soil moisture content, pH, texture etc. The variation of the soil resistivity may be explained by the wide textural variation in the topsoil (Olorunfemi and Fasuyi, 1993; Mohammed, *et al*., 2012). Resistivity value less than 100 Ωm typifies clay while those in the range of > 100 and < 1000 ohm-m may indicate clayey sand, saturated sand while resistivity in the range of > 1000 ohm-m may represent lateritic sand (hard pan), sand and bedrock. The soils of the plantation varied in their physical properties. The variation in the physical properties of the soil could be as a result of leaf litter falls, in which the quantity of leaf litter fall varies from variety to variety. Hybrid cocoa variety with highest number of leaves which determines the leaf falls is expected to have higher soil moisture as leaf litter falls prevent loss of soil water through evaporation (Ogunlade and Iloyanomon, 2009). This current study revealed significant correlation of electrical resistivity measured in-situ with many soil properties-mainly soil moisture content, pH, texture, bulk density, SOM, P, and Ca. Further work should be done using soil electrical resistivity methods to predict soil properties and yield of cocoa in other locations and at different period using modern equipment like land mapper ERM 02.

ABSTRACT

Knowledge of some physical properties in soil as well as physical properties architecture in tree is important for successfully running the precision farming. Hydraulic conductivity, bulk density, water holding capacity, compaction, aggregate stability etc. are known to vary under different water regimes, tillage implementation, soil management, etc. Land use management is also known to have profound impact on some physical properties. Both the soil and tree components are dependent on the abiotic stresses existed in the field or green house condition. This research was carried out to examine the variability of some physical properties of soil under citrus and mango orchards at National Horticultural Research institute (NIHORT). Soil samples were collected from the depths of 0-15cm randomly from both orchards. A total of 16 samples were used for the study. The samples collected were air dried, crushed and sieved in a 2mm sieve and was prepared for laboratory analysis. Means and coefficient of variation were used as statistical tools. The result showed that the textural classes of the site are sandy loam and loamy sandy, which shows that the soil at the studied site is suitable for planting. Saturated hydraulic conductivity of citrus orchard vary from 10.8cm/hr to 48.6cm/hr while, under mango orchard ranges from 18.6cm/hr to 42.0cm/hr that is, ranges from low to high due to slow movement of water, bulk density of citrus orchard vary form 1.22g/cm^3 to 1.4g/cm^3 while, under mango orchard ranges from 1.2g/cm^3 to 1.40g/cm^3 which is moderate. Total porosity under citrus orchard vary from 47.2% to 54% and under mango orchard ranges from 47.2% to 55%. Soil permeability under citrus orchard ranges from 0.01m^2 to 0.05m^2 while, under mango orchard ranges from 0.02m^2 to 0.05m^2. This study provides new insight for soil site specific management in addressing issues such as where to place the proper interventions (tillage, irrigation and crop type to be grown).

INTRODUCTION

Soil, as a natural body, is inherently heterogeneous because of the many factors that contributes to soil formation and the complex interactions of those factors. Variability in soil properties has been found to significantly influence soil management and crop production (Fasina 2003). Apart from inherent soil differences, variation in soil properties are due to soil forming factors (climate, parent materials, organisms, relief and time and differences in weathering rates (Mzuku *et al*., 2005, Udoh *et al*., 2007). Man has contributed to soil variability through factors such as land use, fertilizer application and different management practices (Ogunkunle and Erinle 1994; Ryan *et al*., 1997; Fasina, 2003). Soils vary in time and space (Onweremadu and Akamigbo, 2007). Variations could be as a result of changes in the lithological origin (Onweremadu, 2008), land use and landscape position (Onweremadu, 2007). Variability in physicochemical properties of soils of similar lithological and climatic origin can be ascribed to differences in soil management, and this affects soil quality (Brady and Weil, 2002). Soil spatial variability is an important determinant of efficiency of farm inputs and yield, (Salgam, 2011) as well as crop management and design and effectiveness of field research trials, (Khan *et al*., 2019). These variations differed among soil properties, and may reflect the impacts of plant, soil fauna, precipitation and management practices adopted in the area, Jafari *et al*., 2011). Soil variability is the reason sampling procedures are so important. Soil varies continuously within fields and between farms. Surface variation may be easily seen, but nutrient variability is usually not obvious. The most noticeable differences ate those which are physical because they are visible. Texture, colour, slope, erosion and drainage are some obvious visible differences. Citrus is a genus of flowering trees and shrubs in the rue family, *Rutaceae*. Plants in the genus produce citrus fruits, including important crops like oranges, lemons, grape fruits and limes. Citrus generally require 12 elements apart from C, H and O. Which include N, P, K, Mg, Ca, S (macronutrients), Mn, Cu, Zn, B, Fe and Mo (micronutrients) (Davies and Albrigo 1994). Since nutrient uptake efficiency ranges from 20-50% in citrus groves, nutrient application must exceed the minimum requirement of the tree. However, split application of 2-3times per year has been advocated for, to avoid placing a large amount of fertilizer in the soil and thereby encouraging leaching loses (Avav *et al*., 2002). Mango is a juicy stone fruit (drupe) belonging to the genus *Mangifera*, consisting of numerous tropical fruiting trees cultivated mostly for edible fruit. The majority of these species are found in nature as wild mangoes. They all belong to the flowering plant family *Anarcardiaceae*. Therefore, the objective of this study is to evaluate the variability of selected soil physical properties and to determine the relationship between some soil properties in citrus and mango orchard.

MATERIALS AND METHODS

The experiment was carried out at the National Horticultural Research Institute Ibadan, Oyo State. The area lies between Latitude 7^{o}40'N, Longitude 3^{o}84'E and 213m above sea level in the Greenwich Meridian, its average rainfall is about 1250mm while average annual mean temperature is 26^{o}. The average relative humidity is 74.53% (NIHORT, 2013). The soil samples were taken from NIHORT citrus and mango orchard. The citrus orchard was established in the year 1996, at a spacing of 7m by7m per stand and the mango orchard was established between the years 1987-1989 at a spacing of 10m by10m per stand. Soil samples were collected within the field and 16 soil samples were randomly collected at 0-15cm depth. Soil physical properties was analysed in the laboratory which include: Particle size distribution, saturated hydraulic conductivity, soil bulk density, permeability. Data collected was statistically analysed using mean, standard deviation and coefficient of variation. Data collected was statistically analysed using mean, standard deviation and coefficient of variation

RESULTS AND DISCUSSIONS

Mean values of physical properties of soils under citrus and mango orchards is as presented in Table 1. Saturated hydraulic conductivity Ksat of citrus orchard has the least value of 10.8cm/hr and for mango orchard is 18.6cm/hr (Table 2). This is in agreement with the report by Ezeaku *et al*., 2005 that the implication of low values of Ksat can be as a result of limited crop production due to unavailability of little or too high water transmission at the root zone. The Citrus and Mango orchard observed in the study area was highly variable with 48.6cm/hr and 42.ocm/hr value respectively. This is in line with the findings of Ezeake *et al*., 2005 who reported that high value of Ksat can be as a result of high water transmission and this result of higher bio- turbation (e.g. burrowing activities by animals and root movement in soils) which may results to higher bio-pores and cross sectional area that contribute to flow and such soils could be regarded as a hydraulic conductivity. Bulk density in citrus orchard ranged from 1.22g/cm3- 1.40g/cm3 (Table 3), which ranges from fine texture soil (FTS) to medium texture soil (MTS) while under mango orchard it ranges from 1.20g/cm3-1.40g/cm3 which is also regarded as fine texture soil (FTS), and medium texture soil (MTS). Ezeaku (2005) reported and suggested that lower mean obtained from the result could be as a results of constant cultivation, high organic matter due to mulching, addition of other organic material and biodegraded. In order to compare the variability of soil properties in citrus and mango orchard of studied site, the co-efficient variation(CV) was used and the result was categorized according to (Wild and Dress 1983) 0-15 is regarded as low variability, between 15 and 35 is regarded as moderately variable while greater than 35 is regarded as highly variable (Tables 4 & 5).

CONCLUSION

The result shows the variability of some soil physical properties in citrus and mango orchard. The result of the studied site shows the bulk density in citrus orchard ranged from 1.22g/cm^3 -1.40g/cm^3 which is regarded as fine texture soil (FTS) and medium texture soil (MTS). Mango orchard ranges from 1.20g/cm^3 -1.40g/cm^3 which is also regarded as fine texture soil (FTS), and medium textured soil (MTS). Saturated hydraulic conductivity of the two orchards vary from 10.8cm/hr to 48.6cm/hr which ranges from low to high variable, due to slow movement of water, bulk density was moderate which ranges from 1.20 – 1.40g/cm3, total porosity varies from 42.7% -54%, the permeability values are very low which shows that variability occur at different sampling point. The study revealed that there was increase in the soil properties in (saturated hydraulic conductivity, bulk density, particle size distribution and permeability) of the study area. Hence, the characteristics of these parameters showed that variability occurs at different sampling points. This study provides new insight for soil site specific management in addressing issues such as where to place the proper interventions (tillage, irrigation and crop type to be grown.

ABSTRACT

Soil samples were collected from randomly selected cocoa farms and their respective adjacent forests from nine cocoa producing local government areas across Abia, Cross River and Edo States. The soil samples were thereafter subjected to heavy metals/physicochemical analyses. Out of all the heavy metals tested, chromium was highest, with a range of 3.05-5.448mg/kg, 1.558-6.553mg/kg and 0.918-6.373mg/kg for samples obtained from Cross River, Abia and Edo States respectively. Also, the heavy metal contents in Cross River State are the highest, while those of Abia and Edo much lower ranges. The heavy metal contents of the cocoa farm soils were higher than their respective adjacent forests across all the locations sampled. While the value of chromium across all the locations were within the permissible limits. Other heavy metals were however below permissible limits. Thus, the metals do not yet constitute a source of contamination to the soils. The higher heavy metal values recorded for soil samples obtained from cocoa farms compared with those of the adjacent forests across the sample locations is however, an indication of pesticide usage on the farms.

Key words: cocoa, heavy metals, contamination, permissible limits

INTRODUCTION

Cocoa production is distinctive to tropical environments and provides livelihood for millions of small-holder farmers in Africa, Latin-America, The Caribbean and Asia. The crop does well in deep, well drained and good moisture holding capacity soils with pH range of 5.0 to 7.5. Worldwide, cocoa comes from small scale farmers out of which West Africa produces over 70% (FAO, 2007). Nigeria produces about 367,000 tonnes of the world production in 2013. Studies on cocoa chemical composition and properties shows that a moderate consumption of cocoa may be beneficial for human health, mainly due to high content of polyphenolic compounds such as flavonoids, as antioxidants. In spite of the many health benefits of cocoa and cocoa products, there are still safety worries in respect to occurrence and levels of heavy metals in cocoa and cocoa products, such as cadmium (Cd), chromium (Cr), nickel (Ni) and lead (Pb). It was reported by Rankin *et al*., 2005 that cocoa and cocoa products from Nigeria contains high amount of Lead (Pb).

The use of pesticides and herbicides is common among cocoa farmers to control disease causing pest, and weed control. Most of these agrochemicals are not biodegradable and their continuous usage can lead to soil contamination with heavy metals (Aikpokpodion., 2012). Heavy metals pollution of soil is of grave concern because of its effect on the food chain (Singh *et al*., 2011). It is essentially caused but not limited to Cu, Ni, Cd, Zn, Cr and Pb, while some few heavy metals (Zn, Fe, Ca, Mg) have been reported to have bio importance to human and plants at very low concentration (Singh, 2011 and Duruibe et al, 2007). The aim of this study is evaluate the contamination of some heavy metals in soils of selected cocoa farms and adjacent forest in the study areas.

MATERIALS AND METHODS

Physicochemical/heavy metal analyses

Soil samples were collected from randomly selected cocoa farms and adjacent forests from nine cocoa producing local government areas across Abia, Cross River and Edo States. The samples were separately taken at 0-20cm (top soil) and 20-40cm (sub-soil) depths with the aid of a soil auger. Six (6) core soil samples were randomly collected at about 6m intervals within each plantation to obtain a representative sample of each farm. The composite soil samples were properly labeled and their respective locations geo-referenced. The samples were properly processed and sieved. Each of the composite samples was then sub-sampled for laboratory (heavy metals, pH, texture, total nitrogen and cations) analyses using standard methods.

RESULTS AND DISCUSSIONS

The heavy metals concentration: cadmium (Cd), lead (Pb), chromium (Cr) and nickel (Ni) in soils across the study areas is presented in Table 1. The distribution of heavy metals shows an increasing order of Cr > Pb > Cd > Ni across the states. Cd, Pb, Cr and Ni contents of the soils varies across locations. The range of Cd contents in selected farms and adjacent plots in Abia, Edo and Cross River as seen in Table 2 shows that Abia had a mean value of 0.675mg/kg for cocoa farms and 0.691mg/kg for its adjacent plots. Values obtained from some of the locations were slightly higher than the permissible values with all the states having a mean value less than the permissible range. There appeared not to be a significant difference in the soil cadmium contents between cocoa farms and adjacent forests in the three states. This suggests an edaphic nature of Cadmium in the area due to weathering of parent rocks (Alloway,1995) which collaborates earlier findings by Ogunlade *et al*. (2011) that most farmers don't use fertilizers in their cocoa farms but the use of agrochemicals is already gaining momentum amongst cocoa farmers (Issa, 2016). The cadmium values in both cocoa farms and adjacent plots across the states are within the permissible levels of cadmium by various authorities (0.8mg/kg WHO, 1996, 0.76mg/kg, Commentuijn *et al.* (1997), 0.5mg/kg (Saadia *et al*., 2016). It is important to stress that excessive levels of cadmium in soil (>1 mg/kg) presently found in samples maybe due to closeness of such farms to some industrialized areas and may largely be as a result of emissions (Oversteyns.,1992).

The amounts of lead in the cocoa farm and adjacent forest soils across the three states were generally lower than permissible standards. The values were lower when compared with the National Environmental Quality Standard (NEQS) of 25mg/kg as reported by Saadia *et al*. (2016) and 85mg/kg (WHO,1996) (Table 3). This shows that lead content was natural in the samples and so, did not pose any contamination threat to cocoa or other crops in the area under evaluation.

The highest Cr values detected from the samples taken from Abia, Edo and Cross-River States were 6.553, 6.373 and 5.448mg/kg in both cocoa farms and adjacent plots. These were however far below the permissible levels of 20mg/kg(NEQS), 150mg/kg(EU,2002) and 100mg/kg (WHO., 1996) indicating there was no contamination threat as regards the heavy metal. The Ni contents both in the soil of cocoa farms and adjacent plots sampled in the three States were very low (Zarcinas *et al.,* 2004) and does not pose any contamination threats to consumption of cocoa and cocoa products from the area.

Mn, Fe, Cu and Zn

The concentration of Mn, Fe, Cu and Zn (required for cocoa production in very small quantities) in the soil samples were below the permissible levels (Cu: 140mg/kg EU 2002, 100mg/kg, WHO/FAO 2001, Zn: 50mg/kg WHO,1996) (Table 3).

Physiochemical Properties

Results of the baseline analysis of the physical and chemical properties of the soil samples across the states are as presented in Table 4. The textural classes of the samples were sandy-loam. The pH, a useful factor that influences heavy metals availability in agricultural soils tended towards acidity, ranging from between 4.22 and 6.38. At high pH (alkalinity), some metals are not available for uptake. Mg, Ca, and K are available at pH>8 but Fe, Zn and Cu are less available. The nitrogen content of all the samples was adequately above the critical value of 0.09 %N for cocoa soil (Egbe *et al.*, 1989). Majority of the samples did not meet the phosphorus and potassium critical values of 10mg/kg and 0.3cmol/kg required for cocoa cultivation. The exchangeable calcium and magnesium was moderately adequate across the states for cocoa soils (Egbe *et al.*, 1989). The physiochemical properties of soils influence the mobility and pathways of nutrients and pollutants in soils. Similarly, the accumulation of heavy metals in soils is also governed by a number of soil properties such as pH, organic matter, conductance, inorganic ions (Vern and Don, 2011).

CONCLUSION

The number/type of pesticides used on cocoa farms in the study areas varied with location and farmers' perceived effectiveness/availability of those chemicals. Farmers in Cross River States impressively made use of government approved chemicals to control pests and diseases on their cocoa farms. This was a clear contrast to what obtained in Edo State. An average compliance was, however, noticed among farmers in Abia State.

ABSTRACT

Field experiment was conducted during 2018 planting season at Omuo Ekiti in the rainforest zone of Southwest Nigeria on sandy loam to develop soil management practice to enhanced soil productivity of sweet potato (Ipomoea batatas). Ten mulch-tillage practices involving five mulch rates (0, 5, 10, 15, and 20 t/ha) and two tillage methods (no-tillage and manual ridge) were investigated. Soil physical and chemical properties and growth and yield parameters of sweet potato were evaluated. It was found that soil moisture content and porosity increased with increase in rate of mulch whereas soil temperature and bulk density reduced irrespective of tillage method. No-tillage had lower soil temperature, high moisture content and lower porosity compared with manual ridge. Soil organic matter (OM), N, available P, K, Ca Mg and pH increased with mulch rate and No-tillage had higher values of OM, N, P, K, Mg, and pH relative to manual ridge. Number and weight of tubers increased with mulch rate. Relative to the control, the 5, 10, 15 and 20 t/ha mulch increased yield by 25, 38, 66, and 67% respectively. Considering the need to maintain high soil fertility and more suitable soil physical conditions for enhanced potato yield, it is recommended that no-tillage be combined with 20 t/ha mulch.

Keywords: Tillage, Weed Mulch, Soil Productivity, Sweet potato, Omuo Ekiti

INTRODUCTION

Sweet potato (*Ipomoea batatas* L.) is cultivated largely in tropical and subtropical agro-ecologies. The tuber is eaten boiled, roasted, fried and baked or made into syrup and also serves as raw materials for the manufacture of starch, glucose and alcohol (Yasmin *et al.,* 2007). The leaves are also used as vegetables in some communities in Nigeria and widely used as fodder for livestock. The tuber is an excellent source of anti-oxidants and carotenes chiefly in the orange flesh colour varieties thus providing cheap and rich source of vitamin A for poor people (Woolfe, 1992). Sweet potato production is constrained by depletion of soil fertility and degradation of soil physical properties and inadequate fertilizers. It is established that chemical fertilizers have failed to make necessary impact in tropical agriculture and Nigeria in particular, sustainable crop production is not possible with dependence on chemical fertilizers alone (Ojeniyi, 1995). Sweet potato is often grown on raised beds and mounds, but it is established by research that no-tillage is important in soil and water conservation and has been favourable to crops performance in the humid zones (Adekiya and Ojeniyi, 2011; Agbede, 2008). Tillage affects soil properties such as temperature, moisture content, bulk density, porosity and infiltration which affect crops performance. If intensively performed or mechanized it causes rapid degradation of soil physical, chemical and biological qualities especially in humid zones of southern Nigeria.

Mulch on the other hand is a layer of plant residue applied to the surface soil to conserve moisture and improve its fertility and it is a common practice recommended for tropical small holder farming (Akanbi and Ojeniyi, 2007). The technique improves biotic activity and adds nutrients thereby improving soil fertility and crops yield. Akanbi *et al.* (2013) recognized the need to intensify studies into locally sourced, cheap, adoptable organic sources of plant nutrients. In order to alleviate the problems of low soil fertility and quality affecting yield of sweet potato, there is the need to develop an organic base soil management for sustainable production of crop. The problems of low soil fertility and soil quality affecting yield of sweet potato can be alleviated with repetitive cultivation, therefore there is need to develop an organic no-till bared soil management for sustainable production of the crop. It is already established that total dependence on chemical fertilizer has failed to sustain crop production in the tropics (Ojeniyi, 2000; Ano and Agwu, 2005). The importance of no-tillage and mulching in soil and water conservation, growth and yield of crops in Nigeria has been reported (Agele *et al.,* 1999). However, research information is scarce on response of sweet potato to tillage and mulching in different agro ecological zones of Nigeria. Ossom et al. (2001) in Papua New Guinea reported the benefits of applying mulches to sweet potato to stabilize yield. The main objective of this work was to develop tillage- mulch practices for sustaining soil quality and yield of sweet potato in Omuo Ekiti rain forest Zone of Nigeria.

MATERIALS AND METHODS

The study was conducted during 2018 cropping season at Omuo-Ekiti, Ekiti State Nigeria. Omuo-Ekiti is located on latitude 7 ° 76` N and longitude 5 ° 72` E and Altitude of 460 m. The location has a bimodal rainfall of 1250 to 1460 mm with mean annual rainfall of 1367 mm and average number of rainy days of about 112 per annum. Temperature is almost uniform throughout the year 23 – 32°C with little deviation from mean annual of 27 °C. The area falls within the high forest zone where the rich tropical forests once thrived. The location has a tropical humid climate with distinct wet and dry seasons. The wet season is from late March to October with little dry spell in August.

Experimental design and treatments

The experiment was laid out using split plots design arranged in a randomized complete block with each treatment replicated four times. The area used was 697 m^2 in size having a total of 8 main plots and each main plot has 5 sub-plots. Each main plot measured 19 x 2.5 m with discard of 3 m within the main plots and 2 m in between sub-plot and 2 m round the whole plot. The trial consisted of 2 x 5 factorial combinations of two tillage methods {(1) No-tillage, NT i.e. manual clearing with cutlass and weeds removed from plots before planting on flat without primary or secondary tillage operation and (2) Manual tillage, MT i.e. preparation of ridges by heaping the soil surface layer using the traditional hoe after cleared weeds were removed from the plots} and five levels of mulch, Siam weed (*Chromolaena odorata)*, (0, 5, 10, 15 and 20 t/ha). These were combined to make 10 treatments. Tillage operation was carried out in May.

After tillage operations, planting of 30 cm sweet potato vines variety TIS87/0087 obtained from National Root Crop Research Institute, Umudike, Nigeria was done in May 2015 at the spacing of 0.5 x 1m while mulch application followed a day after the planting. Fresh Siam weed collected from a nearby farm and hedge containing green tender stems and the leaves equivalent to 0, 5, 10, 15 and 20 t/ha was applied to cover the soil. Weeding operation was done manually at 3 and 8 weeks after planting at each site.

Analytical Procedures

One month after planting sweet potato / mulch application, determination of certain soil physical properties in all plots at the site commenced and this was done at one- month interval on four occasions. Six samples were collected at 0-10 cm depth from each plot using a steel cone sampler and were used for evaluation of bulk density, total porosity and gravimetric water content after oven-dried at 100°C for 24 h. Total porosity was calculated from the values of bulk density and particle density. Soil temperature was determined at 15.00 h with a soil thermometer inserted to 10 cm depth. Six readings were made per plot at each sampling time at 1-month interval and mean data were computed.

Prior to commencement of experiment, soil samples randomly collected from 0 – 20 cm depth were thoroughly mixed inside a plastic bucket to form a composite which was later analyzed for physical and chemical properties. At the harvest, another set of composite samples were collected per plot basis and similarly analyzed for routine chemical analysis as described by Carter (1993). The soil samples were air-dried and sieved using a 2 mm sieve before making the determinations. Soil organic matter was determined by the procedure of Walkley and Black using the dichromate wet oxidation method (Nelson and Sommers, 1996), total N was determined by micro-Kjeldahl digestion method (Bremner, 1996), available P was determined by Bray-1 extraction followed by molybdenum blue colorimetry (Frank et al., 1998). Exchangeable K, Ca and Mg were extracted using 1.0 N ammonium acetate. Thereafter, K was determined using a flame photometer and Ca and Mg were determined by EDTA titration method (Hendershot and Lalande, 1993). Soil pH was determined in soil water (1:2) medium using the digital electronic pH meter. Particle size analysis was done using Bouyoucos hydrometer method (Sheldrick and Hand Wang, 1993). Soil bulk density was determined using the core method (Campbell and Henshall, 1991).

Yield components

Ten plants from the sub-plots were randomly selected for the yield determination. Yield parameters assessed included tuber length, tuber diameter, number of tubers, tuber girth and tuber weight. These were determined at harvest (5 months after planting).

Statistical analysis

The data collected were subjected to analysis of variance (ANOVA) using the SAS package (SAS, 2001) and Microsoft Office Excel 2007 packages and treatment means were compared using the Duncan's multiple range test (DMRT).

RESULTS

Pre-Planting Soil properties

Table 1 shows pre-planting soil properties of the experimental site at Omuo Ekiti. The values of soil Bulk density was 1.31 g/cm^3, Porosity 50.6%, Soil temperature 36.1 and Soil moisture 6.31%; other parameters were soil pH 5.6, total N 0.15 %, available P of 12.1 mg/kg, exchangeable K 0.18 cmol/kg, Ca 3.2 cmol/kg, Mg 1.2 cmol/kg and Organic matter (OM) 2.38 %. The soil at the location was acidic, low in N, available P, exchangeable K and OM based on rating of Akinrinde and Obigbesan (2000).

TABLE 1: Pre-Planting Soil properties

Property	Value
Sand (%)	66
Silt (%)	18
Clay (%)	16
Textural Class	Sandy Loam
Bulk density g/cm^3	1.31
Total porosity (%)	50.6
pH (H_20)	5.6
Organic Matter (%)	2.38
Total N (g/kg)	1.5
Available P (mg/kg)	12.1
Exchangeable K cmol/kg	0.18
Exchangeable Ca cmol/kg	3.2
Exchangeable Mg cmol/kg	1.2

Table 2 presented data on effect of tillage and mulch on soil physical properties in Omuo Ekiti, the result revealed that Soil moisture and porosity increased with mulch rate irrespective of tillage methods, NT had more moisture than ridge irrespective of mulch rate. Irrespective of mulch rate, soil moisture content under NT and MR were 8.1 and 7.8% respectively, the mean moisture content for 0, 5, 10, 15 and 20 t/ha Mulches were 6.4, 7.3, 7.9, 8.9 and 9.1% respectively. Effect of mulch was significant, whereas tillage had no significant effect. Overall mean values of porosity for 0, 5, 10, 15 and 20 t/ha mulch were 38.0, 42.6, 44.5, 50.3 and 51.7% respectively. The values of porosity were similar for no-tillage (NT) and manual ridging (MR), although were often slightly higher in case of MR at every mulching rate. The mean total porosity for NT and MR in Omuo Ekiti were 45.5 and 46.4% respectively.

Temperature and soil bulk density reduced with increase in mulch rate irrespective of tillage method. Bulk density mean values for 0, 5, 10, 15 and 20 t/ha mulch rate were 1.31, 1.20, 1.17, 1.13 and 1.18 g/cm^3, mulch effect was significant, NT had less soil temperature than MR irrespective of mulch rate. The mean soil temperature and soil bulk density under NT and MR in Omuo Ekiti were 30.5^{0}C and 33.0^{0}C and 1.19 and 1.17 g/cm^3 respectively. Hence, NT reduced soil temperature and bulk density relative to manual tillage.

Table 2: Effect of Tillage-mulch combination on Soil physical properties in Omuo Ekiti

Treatment	Moisture (%)		Temperature (^{0}C)		Porosity (%)		Bulk density (g/cm^3)

ISSN: 2814-0508

Soil pH, OM, N, P, K, Ca and Mg increased with increase in mulch rate between 0 to 20t/ha irrespective of tillage treatments. Soil pH, OM, N, P, K, and Mg recorded higher value for NT than MR irrespective of mulch rate. Exchangeable Ca values were similar between the two tillage treatments. The mean values recorded for NT and MR were 3.82 and 3.78 as presented in Table 3.

Table 4 presented data on yield and yield components of sweet potato in Omuo Ekiti, the result revealed that tuber length, Tuber girth, number of tuber and tuber yield of sweet potato increased with increase rate of mulch from 0 to 5 t/ha mulch at $P < 0.05$. With respect to tillage method, mean values for NT and MR were not significantly different from each other.

DISCUSSION

This work shows that mulch improved soil physical properties by reducing soil temperature and bulk density which reduced with increase in mulch rate irrespective of tillage method. Soil moisture content and porosity increased with increase in mulch rate irrespective of tillage method. Returning crop residues to the soil is known to improve soil quality and productivity through favourable effects on soil properties (Lai and Stewart, 1995). Favourable effects of residue mulching on soil organic carbon, water retention and aggregate stability have been reported on soil surface layer (Duicker and Lai, 1999). Conservation of soil moisture is one of the major advantages of mulch farming. Plant residues shade the soil, serve as major barrier against moisture losses from soil, slow surface runoff and increase infiltration. Hence this work found that soil moisture content increased with mulch rate. The increase in moisture content expectedly reduced soil temperature (Agele *et al.,* 1999). The finding that mulch increased porosity and reduced soil bulk density is consistent with the findings of Noltidge *et al.,* (2005) and Akanbi and Ojeniyi (2007)

Soil fertility as indicated by concentrations of organic matter, N, P, K, Ca and Mg was increased by mulching. The values for these nutrients increased with increase in mulch rate. The NT had higher concentrations of soil OM, N, P, K, Mg and higher pH than tilled MR. this is attributable to presence of plant residues and roots in surface soil. The residues decomposed to improve soil OM and hence nutrients concentration. The weight and number of tubers increased with increase in rate of mulch but values were similar for NT and MR irrespective of mulch rate. This indicated that sweet potato can be cultivated using no-till without significant loss of yield. The maximum and higher yield were given by combination of MC and 15t/ha mulch. Relative to the control, the 5, 10, 15 and 20 t/ha mulch increased potato yield by 25, 38, 66, and 67% respectively. Combination NT + 20 t/ha mulch gave highest values, for tuber weight, number of tubers, exchangeable soil K, Ca, Mg, total N, OM, available P and moisture content. This indicated that these soil properties are influential and determining performance of sweet potato. It also implies that nutrients availability overrides effect of tillage in determining performance of sweet potato (Ojeniyi and Adejobi, 2005).

ISSN: 2814-0508

CONCLUSION

Field experiment was conducted in Omuo Ekiti (Rainforest zone) to develop affordable low external input soil management system for enhanced soil productivity and production of sweet potato. Relative to control, mulching at 5, 10, 15 and 20 t/ha increased soil moisture, porosity and reduced bulk density irrespective of tillage method. Soil organic matter (OM), N, P, K, Ca, Mg and pH increased with increase in rate of mulch. No-tillage also increased soil OM, N, P, K, Mg and pH. Relative to ridging, 5, 10, 15 and 20 t/ha mulch increased sweet potato yield by 25, 38, 66, and 67% respectively. Whereas tillage method did not influence potato yield parameters significantly. It is concluded that no-tillage is suitable for production of sweet potato in the agro ecological Zone studied; it also conserves soil fertility relative to ridging. Mulching is highly advantageous to ensuring improved soil nutrients content, improving soil physical properties and performance of sweet potato. A combination of no-tillage with 20 t/ha mulch is recommended for production of sweet potato.

ABSTRACT

Increasing global climate change continues to impact agricultural productivity especially soil properties in sub-Saharan Africa. Therefore, the need for sustainable food production and climate change adaptation measures, like tillage practices, becomes imperative. A field experiment was established to examine the effect of tillage practices on the growth and yield of Zea mays (maize) and selected soil properties. The experiment was laid out in a Randomized Complete Block Design (RCBD) replicated three times. The treatments were manual, no tillage and zai pits. Each experimental (3m by 3m) had fifteen seedlings at a spacing of 75cm by 50cm given a total of 100m² plot. A composite soil sample was obtained from the experimental plot before tillage (0-15cm) and at the end of the experiment and was analyzed for soil properties in the laboratory. Data were collected on plants height (cm), numbers of leaves per, stem diameter(cm), and grain yield and were subjected to analysis of variance (ANOVA) after which means were separated using Duncan Multiple Range Test (DMRT) at p≤0.05. Plant height ranged from 58.7cm in the zai pit plot to 159.9cm in the manual ridge plot. Stem diameter, number of leaves also increase appreciably across the treatments. Manual ridge gave the highest yield of 5.1 tonnes per hectare while no ridge gave the yield of 2.40 tonnes per hectare. It can be concluded that all the tillage methods may be adopted and also the manual ridge tillage should be utilized the most since it gave the highest grain yield of maize.

Keywords: tillage, Zai pits, maize, soil properties, growth, and yield parameters**.**

INTRODUCTION

Maize is a major staple food for humans and a primary constituent of animal feed. It also plays important role in food security, employment, and income generation for families especially in underdeveloped countries where hunger and starvation are prevalent (Ayoola and Makinde, 2007). This has led to huge demand and the need to expand production through modern tillage practices. Tillage practices have been reported to have a significant and positive impact on crop production especially soil properties which enhance germination through enhanced root growth by improving vertical and horizontal proliferation of roots through the reduction in soil strength in the subsoil (Okeleye and Oyekanmi 2003, Barry, 2007). This practice involves the mechanical manipulation of soil to keep it loose for plant growth which includes: preparation of a suitable seedbed for germination. Soil tillage management can also affect factors controlling soil respiration including substrate availability and microbial abundance, soil temperature, water content, pH, redox potential (Kladivko, 2001), and soil aggregate stability. However, improper use of tillage operations can be harmful to the soil's properties (physical, chemical, and biological). Therefore, currently, there is a significant interest in the shift to conservational and no-tillage methods to control the erosion process (Iqbal *et al.,* 2005). The choice of a tillage method amongst others however is site-specific according to the soil properties and water regime of the farmland. The specific objectives of the study are to determine the effect of tillage practices on selected physical and chemical properties of soil and the growth and yield of maize.

MATERIALS AND METHODS

The experiment was carried out at the Teaching and Research Farm of Federal College of Forestry, Ibadan which falls within the Northwest Local Government area of Oyo state. The area is situated in the rain forest agro-ecological zone of Nigeria and lies between latitude7^0 54^1 N and longitude 3^0 34^1 E. The annual rainfall range from 1400 mm-1500 mm. The average temperature is about 32^{0}C with a relative humidity of 80-85% with two distinct seasons of wet (April – October) and dry (November- March) (FRIN, 2018). The experimental field (100m²) was cleared and tilled manually with cutlass and hoe which was partitioned into nine experimental plots each measuring 3m by 3m and fifteen stands respectively. The experiment was laid out in a Randomized Completely Block Design [RCBD] with three replicates. Three tillage methods: (1) Manual ridge (the ridge was prepared by heaping the soil surface using the traditional method), (2) No ridge (the soil was not manipulated, seeds were planted on the recommended spacing), (3) Zai pit (the digging of planting pits of 30cm diameter and 15cm depth before planting at a recommended spacing). Planting was done at a spacing of 75 by 50cm at 2cm depth and two seeds per hole. Before planting, soil samples were collected randomly (0-15cm topsoil) from the experimental plots which were composited and analyzed for physical and chemical properties. Data was collected on the following parameters: plant height (cm), number of leaves, stem diameter (mm), and grain yield were recorded.

RESULTS AND DISCUSSIONS

Table 1 shows the results of the physical and chemical properties of soil at the experimental site before planting. It was observed that the soil of the study area is characterized by a low level of nitrogen (0.08) while the pH was slightly acidic (6.7) which is conducive for maize production. Exchangeable Ca and Mg concentrations were 0.14 and 0.16 cmol/kg respectively. The exchangeable cations indicated low concentration of K+ with 0.66 cmol/kg and Na+ 0.26 cmol/kg. The particle size distribution indicated sandy loam using the textural classes. According to Metson (1961), textural class of the soil has high influence on the physical and chemical properties of the soil.

TABLE 1: The physical and chemical properties of soil of the experimental site before planting

The effect of tillage practices on the height of *Zea mays* is represented in Table 2. Plant height increases appreciably with the number of leaves. Plant height differs significantly (p=0.05) across the treatments. The mean height values range from 6.5 – 159.9 cm at 2 and 8 WAP. The manual ridging treatment had the highest mean height value from 2 - 8 WAP. However, the Zai pit treatment had the highest mean values at 2, 6, and 8 WAP with 7.7, 39.3, and 58.7 cm respectively. the least mean value for Zea mays was observed with the No-ridging treatment at 2WAP while the highest was observed with Zai pit at 8 WAP. These results are in tandem with Kayode and Ademiluyi (2004), who observed the shortest height of maize in the No-tillage practice compared with the tilled plots on sandy loam soil in the southwest part of Nigeria. Alkins and Afuaka (2010) also reported taller cowpea plants in the tilled plots compared to that of the No-tilled plots.

The effect of the three different tillage practices on the number of leaves of maize is as represented in

Table 3. The number of leaves differs significantly (p=0.05) across treatments between 2 and 8 WAP. The mean value of the number of leaves ranges from 4.9 to 159.9 in the Zai pit and manual ridging plot at 2 to 8 WAP respectively. The highest value was observed with the manual ridging plot at 8 WAP. Similar results were obtained by Aikins and Afuaka (2010) for cowpea.

TABLE 2: Effect of tillage practices on the height of Z*ea Mays* (cm)

Treatment	Weeks After planting (WAP)			
	2	4	6	8
Manual ridge	8.6ab	15.2a	68.2ab	159.9a
No ridge	6.5a	12.8a	24.7a	81.9a
Zai pit	7.7ab	11.8a	39.3a	58.7a

*Means in the same column having the same alphabet are not significantly different from each other at a 5% level of significant difference.

TABLE 3: Effect of tillage practices on the number of leaves of maize

Treatment	Weeks After planting (WAP)			
	2	4	6	8
Manual ridge	6.22b	8.44ab	10.56ab	15.9a

Zai pit	4.89ab	6.56a	8.11a	11.67a

*Means in the same column having the same alphabet are not significantly different from each other at a 5% level of significant difference.

The effect of tillage practices on the stem diameter of maize is shown in Table 4. Stem diameter differs significantly (p=0.05) across the treatments between 2 and 8 WAP with a mean value ranging from 1.52mm in the No-ridging plot and 5mm in the Manual ridging plot. A similar result was obtained by Aikins and Afuaka (2010) for cowpea.

TABLE 4: Effect of tillage practices on stem diameter of maize (mm).

Treatment	Weeks After planting (WAP)			
	2	4	6	8
Manual ridging	2.3ab	3.6a	4.9ab	5.0ab
No ridging	1.5a	2.8a	3.8a	4.1a
Zai pit	1.7a	3.3a	3.8a	3.8a

*Means in the same column having the same alpHabet are not significantly different from each other at 5% level of significant difference

Table 5 shows the effect of tillage practices on maize yield. Among the tillage treatments ridge-tillage plot Presented weight of 1000 grains and grain yield (t/ha) this might be due to proper soil loosening which led to deep rooting ability, water utilization and nutrient uptake for crop growth and yield. The lowest yield (t/ha) were obtained in no-tillage systems. These results are in agreements with that of Videnovil *et al.,* (2011) who observed higher maize yield in conventional tillage plots in comparison with that of the no-tillage plots. Clear indication of better moisture availability to the root zone in the zai pits plot account for the maize growth and better yield. The main cause for the low yield from no tillage system could be due to a very shallow impeded root development moisture infiltration near the plant root. Moreover, this treatment had also number of leaves, plant height and stem diameter which all lead to low yield.

TABLE 5: Effects of Tillage practices on Maize Crop Yield (t/ha)

Treatment	Yield
Manual Ridge	5.066b
No ridge	2.40a
Zai pit	4.67ab

*Means in the same column having the same alpHabet are not significantly different from each other at 5% level of significant difference

Table 6 shows the effect of the different tillage practices on soil physical and chemical properties after planting. It was observed that the Nitrogen level is low, the pH was slightly acidic though conducive for maize production. A general reduction in the pH levels was observed for all the treatments after harvesting. The decline in the total nitrogen concentration of the soil after harvesting indicates high N uptake by the maize. Hanway (1971) observed that nitrogen tends to be depleted rapidly from the soil with grain farming such as maize. The exchangeable cations indicated moderate K+ concentrations with 0.6 cmol/kg and Na+ 0.24 cmol/kg. Total organic carbon ranged from 9.5 % before the experiment to 8.91% in the manual ridge plot and 8.71% in the Zai pit plot. The particle size distribution indicated sandy loam using the textural class. Although the no-ridge plot had higher values of both chemical and physical properties, the growth and yield values were lesser compared to the manual ridge and Zai pit. This could be attributed to soil compactness, bulk density, porosity which may hinder root proliferation, and water and nutrient movement with the soil which is essential for plant growth.

CONCLUSION AND RECOMMENDATION

The physical properties of the soil are important in food production. It enhances all other components including the chemical and biological properties. A good soil structure is essential for the distribution of air, water, and nutrients. This study has clearly shown that manual tillage pulverizes the soil and improves the growth and yield of maize than the no tillage type.

However, the result of this study showed that the various tillage methods had no significant effect on the soil properties. It can be concluded that the manual ridge and Zai pit methods can be adopted or utilized for maize production although manual ridge gave the highest maize grain yield

ABSTRACT

Changes in some soil physical and chemical properties, associated with Forest derived land uses were compared with natural or primary forest (NF) in the rainforest Zone of Nigeria. The land use systems were mature oil palm plantation (OP), bush fallow or Secondary forest (BF), alley cropping (AC), with multi-purpose trees [MPTS] and continuous Cassava (Manihot esculenta Crantz) cropping, with and without fertilizer (FC and UC, respectively). The study was conducted on adjacent large unreplicated plots with different histories and length of cultivation but uniform characteristics (slope, elevation and soil type and texture). Soil pH was generally acidic, decreased with depth (0 to 10, 10-20 and 20 - 40-cm) and was significantly different (p = 0.05) among the land use systems, with OP having the highest pH values. Exchangeable K, Mg, Na and Al, cation exchange capacity(CEC) and exchangeable acidity were highest for NF, while Ca, base saturation were highest for OP, when compared to the other land use systems. Five, ten and thirty years of BF, AC and OP respectively were not sufficient to re-establish fertility levels similar to the primary forest. The effect of fertilizer was not significant for most of the soil properties. Soil bulk density was significant, in all three depths, while C: N ratio was not.

Key words: Land use systems, Soil properties, Rain forest zone

INTRODUCTION

Primary forests and forest derived land uses play vital roles in global carbon cycles and Nutrients dynamics in terrestrial ecosystems (Sharma and Rai, 2007; Don *et al*., 2009; Nair *et al*., 2009), especially in the tropics, where the conversion of forest to agricultural and other land uses have been on the increase over the past few decades (Fernandes *et al*., 1997; Lal, 2005). Clearing primary forest for agriculture leads to unsustainable land use characterized by declining soil fertility, and quality, low Productivity and the overall alteration in the global biogeochemical cycles (Schrot *et al*., 2002, McGrath *et al*., 2001; Celik, 2005; Sharma and Rai, 2007). Forest conversion affects the soil through its effect on soil organic matter (SOM) content, which influences ecosystem cycles of carbon, nitrogen and other nutrients as well as on soil physical properties (Brown and Lugo 1990; Lal, 2005; Celik, 2005; Puget and Lal, 2005; Kong *et al.,* 2006; Jelinski and Kucharik,2009; Nair *et al*., 2009). Loss of SOC stock upon conversion from forest to crop has been documented in several studies. For example, Carter *et al*., (1998) reported that based on an equivalent soil mass, to accommodate differences in soil bulk, paired forest and cultivated site showed that cultivation decreased the mass of organic carbon (35%) and total nitrogen (10%) in the soil profile of Podzolic soils. Kern and Johnson (1993) and Murty *et al*., (2002) reported the decrease of SOC stock in the major US cropland soils at approximately 16% and 12-25% respectively. In their own study, Guo and Gifford (2002) reported that soils lost 42 and 59% of their SOC stock upon conversion from forest to crop and from grassland to crop respectively. For a Mollisol in central Ohio, Puget and Lal (2005) reported that cropped systems had 51+ 4 (equivalent mass) Mg ha^{-1} lower SOC and lower 3.5 + 0.3 (equivalent mass) Mg ha^{-1} N in the top 30 cm soil layer than under forest. Research information on the effect of conversion of forest into agricultural land on Other soil properties like bulk density, total porosity and C.N etc. have been contradictory. However, a majority of the studies showed that soils under forest had lower bulk density than adjacent soils under cultivation. The study of the effect of conversion of natural ecosystems e.g. forest to agriculture on Soil properties and SOC sequestration has continued to remain a major global issue, especially in recent times because of our collective concern of environmental degradation and climate change. With the renewed emphasis on deforestation and its effect on CO_2 and other greenhouse gases (GHGs) emissions into the atmosphere, there is a need to intensify scientific research in this area, especially in the different ecological zones of the tropics, where such information is limited. It is also reported that agroforestry systems have a higher potential to sequester C than field crops and pastures (Sanchez, 2000; Sharrow and Ismail, 2004; Kirby and Potvin, 2007; Nair *et al*., 2009). Such information is lacking in the rainforest zone of Nigeria and need to be generated from research. This Study, therefore, was undertaken to evaluate the effect of natural forest and forest derived Land uses on changes in soil physico-chemical properties in an ultisol in the rainforest zone of Nigeria. The specific objective is to determine changes in soil bulk density, porosity, PH. exchangeable cations and acidity, CEC and base and Al saturations in the topsoil.

MATERIALS AND METHODS

Soil samples for this study were collected from the research stations of Michael Okpara University of Agriculture, and National Roots Crops Research Institute, both located at Umudike (5^0 25' N and 7^0 35' and 125 m elevation) in south-eastern Nigeria. Eleven closely sited (within 1.5 km radius) land use systems were used for the study. The NF and BF plots are adjacently located at the Michael Okpara University of Agriculture. While the AC, OP, TA, IS, MI, DB, PM, UC and FC plots are adjacently sited at National Root Crops Research Institute. Details of site and vegetation characteristics of these land use Systems have been reported elsewhere (Uche, 2006) and are only summarized here.

Soil Sampling and Chemical Analysis

For all land use systems, soil texture of the topsoil and slope position (middle slope) in a Chrono sequential transect were used as criteria to locate sampling areas. This was necessary in order to minimize error in data interpretation arising from spatial variability. Soil sampling was done in unreplicated 100 m by 100 m quadrants in each land use type. Each quadrant was subsequently divided into 10 sub quadrants, each measuring 10 m by 10 m from which three were randomly selected and from which samples were collected. Disturbed (composite) samples by auguring and undisturbed (core) samples using cylindrical metal cores of 5.0 cm internal diameter and 5.0 cm height were taken in three replicate from each of 0- to 10-, 10- to 20- and 20- to 40- cm depths. The core samples were taken with a hammer-driven sampler. Core samples were used to determine physical properties (bulk density and total porosity) as described by Grossman and Reinsch (2002), while the auger samples were used to determine chemical properties (PH), organic C, total N, exchangeable acidity and cations {K, Ca, Mg, Na, Mn and Al).

Statistical Analysis

The eleven land use systems were not replicated in the field. Each land use type was represented by 100 m by 100 m quadrant, sub-divided into ten (10 m by 10 m) sub-quadrants from which three were randomly selected and then used as pseudo-replicates for the statistical analysis. The land use plots were all located in the same area (within a $1^{1/2}$ m radius) and soil sampling sites were selected on the basis of uniformity in characteristics which included slope, elevation, soil type and texture as well as present land use. The actual ages of the site and their land use histories are well documented. Research studies which use pseudo replication as a technique to overcome the lack of replication in on-farm and land use experiments have been documented in the past (Brown and Lugo, 1990; Blanco-Canqui and Lal, 2008; Jelinski and Kucharik, 2009). Significance of differences for the Different soil parameters among the different land use systems and soil depths was analysis of variance (ANOVA) using Statistical Analysis Systems (SAS, 1999). Significance was assigned to probability level of p = 0.05.

RESULTS

Soil Bulk Density and Total Porosity

Forest and forest derived land use systems had significant effect on soil bulk density (Table 1) and total porosity (Table 2) in the 0- to 10-, 10- to 20, 20- to 40- cm depths. In all these depths, lowest bulk density and highest total porosity were obtained for cassava based Systems (UC and FC). In the 0- to 10- cm depths, the NF, TA, PM, UC and Fc systems had bulk density values lower than 1.40 g cm^{-3}, while the BF, AC, OP, IS, MI, and DB systems had21 values higher than 1.40 g cm^{-3}. Similarly, for the 0- 10- cm depth, the UC and FC systems had total porosity values higher than 50%, while the other land use systems have porosity values lower than 50%. In the 10-to 20- and 20- to 40- cm depths, bulk density and total porosity did not differ significantly between the NF, BF, AC, OP, IS, MI, DP, and PM systems. Generally, bulk density increased with soil depths, while total porosity decreased for all land use systems.

Table 1. Soil bulk density of 10 – 10, 10 – 20 and 20 – 40 cm depths under different land use

Systems Land use system	Soil bulk density (Mg m^{-3}) Soil depth (cm)		
	0 – 10	10 – 20	20-40
Natural forest (NF)	1.37 ± 0.06	1.52 ± 0.11	1.56 ± 0.18
Bush fallow (BF)	1.53 ± 0.10	1.59 ± 0.13	1.71 ± 0.12
Alley cropping with MPTs (AC)	1.48 ± 0.08	1.62 ± 0.09	1.67 ± 0.15
Oil palm plantation (OP)	1.42 ± 0.11	1.64 ± 0.09	1.69 ± 0.09
Alley cropping (TA)	1.36 ± 0.07	1.43 ± 0.10	1.49 ± 0.06
Alley cropping (IS)	1.43 ± 0.09	1.53 ± 0.12	1.62 ± 0.11

Fertilized cassava (FC)	50.6 ±2.2	48.3 ± 3.1	44 .2 ± 1.8

Mean (n = 3) and standard deviation.

Soil pH

Soil pH values over the entire sampled depths were acidic and significantly different among the different land use systems (Tables 3 – 5). In all three depths, soil pH was highest for OP system and lowest for NF system. Generally, for each land use system, soil pH for the 0- to 10-, 10- to 20- and 20- to 40- cm depths did not show any definite trend and did not differ appreciably.

Exchangeable Potassium, Calcium, Magnesium, Sodium, Manganese and Aluminium.

Significant differences among the different land use systems were found in the measured soil characteristics in the 0- to 10- cm depth (Table 3), 10- to 20- cm depth (Table 4), and 20- to 40- cm depth (Table 5). In addition, differences between the highest and lowest values of each of these characteristics ranged widely. For example, in the

0- to 10- cm layer, the highest value of K was 0.41 cmol kg^{-1} (NF) and the lowest was 0.076 cmol kg $^{-1}$ (IS), showing a difference of 439% for the variability in K content that existed among the land use systems. Similarly, the highest value of Ca was 2.20 cmol kg^{-1} for OP and the lowest was 0.16 for TA system, showing in difference of 128% and also illustrating a high variability in Ca content among the different land use systems. Exchangeable K, Na and Al in all three depths were highest for NF, while Ca was highest for OP, when compared with the other land use systems. Exchangeable Ca and Mg in all three depths were lowest for TA, while exchangeable Al was lowest for OP system in comparison to the other systems. The study found that the content of exchangeable K, Ca Mg, Na and Mn decreased with soil depth in all the land use systems, while the content of exchangeable Al increased with depth in all the land use systems. For example, under the NF system, exchangeable K, Ca, Mg, Na and Mn showed a decrease of 39.90, 88, 42 and 90 percent respectively from the 0- to 10- cm to the 20- to 40- cm depth. On the other hand, exchangeable Al showed an increase of 22 percent between these two depths. Similarly, for the OP systems, the decrease in the concentrations of exchangeable K, Ca, Mg, Na and Mn was 30, 42, 31, 44 and 59 percent respectively, while the increase in Al concentration was 91 percent from the 0- to 10- cm to the 20- to 40- cm depth. These results showed that nutrient dynamics under the land use systems varied considerably.

Land use system abbreviation as in Table 1.

Exchangeable Acidity, CEC

Exchangeable acidity and CEC were significantly highest in the NF system in the 0- to 10-, 10- to 20- and 20- to 40- cm depths when compared with the other land use systems (p=0.05) (Table 3 – 5). Similarly, base saturation and Al saturation were higher in the OP and TA systems respectively in all three depths than in any of the other land use systems (Table 3 – 5). On the other hand, in all three depths, exchangeable acidity, CEC and Al saturation were lowest in the OP system, while base saturation was lowest in the TA system, when compared with the other systems. Averaged over the three depths, exchangeable acidity was 4.65, 3.01,

2.86, 2.67, 2.52, 2.36, 2.21, 2.18, 1.92 and 0.16 cmol kg^{-1} for NF, FC, TA, AC, UC, BF, MI, PM, DB, IS and OP systems respectively. Similarly, averaged over the three depths, CEC was of the order NF > AC > FC > DB > UC > BF > TA > MI > PM > IS > OP systems. As with exchangeable acidity and CEC, base saturation and Al saturation averaged over the three depths did not follow any definite trend among the different land systems. Base saturation and Al saturation values varied between 7.05% (TA) to 92.50% (OP) and 6.22% (OP) to 89.24% (TA) respectively.

DISCUSSION

The lower bulk density and higher porosity in the 0- to 10-, 10- to 20- and 20- to 40- cm depths of soils under continuous cassava cultivation than soils under forest plantation and alley cropping might be ascribed to the loosening of the topsoil by the tuberous roots of cassava over time. This effect might have overshadowed the effect of continuous cultivation on loss of soil organic matter (SOC) and decline in soil aggregation both of which would otherwise result in increased bulk density. Opara-Nadi and Lal (1987) observed that the development of tuberous roots under cassava in the topsoil (0—20 m) led to a decrease in bulk density which is intimately connected with increased porosity and alteration of pore size distribution.

The acidic nature of the soils under all the land use systems was more a reflection of the nature of the parent material (quartz rich, coarse textured and strongly leached) as reported by Ojanuga (1991) than the effect of land use systems. The higher soil PH in the 0- to 10-, 10- to 20- and 20- to 40- cm depths under oil palm plantation than any of the other systems may be attributed to high calcium content, high base saturation and low aluminium content. The long-term inorganic fertilizer input in the FC system did not affect the soil PH as there was no significant difference in pH between the fertilized and unfertilized and cassava plots.

The higher values of exchangeable K, Na and Al, CEC and acidity under forest soil than soils under any of the other land use systems as well as the relatively high concentrations of Ca and Mg under forest soil demonstrate the high capacity of forest soils to conserve and enhance SOM, which in turn, has positive implications on the conversation of nutrients. The result of this study confirms those of other studies on tropical ecosystems and other ecosystems (Fernandez et al., 1997; Sanchez, 2000; McGrath *et al*., 2001; Lal, 2005; Jelinski and Kucharik, 2009; Nair *et al*., 2009). The relatively lower levels of exchangeable nutrients and acidity as well as CEC under bush fallow, agroforestry and oil palm plantation than primary forest demonstrate the fact that the recovery of these systems in terms of nutrient addition is a rather slow process. Similar studies showing that the rate of recovery of bush fallows following forest clearing in terms of nutrient build-up and fertility status is rather a slow process have been reported (Brown and Lugo, 1990; Szott and Palm, 1996). These studies also show that rate of recovery of bush fallows and fertility status depends on a number of factors such as climate, type of secondary vegetation, rate of turn-over of SOM as well as nutrient and fertility levels at the onset of fallow regeneration. These factors were not examined in study but it may suffice to mention here that the tree species in the alley cropping systems were not leguminous tress capable of fixing atmospheric nitrogen and also having high rate of SOM turn-over in the soil. The very high base saturation in the 0 – 40 cm depth of soil under OP system demonstrates the high levels of exchangeable acidity and Al saturation under this system. Exchangeable Ca, Mg and K in that order contributed to the high base saturation of soil under OP system. Both Ca and Mg distributions in the OP system as well as K distribution in the NF system were strongly stratified with depth in these two systems, which had the highest concentrations of these elements in the top 40 cm depth in comparison to the other land use systems. These three elements were dominant in the CEC level in the soil. The effect of CEC was perhaps a more important action than exchangeable cations and acidity in determining the nutrient status and overall fertility of soils under most of the land use systems.

CONCLUSION

This study, showing the concentrations of exchangeable K, Ca, Mg, Na, Mn and Al, exchangeable acidity and CEC on conversion of natural forest to agriculture in southeastern Nigeria, is in agreement with other studies in other ecological zones. The higher concentrations of exchangeable K, Na and Al, CEC and acidity under the forest site than under any of the other land systems as well as relatively high concentrations on Ca and Mg under forest demonstrate the high capacity of forest ecosystems to conserve and enhance SOM, which in turn leads, to soil nutrient conservation. In addition, 5, 10 and 30 years of bush fallow (forest regrowth), alley cropping with MPTs and oil palm plantation respectively were not sufficient to establish the fertility levels similar to the natural forest. Overall, land use change from forest to agriculture in the study area affected the primary soil chemical properties that characterize soil fertility such as organic carbon, total nitrogen and CEC.

ABSTRACT

Subsoils play vital roles in the performance of crops. Constraints in the subsoil are major limitation to soil fertility and productivity. Therefore, there is need for information on subsoil properties how they affect agricultural production. Soil profile pits were dug and characterized for sub soil constraints to horticultural crops production. Constraints to horticultural crops production include high gravel content (>40%), high bulk density (>1.8mg/m3), stoniness (very stony to extremely stony), soil acidity, low ECEC (<5cmol/kg), shallow effective soil depth (<50cm), high water table and poor to imperfect drainage. Biological sub soil constraints include presence of nematodes such as Melodogyne incognita, Tylenchulus semipenetrans and Pratylenchus. Due to the presence of sub soil constraints, plants roots were few to common at the lower depth and in some case showed lateral extension. Management options recommended include drip irrigation, soil modification and soil fertility management. Subsoil constraints affect crop performance and yield. Therefore, it is important to amend and manage the soils to attain optimum plant growth and enhance food security.

Key words: subsoil constraints, stoniness.

INTRODUCTION

Soil are important natural resource but constraints to its productivity exist in different forms. This may be physical (Suganthi *et al.,* 2017), chemical (Wokocha *et al.,* 2016), biological (Ackermann *et al.,* 2007), or morphological (Osujieke, 2017). These constraints may be spatial temporal, within and between soil types. Subsoils are very important in crop production as they serve as reservoir for soil water and nutrient retention (Brady and Weils). Subsoil properties are valuable to final yield of crop. Horticulture is vital to healthy living (Olufolaji, 2021) and economic empowerment. However, different subsoil constraints to crop production can occur simultaneously and negatively impact growth and performance of horticultural crops. Therefore, integrated management options are required especially for tropical soils. Attainment of full crop genetic potentials is not very feasible without suitable soil conditions (Bandyopadhyay *et al.,* 2009). Options to be adopted should be based on environmental, ecological, health, economic, climatic, agronomic and technical, geographic considerations; so as to enhance adequate management of roots and soil environment for crop production. Strategies that can be adopted in managing subsoil constraints include

1) Modifying the rhizosphere (root zone) to make it suitable for crop growth
2) Altering agronomic management practices to minimize reliance on the sub soils. E.g. the use of mounds or beds.
3) Use of compost/farmyard manure.
4) Use of tillage to break hard soils
5) Selection of adaptable or tolerant varieties
6) Land use based on soil suitability
7) Site specific management and precision agri- horticulture

Types of soil constraints

Soil constraints to crop production can be grouped into 4 as shown in Table 1.

Table 1: Classification of soil constraints to crop production

Constraints	Examples
Chemical	Low ECEC, nutrient deficiency, nutrient toxicity, acidity, sodicity, salinity, alkalinity, nutrient imbalance, aluminum saturation.
Physical	High bulk density, high clay or sand content, high porosity, shallow soil depth,, high permeability, water repellency, crusting, water logging, low or high infiltration rates, surface crusting, sub soil impedance, low water holding capacity
Morphological	Presence of Impervious layer (pans),high stoniness and gravel content, excessive wetness, excessive drainage, imperfect drainage
Biological	Presence of nematodes, bacteria and other pathogens, termite mounds

Causes of soil constraints

Subsoil constraints to crop production are product of several factors. These include

a) Natural factors: These include pedogenic processes such as formation of stone lines, presence of intrusive igneous rocks, formation of clay pan, sand stone etc.
b) Anthropogenic activities: Various anthropogenic activities such as indiscriminate fertilizer use, tillage operation, use of recycled water which can cause soil water repellency over time, etc. Al and Ca are binding agents. There can be formation of aggregates due to increase in their release into the soils as a result of indiscriminate use of phosphate and phosphoric fertilisers, Furthermore, ammonium based fertilisers can cause increase in clay dispersion.

MATERIALS AND METHODS

The study was carried out on four pedons in Ido Local Government Oyo state, South western Nigeria. The study site is found in Zone Q of the agro ecological zones of Nigeria. It is located on Basement complex rock geology in the rainforest savannah transition ecology of Nigeria. The area has an undulating topography with characteristic sub soil stoniness and presence of localized hard pans and impenetrable layers in some points of the farm. A detailed soil survey of each of the site was carried out. The areas were divided into grids of 50m X 50 m. Soil examination was done with the aid of a soil auger at the depths of 0 -30 cm, 30 – 60 cm and 60 – 90 cm. to determine the different soils types within each site and to locate their boundaries. Soil morphological and physical characteristics such as texture, consistency (determined by hand feel), effective soil depth, drainage, concentration of gravels and stone, size and abundance of concretions and mottles were determined. Soils with similar characteristics were grouped together into mapping units. Modal profile pits of 1 m x 1.5 m x 2 m were dug at points representative of each mapping unit. The soil profiles were characterised and described using FAO (1990) guidelines for soil profile description. Soil samples were taken from the lowest genetic horizon to the topmost to avoid contamination. The samples were labelled and taken to the laboratory, air dried and processed for analysis. Results of the morphological, physical and chemical analysis were used for soil classification and land evaluation crop production.

RESULTS

Roots distribution, abundance, drainage and level of stoniness are presented in Table 2. There was high root abundance in the A horizon compared to the common and medium to coarse root in the lower B horizon of the soils. Soil fertility status affects the performance of crops. The high abundance of roots in upper layer of the soil may be due to the higher fertility status usually observed in A horizon due to accumulation of nutrients in the surface soils. No stones were recorded in the horizons of Pedon A which led to higher root abundance. There was extreme stoniness in the lower horizons of Pedons B and C with few mottles. Decomposing rock (saprolite) was observed in Pedons B, C and D with no presence of roots recorded in lower depths. Saprolites were observed in Pedon B (>150cm), Pedon C (96cm-154cm) and Pedon D (90-128cm). Pedon D occurs in the lower slope/valley bottom and showed evidence of mottling due to imperfect drainage. Excessive drainage or wetness due to high infiltration and poor drainage resulted in lower root volume in pedons B, C and D.

Table 3 shows the impact of high gravel and stoniness on the performance of citrus in two orchards. Higher tree loss was recorded in orchard with high stone/gravel content (24 trees) compared to the soil with low to medium stoniness (4 trees).

Table 2: Distribution of roots, stoniness and drainage pattern in four pedons

Pedon	Depth (cm)	Roots abundance	Roots size	Stoniness	Drainage
A	0-10	Many	Very Fine	No stones	Well drained
	10-25	Many	Fine	No stones	Well drained
	25-34	Common	Fine	No stones	Well drained
	34-95	Very few	Medium	No stones	Well drained
	95-144	Very few	Medium	No stones	Poorly drained
	144-173	Very few	Medium	No stones	Poorly drained
B	0-22	Many	Very fine		Well drained
	22.44	Many	Fine		Well drained
	44-72	Few	Coarse/medium		Well drained
	72-100	No roots	-	Extremely stony	Excessively drained
	100-150	No roots	-	Very stony	Excessively drained
	>150	No roots	-	(Decomposing saprolite)	Excessively drained
C	0-25	Medium	Many		Well drained
	25-47	Coarse	Many		Well drained
	47-56	Fine/medium/ coarse	Few		Well drained
	56-96	Fine/medium/coarse	Very few-few		Excessively drained
	96-111	No roots	-	Decomposing rock (saprolite)	Excessively drained
	111-154	No roots	-	Decomposing rock (saprolite)	Excessively drained
D					
	0-26	Fine	Many		Well drained
	26-40	Fine/medium	Many		Well drained
	40-74	Fine	common	Stony	Imperfectly drained
	74-90	No roots	-	Very stony	Imperfectly drained
	90-128	No roots	-	Decomposing rock (Saprolite)	

ISSN: 2814-0508

Table 3: Citrus tree loss in two soil types with different degrees of stoniness after 18 years of establishment

Abundance of stones	Tree loss
Very stony	24
Fairly stony	8

DISCUSSION

Morphological properties of the soils affect crop root development and its eventual productivity. The roots of crops serve as medium for nutrient and moisture uptake. Subsoils are reservoirs for nutrients leached from the top soil. Higher root abundance is usually recorded in the top soil layer of the soils due to higher soil fertility, friability of the soil and of fair to low abundance of gravel and stones. This enhances deeper root penetration and improves crop yield. Low root restriction due to absence of hardpans and impervious layers enhanced more volume and distribution of roots to lower depth. In cases where root restrictions such as stoniness occur in high abundance, root penetration cannot go beyond certain depth. There were fewer roots beyond certain lower depth as seen in the pedons. With high stone/gravel content, soil moisture retention is reduced. To ensure productivity of such soils, supplemental irrigation and integrated soil fertility management (ISFM) should be used. This includes planting of cover crops and use of compost. Poor root depth and anchorage affect the extent of soil nutrient uptake. Modifications are needed to improve root zone conditions for better crop growth (Ityel *et al.,* 2011). According to (Helman, 2004), deep soils tolerate larger root system and this can support vigorous tree growth and ability to withstand moisture trees and production of bigger trees. Furthermore, Ndo *et al.,* (2019), identified soil properties as having effect on incidence and severity of pest and diseases. Poor utilization of information on subsoil properties affects soil management for increased productivity (Ahukamere *et al.,* 2012). Shallow rooting depth can lead to loss of farms; especially orchards due to tree loss. High gravel content and rock outcrops are serious restrictions to crop production (Orimoloye, 2016). It is recommended that soil depth of over 100cm is suitable for crop production especially tree crops. Therefore, shallow rooted crops such as vegetables should be cultivated on shallow soils. Land form is a factor to consider in assessment of suitability or classification of soils for tree crops production. Depth of occurrence of subsoil constraints can be as a result of the location of soils on the catena. In situations where there is poor drainage within the rooting zone, roots diseases such as root can occur in the subsoil and reduce crop yield. Some constraints to tree crop production include sodicity, salinity, acidity and low nutrient reserves. Others are biological constraints such as presence of pest and disease. Srivastava and Singh (2009), stated that beyond soil fertility constraints, decline in citrus productivity is caused by factors such as presence of acidic or alkaline argillic (clay enriched) or spodic (organic hardpan) horizon. With occurrence of hard pans and other restrictive layers, there could be soil mechanical impedance leading to limitation in aeration and permeability. With such, infiltration is reduced under irrigation or rainfed conditions leading to poor utilization of available soil water. In addition, fertilizer materials supplied are also lost due to seepage and low infiltration of water into the soils. These culminate in yield decline, loss of farm inputs and low economic returns to the farmers. High stone/gravel content can lead to low water retention while excessive clay in the subsoil can cause poor aeration (oxygen stress) and make the plant vulnerable to drought and lodging during prolonged dry season, especially in crops like plantain and Banana. In order to make such crops less vulnerable to the effect of prolonged dry season, regular and adequate supplemental irrigation should be provided. Soil properties affect farm operations such as tillage which on the other hand affects yield and crop performance (Alam *et al.,* 2014). High clay and gravel contents in surface soils also affect germination of seeds especially if used for seedling production in the nursery. With modification of such soils through increase in soil volume, germination can be enhanced.

ABSTRACT

Termite mound soil amends soil fertility and utilized as an alternative to npk fertilizers by smallholder farmers in Africa. A research was carried out to investigate the effect of soil modification using termite mounds and its effects on the growth and yield of Celosia argentea. The experiment was conducted at the Federal College of Forestry, Ibadan. It lies between latitude 7⁰ 23ᴵN, and longitude 3⁰ 15ᴵE. The climatic condition of the area is tropically dominated by rainfall pattern from 1400mm to 1500mm (FRIN, 2015). The experiment was laid out in a Completely Randomized Design with five treatments replicated six times. The Treatments were; Termite mound, degraded soil, soil + termite mounds (3:1), Soil + Termite mound (2:2), Soil + Termite mound (1:3). The parameters assessed were plant height, stem girth, number of leaves and yield. The data collected were subjected to Duncan Multiple Range Test at 5% level of probability. The results showed that there were significant ($P < 0.05$) differences among the treatments used with respect to plant height, stem girth, numbers of leaves and yield respectively. At 8 weeks after transplanting, number of leaves ranged from 24 in the degraded soil + termite mound (1:3) plot to 14 in the plot where degraded soil was used. Stem girth also increases appreciably across treatments. Plant height ranged from 31.77cm in the degraded soil + termite mound (1:3) plot to 17.73 cm in the plot where degraded soil was used. Degraded soil + termite mound (1:3) gave the highest yield of 44.85kg/ ha while the degraded soil gave the lowest yield of 10.12 kg/ha. This result suggests that the incorporation of termite mound into cropping systems will increase productivity and yield (kg/ha) of Celosia argentea. Hence, degraded soil + termite mound (1:3) may be recommended for the production of Celosia argentea especially in the study area. Therefore, it can be recommended that degraded soil + termite mound can be used by farmers to increase Celosia argentea production especially in the study area.

Key words: Soil modification, Termite mound*, Celosia argentea,* Growth and yield.

INTRODUCTION

Termite mounds is a mixture of soil, organic debris or living plants tissues collected often over extensive foraging areas, transported to their domain and subjected to increase degradation when it is digested by termites (Ekundayo and Orhue, 2011). Orhue *et al.,* (2007) noted that plant nutrients and organic material are withheld from circulation in plant – soil system until they finally decay. Detailed studies of termites' mound have been reported in the Niger Delta region of Nigeria (Ekundayo and Orhue, 2011). Study on termites' mounds on soil and crop productivity in tropical and subtropical areas lacking. Reports have shown the benefits of using termite's mounds as soil plant-soil system amendments. These includes; contribution of nutrients to improve soil fertility and crop productivity (Shepard *et al.,* (1995). Studies have shown significant higher amount of exchangeable cations, macronutrients, organic matter and pH in termites' mound soil Semnhi *et al., (*2008) identified termites as common biological agents that produce symptoms physical and subsoil soils. It is also reported that activities increase the content of organic matter in the soils they use for construction of their nests and also modifies clay minerals composition of these minerals (Jouquet *et al.,* (2002). Despite the benefits derivable from the use of plant-soil systems in tropical and subtropical areas, they have their limitations to use by farmers. It is reported that the problem associated with the use of termite mounds is how to get the huge quantities reported to satisfy the nutritional needs of crops.

Celosia argentea is one of the most important leafy vegetable in South Western Nigeria (Adeyeye *et al.,* 2013). It is a vegetable of high economic value particularly in the dry season as it provides a source of living for most rural vegetable farmers. (Akinfasoye *et al.,* 2008). The leaves and succulent stems are consumed as vegetable because it constitutes a cheap and rich nutrient source of the income earners, and the seed could also be processed into food items supplements and additives (Adeyeye *et al.,* 2013). It also has some medicinal properties for example, in Kenya, the Ma sai use the liquid extract from the leaves and flowers to bathe a patient recovering from illness and as an antidote for snake bites (Akinyeye *et al.,* 2013). The root is also used to treat chronic eczema and gonorrhea while the seeds are used to treat diarrhea (Denton *et al.,* 2001). One of the reasons for the *interest* of celosia is because of its nutrients qualities. It has been reported to contain protein 4.7g, Fat 0.7g, Carbohydrate 7.3g, Fiber 1.8g, Water 83.8g, Calcium 260mg, Phosphorous 43mg, Iron 7.8mg, per 100g edible portion (Grubben and Denton, 2004). Celosia thus has high potentials for reducing malnutrition which is rampant in Nigeria. In spite of the limitations, the long-term benefits in terms of improving soil fertility and enhancing food production cannot be over emphasized (Fragoso and Lavelle, 1992). Studies ascertaining the yield of vegetable affected by the use of termite mound are scanty in Ibadan, South West region of Nigeria. The objective of this study is to determine the best rate to modify termite mounds on the growth and yield of *Celosia argentea.*

MATERIALS AND METHODS

The experiment was carried out at Federal College of Forestry (FCF), Jericho (latitude 7^0 23^IN, and longitude 3^0 15^IE) Ibadan, Oyo state. The climatic condition of the area is tropically dominated by rainfall pattern from 1400mm to 1500mm (FRIN, 2015). *Celosia argentea* seeds were sown into germination box filled with top soil and watered daily to keep the soil moist but not drenched. Sprouting started at five days after sowing. The seeds were later transplanted into the pots already filled with termite mounds and degraded soil.

Screen house studies

The air dried termite mound was bulked to form a composites sample. The dried termite mound soils were crushed to disintegrate the lump structures into smaller aggregates particles and thereafter variously combined to serve as treatments. Composite termite mounds samples from the surrounding field and degraded soils serve as control for standardization. The experiment was completely randomized design (CRD) replicated six times. Treatments used for the experiment were: T1 = Termite mound, T2 = degraded soil, T3=termite mound (3:1), T4 = soil + termite mound (2:2) and T5= soil + termite mound (1:3). Four (4) kilogram soils was weighed into polythene pots, thereafter soil in each pots were turned, properly mixed and watered (200ml) prior to planting. Seedlings were sown into each pot at a depth of 3cm

Data collection

Two plants from the experimental unit were randomly selected and used for data collection on Plant height, Stem girth, Number of leaves, at 2, 4, 6, and 8 weeks after planting. data was also collected on the yield of *Celosia*

Data analysis

Data collected were analyzed statistically using statistical software package for social sciences. Means were separated using Duncan Multiple Range Test at 5% level of significance.

RESULTS AND DISCUSSION

The soils at the experimental site have been classified as an Alfisol (Smyth and Montgomery, 1962) with its distinctive characteristics. The data in Table 1 further confirms this assertion and also reveals that the soils are moderate in zinc, high in potassium and phosphorous. Organic carbon and total nitrogen content of the degraded soil were 4.52 and 0.54 g kg^{-1} respectively which is below the critical level of 10 – 14 g/kg and 1.6 – 2.0 g/kg respectively, while that of termite mound were 10.16 g kg^{-1} and 1.12 g kg^{-1} which is moderate (Adeoye and Agboola, 1985) and nearly neutral pH. This implies that the soil is suitable for vegetable production. The extractable Mn and Fe contents of the termite mound are high with 275 and 288 mg kg^{-1}, respectively, and that of degraded soil were 410 and 405 mg/kg. The texture of termite mound was loamy sand and that of degraded soil was loamy sand texture indicating a well-drained soil suitable for growing vegetable. Soil modification using termite mounds and its effects on plant height of *Celosia argentia* at 2, 4, 6, and 8 WAP were represented in table 2. There were significant differences among the treatments on plant height of Celosia. Among the five treatments used, T5 (Degraded soil +Termite mounds 1:3) had the highest plant height (31.88cm) followed by T1 (termite mounds) (31.06cm), followed by T4 (Degraded soil + Termite mounds 2:2) (29.09cm), followed by T3 (Soil incorporated with Termite mound mounds 3:1) (27,22cm) and least by T2 (Degraded soil) (17.73cm). This is in line with Garba *et al.,* (2011) who reported the same trend in their work on effects of termite mound material on the physical properties of sandy soil and the growth characteristics of tomatoes (*Solanum lycopersium*. L.) In Semi-Arid of Niger. Soil modification using termite mounds and m effects on numbers of leaves of *Celosia argentia* at 2, 4, 6, and 8 WAP were represented in table 3. There were significant differences among the treatments on number of leaves of Celosia. Among the five treatments used, T5 (Termite mounds + Degraded soil in (1:3)) had the highest numbers of leaves (23) followed by T1 (termite mounds) (22), followed by T4 (Degraded soil + termite mounds in ratio of 2:2) (21), followed by T3 (Soil incorporated with Termite mound mounds with ratio of 3:1) (20) and least by T2 (Degraded soil) (14). This is in accordance with Elker Deweer *et al.,* (2014) who reported the same trend in their work on growth response of *Amaranth* to admixture of termite mound material. Soil modification using termite mounds and its effects on stem girth of *Celosia argentia* at 2, 4, 6, and 8 WAP were represented in table 3. There were significant differences among the treatments on Stem girth of leaves of *Celosia*. Among the five treatments used, T5 (Degraded soil = Termite mounds in ratio of 1:3) had the highest stem girth (1.88) followed by T1 (termite mounds) (1.0), followed by T4 (Degraded soil + termite mounds in ratio of 2:2) (1.5), followed by T3 (Soil + with Termite mound mounds with ratio of 3:1) (1.3) and least by T2 (Degraded soil) (0.44). This is in line with Garba *et al*., (2011) who reported that significant differences were observed in different treatments on effects of termite mound materials on the physical properties of sandy and on the growth characteristics of Tomato (*Solanum lycopersicum* L) in semi-arid Niger. Soil modification using termite mounds and its effects on yield of *Celosia argentia* is presented in table 4. There was a significant difference among the treatments. Among the five treatments used, T5 (Termite mounds+ Degraded soil (1:3) had the highest yield (44.85 kg/ha) followed by T1 (termite mounds) (39.06 kg/ha), followed by T4 (Degraded soil + termite mounds in ratio of 2:2) (39.06 kg/ha), followed by T3 (Degraded soil + Termite mounds 3:1) (37.20 kg/ha) and least by T2 (Degraded soil) (10.12kg/ha). This is in line with Garba *et al*., (2011) who reported that significant differences were observed in different treatments on effects of termite mound materials on the physical properties of sandy and on the growth characteristics of Tomato (*Solanum lycopersicum* L) in semi-arid Niger.

Table 1: Pre-planting soil physical and chemical properties of the experimental site

Soil parameters	Content in Degraded Soil	Content in Termite Mound

TM + DS (3:1)	37.20[a]
TM + DS (2:2)	35.50[a]
TM + DS (1:3)	44.85[a]

Means followed by the same letter in each column for each treatment are not significant from each other by DMRT at 5% level of probability.

CONCLUSION AND RECOMMENDATION

The result of this study showed that clay content in termite mound soils was higher than the degraded soil. Silt content however, was found higher in termite mound. It was also shown that a mixture of termite mound and degraded soil (T5) (Termite mound +Degraded soil 1:3) gave the highest value in the crop parameters measured than the value obtained in degraded soil and there was significant difference. *Celosia argentea* growth performance parameters (plant height, number of leaves, and stem girth) were significantly increased (P<0.05) with a mixture of T5 (Termite mound + Degraded soil) than degraded soil T2. (Degraded soil). Thus, the combined use of termite mound and degraded soil is recommended for great potentials to increase soil and crop productivity. Therefore, it can be concluded and recommended that Termite mound can be used by farmers to increase *Celosia argentea* yield production especially in the study area.

ABSTRACT

Study was carried out at Akera village in Irepodun Local Government Area of Omu-Aran, Kwara State, Nigeria in 2020 to evaluate the soil fertility status of a site proposed for cultivation of cashew. The site was demarcated into three blocks based on existing vegetation cover and topography. Soil samples were collected in a stratified manner in line with these identifiable features. Using soil auger, two soil samples were collected per augering point at 0 – 20 and 20 – 40 cm depths respectively. Samples were labelled, air dried, sieved through a 2 mm sieve for soil physical and chemical properties determination following standard laboratory procedures. Results of the mechanical analysis revealed that the sand (%) contents were 62.20 - 64.25 with a mean of 63.55 and 62.20 - 64.70 with an average value of 63.70 at 0 – 20 and 20 – 40 cm depths respectively. The clay + silt contents indicated that the soil was moderate in clay. The upper slope was more gravely than other parts. The OC, total N, available phosphorus (P), exchangeable cations (Ca^{2+}, Mg^{2+}, K^{+}) contents across the site were low and below the critical levels. Consequently, for the site to support sustainable cashew production, soil nutrients supplementation in form of organic fertilizer application coupled with good agricultural practices that include appropriate choice of intercrops at the juvenile stage of the plantation and effective weed control techniques were recommended.

Key words*:* Augering, cashew, cultivation, soil fertility, suitable site.

INTRODUCTION

Cashew is a perennial crop adaptable to several ecologies considered marginal to many other tree crops and as such classified as a hardy crop. Its ability to adapt to dryer environment makes it useful in curtailing desert encroachment particularly in the northern part of Nigeria (Adeyemi and Nduka, 2019). Research findings have revealed nutrients requirements of cashew plant for optimal growth and yield (Egbe *et al*., 1989; Ipinmoroti, 2016). Cashew cultivation is a long time investment that requires careful site selection for optimal productivity. It is therefore imperative to ensure that the site so selected is suitable and sustainable in terms of soil structure, texture and adequate nutrients. This is necessary as a guide in soil fertility management for sustainable cashew production and to forestall blanket fertilizer application with its deleterious effects such as nutrient fixation and imbalance. The objective of this study therefore, was to evaluate the suitability of the proposed farm site at Akera village in Irepodun Local Government Area of Omu-Aran, Kwara State for sustainable cashew cultivation.

MATERIALS AND METHODS

The site was demarcated into three blocks based on the types of vegetation cover and topography. Soil samples were collected in a stratified manner based on these identifiable features. Two soil samples were collected per augering point at 0 – 20 and 20 – 40 cm soil depths respectively with the use of soil auger. A total of eighteen core soil samples were collected from two depths across the 2.0 ha farm site. These were composited to six samples. The samples were labelled, air dried and sieved with a 2 mm sieve. Samples were partitioned for various properties such as particle size analysis, pH macro and micro nutrients determination among others. The particle size distributions of the soil were determined using the hydrometer method as described by (Gee and Bauder, 1996). The organic carbon (OC) content was by wet digestion method (Nelson and Sommers, 1996), while the pH of the soil in soil to water ratio of 1:2 was by the use of electrical pH meter. The soil total N content was by the use of Micro Kjeldahl method (Bremner, 1996). Available Phosphorus (P) was determined by Bray 1 method (Kuo, 1996). The exchangeable cations of K, Ca and Mg were extracted by leaching the soil with 1NNH4 OAC at pH 7 and the contents determined by the use of flame photometer. Ca and Mg contents were by the use of atomic spectrophotometer (AAS), likewise the soil micro nutrients (Fe, Mn and Cu).

RESULTS AND DISCUSSION

The Particle Size

The mechanical analysis revealed that the site contained 62.20 – 64.25 % sand at 0 – 20 cm depth with a means of 63.55 %, while at 20 – 40 cm depth, it ranged from 62.20 to 64.70 % with an average value of 63.70%. The clay contents (%) ranged from 9.60 to 11.00 with an average of 10.43 and from 5.00 to 11.60 with a mean value of 9.13 at 0 – 20 cm and 20 – 40 cm depths respectively (Table 1). The silt (%) found in the top soil varied from 26.20 to 26.70 while at 20 – 40 cm depth, it was 24.70 to 30.40. This showed that the middle slope of the site was slightly gravely than the other parts at both depths. The soil was predominantly sandy clay loam with some noticeable pebbles on the surface. Percentage sand and silt contents of the study area were within the recommended range, though the clay content was above the critical level (Obatolu, 1996). The average clay + silt contents of each of the three slopes considered were above the critical value of 32 % recommended by Egbe *et al.,* (1989) for cashew cultivation in Nigeria. This implied that the soil should be able to retain soil moisture (water), for plant use during the dry periods, for sustainable cashew production. Nonetheless, provision should be made for alternative source of water, other than rainfall, in lieu of the fact that rain-fed agriculture is no longer fashionable due to the current irregular rainfall pattern stemming from climate change. Consequently, digging of well or sinking of borehole for irrigation purpose in the dry season would be advised.

Table 1: Soil physical characteristics and pH of samples collected at different depths and slopes.

Location	0 – 20 cm depth pH (H_2O)	sand ←	silt %	clay →	TC	20 - 40 cm depth pH (H_2O)	sand ←	silt %	clay →	TC
Upper slope	6.20	64.20	26.20	9.60	**SCL**	6.20	62.20	27.00	10.80	**SCL**
Middle slope	5.65	64.25	24.70	10.60	**SCL**	5.65	64.70	24.70	11.60	**SCL**
Lower slope	6.60	62.20	26.70	11.00	**SCL**	6.60	64.20	30.40	5,00	**SCL**
Mean	**6.15**	**63.55**	**25.87**	**10.43**		**6.15**	**63.7**	**27.35**	**9.13**	

TC Textural classification **SCL** Sandy clay loam

The pH values of the study area within 0 – 20 cm depth ranged from 5.65 to 6.60 with an average mean value of 6.15 and 5.65 – 6.60 with a mean value of 6.15 at 20 – 40 cm depth (Table 1). The pH values across the site were slightly acidic. Cashew has been reported to grow on soils of pH 6.5 – 3.0*;* best growth was obtained between pH 5.0 and 4.5 with 4.5 as the absolute best (Owaiye, 1989). The pH of the site should not pose a threat to good growth and productivity of cashew. However, any activities that will alkaline the soil should be avoided.

The exchangeable cations (Ca^{2+}, Mg^{2+}, K^{+}) content of the site

Calcium (Ca^{2+})

The soil Ca content (cmol/kg) at 0 – 20 cm depth ranged from 0.30 – 0.50 with a mean value of 0.38 as shown in Table 2a and from 0.31 to 0.34 with a mean value of 0.32 at 20 – 40 cm depth (Tables 2b). This showed that the site to be critically low in calcium at both the upper and lower levels when compared with 8.0 cmol/kg soil calcium recommended by Egbe *et al.* (1989) for optimum cashew production in Nigeria.

Table 2a: Exchangeable bases at 0 – 20 cm depth

Locations	Exchangeable bases Ca^{2+} cmol/kg	Mg^{2+}	K^{+}	Na^{+}
Upper slope	0.34	0.16	0.58	0.46
Middle slope	0.50	0.18	0.61	0.42
Lower slope	0.30	0.16	0.56	0.44
Mean	**0.38**	**0.17**	**0.56**	**0.44**

Table 2b: Exchangeable bases at 20 – 40 cm depth

Locations	Exchangeable bases Ca^{2+} cmol/kg	Mg^{2+}	K^{+}	Na^{+}
Upper slope	0.32	0.21	0.53	0.41
Middle slope	0.31	0.21	0.46	0.37
Lower slope	0.34	0.23	0.61	0.42
Mean	**0.32**	**0.21**	**0.53**	**0.40**

ISSN: 2814-0508

Magnesium (Mg^{2+})

The magnesium content of the site was very low as observed and reported above for calcium. The values within the upper depth (0 – 20) cm ranged between 0.16 and 0.18 with an average value of 0.17 cmol/kg soil (Table 2a). At the deeper depth (20 – 40) cm however, the Mg content was higher than at the upper depth (Table 2b), though still low compared to the critical value of 0.8 cmol/kg soil considered optimal for cashew production in Nigeria (Egbe *et al*., 1989).

Potassium (K^{+})

The exchangeable potassium in cmol/kg soil at 0 – 20 cm soil depth varied from 0.56 - 0.61 across the slopes with a mean of 0.56 in Table 2a. At 20 – 40 cm depth, the exchangeable K^{+} ranged from 0.46 to 0.61 with a mean value of 0.53 (Table 2b). The site under consideration had higher K^{+} at the upper depth than at the lower contrary to what was obtained for Mg^{2+} above. The K^{+} contents of the site were equally low (Egbe *et al*., 1989) as reported earlier for Ca^{2+} and Mg^{2+}. The low exchangeable cations (Calcium, Magnesium and Potassium) contents observed in this study are in consonance with the earlier findings of Ipinmoroti and Ogeh, (2012).

Essential macro nutrients of the site

Soil Organic Carbon (SOC)

The soil organic carbon in percentage at 0 – 20 cm and 20 – 40 cm soil depths ranged from 9.85 – 10.70 and 8.62 – 9.69 with the mean values of 10.33 and 9.33 respectively (Table 3). The OC contents across the site were below the critical mean value of 30 % (Egbe *et. al*., 1989). This may be due to previous use of the site for farming activities.

Organic Matter (OM)

The mean soil organic matter content of the site at the upper depth was 17.91 % and lower at the lower depth as shown in Table 3. Although the OM was equally low as reported for OC above, but both could be improved on through fertilizer application (preferably organic) regimes that will put into consideration both macro and micro nutrients need for good cashew seedlings field establishment, growth, development and productivity.

Table 3: Results of the essential macro nutrients of the site

Location	0 – 20 cm OC %	OM	N	AV.P Mgkg	20 – 40 cm OC %	OM	N	AV. P mg/kg
Upper slope	10.63	18.32	0.05	7.95	9.69	16.72	0.04	7.85
Middle slope	9.85	16.98	0.06	8.11	8.62	14.87	0.06	6.92
Lower slope	10.70	18.44	0.07	7.45	9.69	18.05	0.07	7.82
Mean	**10.33**	**17.91**	**0.06**	**7.84**	**9.33**	**16.54**	**0.06**	**7.54**

The Total Nitrogen (N)

The native mean total N (%) of the site was low 0.06 at both the upper and lower levels of soil sampling (Table 3), which is far below the critical level of 1.0 (Egbe *et. al*., 1989). The N content was inversely proportional to the gradient of the site as N was highest at the lowest slope probably due to washing down of the soil nutrients from the upper and middle slopes of the site to the lower as a result of water erosion.

Available Phosphorus (Av. P)

The available P (mg/kg) content varied from 7.45 – 8.11 with mean of 7.84 at the upper depth and 6.92 to 7.85 at the lower depth with a mean value of 7.54 (Table 3). The available P contents were below the critical value of 10.00 mg/kg recommended by (Egbe *et. al*., 1989). Consequently, there would be need to enhance the P of the site through soil amendments for better crop performance.

The proposed farm site was found to be appropriate for cashew cultivation in terms of its physical characteristics and pH. It was however discovered to be inherently low in its fertility status as reflected in the low exchangeable bases (Ca^{2+}, Mg^{2+}, K^{+}), essential macro nutrients (SOC, OM, N, Av. P) probably due to the land use system (excessive cultivation of the land by the native farmers to crops such as cassava and maize which are heavy nutrient feeders. This necessitates the need for nutrient supplementation through fertilizer application, preferably organic based, so as to build-up the soil organic matter content, rectify the low organic carbon as well as the, Ca^{2+} Mg^{2}, K, N and P contents of the soils to ensure optimal productivity of the site. In addition, adoption of efficient management practices such as appropriate cropping systems is inevitable for sustainable cashew cultivation at the proposed site.

CONCLUSION

The proposed site under consideration would support sustainable cashew cultivation if the under-listed good agricultural practices could be adopted:

- Application of appropriate soil amendment (preferably from organic sources) techniques, based on the results of soil analysis, for the supply of needed nutrients in right quantities
- Provision of irrigation facilities to supply water to cashew especially in the dry season
- Adoption of appropriate intercropping systems with cashew at the juvenile stage
- Procurement of planting materials from reputable sources like CRIN

ACKNOWLEDGEMENT

The Executive Director of Cocoa Research Institute of Nigeria is hereby appreciated for the approval to conduct this study and publish its findings.

ABSTRACT

The knowledge of soil fertility status is very much essential for the judicious application of fertilizer and its amendment for sustainable production of kola in Nigeria. Hence, studies were carried out to evaluate the physico-chemical properties of the soil and to determine the leaf nutrient status of kola plantations Osun and Ekiti States. Ten core samples at 0-20cm and 20-40cm were randomly collected using soil auger and bulked into composite samples to obtain representative soil samples which were taken to the laboratory for processing and analysis. Total nitrogen was low in kola plantations evaluated in Osun state. Hence, Nitrogen fertilizer should be applied to kola farms in Osun State. While soil available phosphorus, exchangeable calcium and magnesium contents were adequate in kola plantations evaluated in both states, exchangeable potassium content was grossly inadequate. The potassium level in the kola leaf was also inadequate in Osun and Ekiti states, hence both locations would require potassium fertilizer application.

Keywords: Kola plantations**,** soil fertility, fertilizer application

INTRODUCTION

Kolanut is one of the several tropical tree crops used in local and international trade and was a major export earner for Nigeria before independence when the attention of the Nigerian government shifted to oil and its derivatives (Akinbode, 1982). Production of kolanut in Nigeria ranges from 85,000 to 127,000 metric tonnes annually (Ologunagba, 2009) representing around 70% of World production (Famuyiwa, 1987). The cultivation of kolanut in Nigeria is ecologically limited to the rainforest zones of southern and riverine areas of the savannah region. Kola production levels over the years have been reported to decline due to old age, incompatibility and soil nutrient imbalance. Rehabilitation of old kola plantation by coppicing and total replanting has met with low percentage of success. The increasing land use without adequate and balanced use of chemical fertilizers and with little or no use of organic manure have caused severe fertility deterioration of the soil resulting in stagnation or even decline of kola productivity in Nigeria. The need of the time is to achieve substantially higher kolanut crop yield than the present yield levels from our limited land resources on sustainable basis. The knowledge of nutrient status of soil is very much essential for the judicious application of fertilizer and its amendment for higher crop production. Hence, the objectives of the study were to evaluate the physico-chemical properties of the soil and to determine the leaf nutrient status of kola plantations.

MATERIALS AND METHODS

Soil samples were taken from kola plantations across important kola producing communities covering two states; Osun and Ekiti States. In each of the plantations visited, ten core samples at 0-20cm and 20-40cm were randomly collected using soil auger and bulked into composite samples to obtain representative soil samples which were taken to the laboratory for processing and analysis. The soil samples collected were air-dried, thoroughly mixed, crushed and sieved to pass through 2mm sieve. Samples collected were analyzed for the pH, organic carbon, Nitrogen, Phosphorus, potassium, Calcium and Magnessium contents. The soil pH was measured electronically with glass rod electrode pH meter in soil/water ratio of 1: 2.5 (Mclean, 1982). The soil organic matter was determined by acetate dichromate oxidation method (Nelson and Sommers, 1982). The total Nitrogen was determined by the micro Kjedahl method (Bremmer, 1996). The available P was determined using Bray 1 method (Bray and Kurtz,1945), while the exchangeable cations were activated by leaching 5g of soil with 50ml of 1N NH4OAC at pH 7 and the K, Ca and Mg were measured by atomic absorption spectrophotometer (AOAC, 1990). The soil particle size distribution was determined using the hydrometer method (Bouyoucos, 1951) and soil texture determined using textural triangle. The soil textural class was determined by the hydrometer method using hexametaphosphate as the dispersing agent.

RESULTS AND DISCUSSIONS

The mean soil pH of soil at Osun and Ekiti states were 5.85 and 6.10 respectively at 0- 20cm depth

(Table 1). This is slightly acidic and appropriate for kola production (Egbe *et al.*, 1989), however, any activity that would further decrease the pH of the soil, such as use of ammonium nitrogen based fertilizer should be avoided. Organic carbon content of the soil was low in kola plantations evaluated in Osun State with mean value of 16.45g/kg but moderate in Ekiti State with a mean value of 20.85g/kg. The low organic carbon in Osun State could be attributed to low natural organic matter return to the soil and other human activities such as burning (Ahmed 1995). Total nitrogen content was low in kola plantation soils of Osun state. The mean value (0.88g/kg) was below the critical nitrogen soil content of 1.0g/kgN required by Kola as reported by Egbe et.al 1989. This is a reflection of low organic carbon content in the soil (Onyekwere et al 2009) Therefore; there will be need for nitrogen application in all the kola plantations evaluated in Osun state. The soil nitrogen content in kola plantations assessed in Ekiti State were adequate and would not require nitrogen fertilizer application.

Soil available phosphorus contents were adequate for kola in all the farms evaluated in both states hence there would be no need for application of phosphorus fertilizer. This was well above the soil critical level of 6mg/kg P required for kola production (Egbe *et al.*, 1989) and this is similar to Iloyanomon *et al,* 2011 which reported that high Phosphorus content in leaf litter resulted into high P in the soil as a result of the fast decomposition of the Kola leaves. Soil exchangeable potassium was adequate across the kola plantations examined in the two States. Potassium is important in fruiting of Kola; adequate potassium is required for a good quality of Kola fruit (Adebowale and Odesanya, 2015). Soil exchangeable calcium and magnesium were adequate at both locations examined.

Table 3: Ranges and Mean values of Leaf nutrient content (g/kg) of kola plantations across Osun and Ekiti States

Parameters	Ekiti State			Osun State		
	Min	Max	Mean	Min	Max	Mean
N (g/kg)	12.7	24.6	18.7	12.1	29.2	18.9
P (mg/kg)	0.82	1.4	0.80	0.81	1.00	8.85
K(g/kg)	08.26	12.64	8.90	3.89	7.78	6.15
Ca (g/kg)	2.90	5.94	4.36	3.87	5.84	4.66
Mg (g/kg)	2.17	2.67	2.40	0.22	3.06	2.52
Na (g/kg)	1.94	2.18	2.00	1.71	2.04	1.89

The mean Nitrogen content of the kola leaf was 18.90g/kg in Osun State and 18.70g/kg in Ekiti State (Table 3) which is above the foliar critical level of 10g/kg N required for kola production (Egbe *et al* 1989). The phosphorus content of kola leaf in Osun and Ekiti States were above the foliar critical level of P required for kola production. This is similar to the findings of Iloyanomon and Ogunlade 2011 who reported high phosphorus content in kola plantations in Ibadan but contrary to the findings of Ogunlade and Aikpokpodion (2006) who reported low P in cocoa soils in Southwestern Nigeria. The potassium and magnesium content of the kola leaf was below the foliar critical level of 12g/kg and 3.4 g/kg respectively in Osun and Ekiti States. Calcium content of the kola leaves in both Osun and Ekiti states were slightly lower than the foliar critical level.

CONCLUSION

The study was carried out in Osun and Ekiti states, Nigeria to evaluate the soil nutrient status of some selected kola plantations. Soil pH in both states were slightly acidic with those of Osun State being more acidic. Therefore, any activity that will further acidify the soil should be avoided in both states. Total nitrogen was low in kola plantation soils evaluated in Osun state but adequate in kola plantations assessed in Ekiti State. Hence, Nitrogen fertilizer is needed in Osun State. While soil available phosphorus, exchangeable calcium and magnesium contents were adequate in kola plantations evaluated in both states, exchangeable potassium content was grossly inadequate. The potassium level in the kola leaf was also inadequate in Osun and Ekiti states, hence both locations would require potassium fertilizer application. The study is highly essential to recommending appropriate soil fertility management strategies that will enhance kola yield on sustainable basis in the study areas.

ASSESSMENT OF SOIL FERTILITY IN SOME SELECTED CASHEW FARMS IN ENUGU, KOGI AND OYO STATES FOR PROPER MANAGEMENT AND ENHANCED PRODUCTIVITY

Ibiremo, O.S., Ogunlade, M.O., Iloyanomon, C.I. and Akanbi, O.S.O.

Soils and Plant Nutrition, Section, Cocoa Research Institute of Nigeria, Ibadan Oyo State, Nigeria

ABSTRACT

Soil fertility of cashew plantations in Kogi, Oyo and Enugu was evaluated to evolve strategies for effective management. Soil samples were collected from two pre-selected farms in each Local Government Areas using a soil auger at two soil depths of 0-20cm and 20-40cm. Soil samples were collected at a distance of 1m from the base of selected cashew mother tree. The soil samples were bulked to make composite samples and were analysed using standard laboratory procedures. The sand fraction of the soils of the farms evaluated ranged from 829 to 889g/kg while the clay content of the soil in the six farm locations across the three states ranged from 84 to 154g/kg soil at 0-20cm.The silt fraction ranged from 26 to 146g/kg soil. The soils of all the farm locations fall within the sandy loam textural classification. The pH of the soils in the farms in Enugu State was 5.21 while that of Kogi State was 5.9. The pH of the farms in Oyo State was 6.25. The pH of soils in the three States ranged from strongly acidic to slightly acidic. The N in the soils of the farms across the three States was generally low and hence there is need for N supplementation. The N in cashew farms in Enugu State ranged from 0.26 to 0.65g/kg soil while that of Kogi State ranged from 0.35 to 0.77g/kg soil. The N in Oyo State had a mean of 0.44g/kg soil in Orire LGA and 0.66g/kg soil in Surulere LGA. The available P in Enugu and Kogi States was adequate for cashew cultivation with an average value of 4.3 and 4.5mg/kg soil respectively. However, the available P in the cashew farms in Oyo State was below the level required for cultivation of cashew with an average value of 3.0mg/kg soil. The exchangeable K in Enugu and Kogi States was low with an average value of 0.08 cmol/kg soil. There will be need for external addition of phosphorus and potassium fertilizers. The fertilizers required for optimum cultivation of cashew in the three States ranged from 68 to 134 kg N/ha, 2.8 to 3.2 kgP_2O_5/ha and 9 to 66kg K_2O/ha.

Keywords: cashew, soil fertility, productivity, leaf nutrient, fertilizers

INTRODUCTION

Cashew, *Anacardium occidentale L.*, is grown largely by smallholder farmers in all agro-ecological zones of Nigeria (27 out of 36 States). However, economic production is concentrated around the middle belt and northern parts of the Southwest. Cashew is a major source of income to Nigerian government, farmers, processors, marketers and other stakeholders along the value chain and has average yield per hectare of 450-500kg/ha (The Guardian online, 2019). Currently, the land area cultivated to cashew in the country has increased to almost 400,000 hectares (FAO, 2018; Olubode et al., 2017) and this cultivation progression may be attributed largely to increase in world market demand of its nuts. Cashew is grown from the rainforest zone to savanna area of Nigeria and is grown on wide range of soils. It is known that cashew farmers in Nigeria use little or no fertilizer as they rely on natural means of supplying nutrients through leaf litter fall (Ibiremo and Iloyanomon, 2015, Agbongiarhuoyi, *et. al* 2014). The application of fertilizer is however inevitable for the replacement of soil nutrients that are mined through cashew apple and nut harvest annually. The objectives of this study were to assess the fertility status of soils of some cashew plantations across the three States of Enugu, Kogi and Oyo and evolve strategies for effective management to enhance cashew productivity.

MATERIALS AND METHODS

Two farms were selected from each Local Government Area (LGA) and two LGAs were selected in each of the three States of Enugu, Kogi and Oyo which form the bulk of cashew producing States in Nigeria. Soil samples were collected from each farm using a soil auger at soil depths of 0-20cm and 20-40cm, and at a distance of 10m apart. Soil samples were collected at a distance of 1m from the base of selected cashew mother tree. The soil samples were bulked to make composite samples and analysed for some physical and chemical properties using standard laboratory procedures according to IITA (1982). The information obtained were used as basis for fertilizer computation and recommendations.

RESULTS AND DISCUSSION

Soil textural characteristics of cashew plantations in Enugu, Kogi and Oyo States

The sand fraction of soils in the two farms selected in Udi Local Government Area, Enugu State had an average value of 890g/kg soil at 0-20cm soil depth while the sand fraction in soils of the two farms evaluated in Nsukka LGA was 849g/kg soil which was slightly lower than that of Udi LGA (Table 1). In Kogi state, the mean value of the sand content across the two farms at 0-20cm soil depth in Ofu LGA was 869g/kg soil while that of Dekina LGA was 809g/kg soil which is about 7% lower. However, the sand content of the farms in the two locations of Orire and Surulere LGAs had an average value of 809g/kg soil. The clay content in the two farms of Udi LGA had an average value of 84g/kg soil while that of Enugu was 104g/kg at 0-20cm. In Kogi state, the two farms evaluated in Ofu LGA had a mean value of 94g/kg at 0-20cm while that of Dekina LGA was 154g/kg at the same depth which indicated that the clay in Ofu LGA was much lower than that of Dekina LGA. The mean clay content of the soils of farms locations in Orire and Surelere LGAs was 109g/kg soil. The mean silt content of the soil in the farms evaluated in Udi and Nsukka LGAs of Enugu State was 31g/kg soil at 0-20cm which was relatively lower than the silt content in the soils of farms in Kogi State with an average value of 36g/kg soil at 0-20cm (Table 1). In the farm locations of Oyo State, the mean silt content in the soils of Orire LGA was 86g/kg while that of Surulere LGA was 76g/kg at 0-20. The soils in the three States under consideration indicated that sand fraction was very high and could be classified texturally as sandy loam and suitable for cashew (Egbe *et.al* 1989, Ohler, 1989).

Soil chemical characteristics of cashew plantations in Enugu, Kogi and Oyo States

The pH of the soils in the two farms in Udi LGA was 5.55 at 0-20cm while that of the Nsukka LGA was 4.85 (Table 1). The pH of the soils in Ofu and Dekina LGAs ranged from 5.40 to 6.50. The mean pH of the soils in the two farms in Orire LGA was 6.00 while that of Surulere LGA was 6.30. Cashew thrives well in a wide range of pH and the range obtained in this study is suitable for cashew (Ohler 1989. The organic carbon in the soils of the farm locations in Udi and Nsukka LGAs was 14g/kg which is much lower than the organic carbon obtained in the farm locations of Kogi state with a value of 17g/kg. The organic carbon in the soils of Oyo state was higher with an average value of 17.9g/kg soil compared with soils of Enugu and Kogi States with mean values of 14.12 and 17.09 g/kg soil respectively. The organic carbon content in the soils of the farms in Orire LGA was 19g/kg soil. The higher organic carbon in the soils of Oyo State may impact positively on the fertility status than the soils in Enugu and Kogi States. The N in the soils in the farms evaluated across the three States was generally low and there is need for N supplementation. The N in cashew farms in Enugu State ranged from 0.26 to 0.65g/kg soil while that of Kogi State ranged from 0.35 to 0.77g/kg soil. The N in Oyo State had a mean of 0.44g/kg soil in Orire LGA and 0.66g/kg soil in Surulere LGA. The total nitrogen in the soils of the farms in Udi LGA ranged from 0.26 to 0.65 g/kg. The average total N in the farms evaluated in Udi LGA and Nsukka LGA was 0.45g/kg. In Kogi state, the N in the soils of the farms in Ofu LGA was 0.5g/kg soil while that of Dekina LGA was o.63g/kg soil at 0-20cm. The total N for the soils in the two farm locations in Orire LGA was 0.44g/kg while that of Surulere LGA was 0.66g/kg soil at 0-20cm (Table 1). The average total N across the farm locations in the three States was 0.54g/kg which was less than the critical value (1g/kg soil) for cashew cultivation (Ohler, 1989; Egbe, 1989). The available P in the farm locations in the three states ranged from 2.98 to 5.35 mg/kg soil. The available P in the two farms in Udi LGA was 4mg/kg soil while that of the two farms in Nsukka LGA was 4.6mg/kg at 0-20cm depth. In Kogi state, the farms in Ofu LGA had 3.75mg/kg soil as average value for available P at 0-20cm while that of Dekina LGA was slightly higher with 5.35mg/kg. However, the available P in the two farms of Orire LGA was 3.06 mg/kg and that of Surulere LGA was 2.98mg/kg. The available P in Enugu and Kogi States was adequate for cashew cultivation with an average value of 4.3 and 4.5mg/kg soil respectively. However, the available P in the cashew farms in Oyo State was below the level required for good cultivation of cashew with an average value of 3.0mg/kg soil. It is evident that the level of available P in the soils of cashew farms evaluated in Enugu and Kogi States does not require amendment as at now but this may likely shift toward deficiency in the future. The exchangeable K in Enugu and Kogi States was low with an average value of 0.08 cmol/kg soil. There will be need for addition of potassium fertilizer. Conversely, the exchangeable K in farms in Oyo State was adequate with an average value of 0.14cmol/kg soil. The exchangeable K in soils of farms evaluated in Enugu state was 0.06cmol/kg which is much lower than the critical value required for cashew cultivation which is 0.12cmol/kg soil. The average values of exchangeable K in the four locations evaluated in Kogi and Oyo states were

0.09 and 0.16 cmol/kg soil respectively. These values are also below the critical value of 012cmol/kg. Hence, the need for management of potassium based fertilizers. The exchangeable sodium, magnesium and calcium in the twelve cashew farms evaluated were 0.15, 1.16 and 1.34 cmol/kg soil respectively (Table 1). These values are adequate for good cashew production according to Ohler (1989) and Opeke (2005). The soil available copper across the farms locations in the three states ranged from 0.17 to 2.43mg/kg soil while available Iron ranged from 2.45 to 19.25mg/kg soil. The average values of Zinc and Manganese in the soils of the farms evaluated in the three states were 1.25 15.68mg/kg soil respectively.

Fertilizer computation based on the results of soils at 0-20cm depth

The interpretation of the samples on the various farms is based on the interpretation rules generally adopted for tropical soils. Considering the soil test values from the various farm sites across the three States and the already established critical values for these elements; the fertilizer recommendation indicated that in Enugu, the two farms in Udi LGA required 134 Nkg/ha and 58kgK_2O/ha while in Nsukka LGA the farms will need 78kg N/ha and 65 kg K_2O /ha. In Kogi the two farms in Ofu LGA will require 100khN/ha 38 kg K_2O /ha while the two farms in Dekina will need 74 kgN/ha and 9 kg K_2O/ha. However, in Oyo, the two farms in Orire LGA will require 112kgN/ha and 3kgP_2O_5/ha while that of Surulere LGA need 68kgN/ha and 3kgP_2O_5/ha.

CONCLUSION

Site specific fertilizer is required for optimum returns on its usage and the fertilizers required for optimum cultivation of cashew in the three States ranged from 68 to 134 kg N/ha, 2.8 to 3.2 kgP_2O_5/ha and 9 to 66kg K_2O/ha.

ABSTRACT

Majority of the soils in Nigeria are exposed to leaching effects due to incessant rainfall that leads to low organic matter and nutrient contents. Consequently, the importance of coffee nutrition cannot be exaggerated because nutrition affects the size and coffee bean quality. This study was carried out to review nutritional conditions and fertility status of soils for coffee robusta production in Nigeria. It was revealed that most soils under coffee production in Nigeria are moderate to marginally suitable in fertility status. However, some of the soil contents for the nutrients needed for high yield coffee sustainability were above the critical values. Therefore, good management practices that would replenish lost nutrient elements in the soil and leaf were considered necessary.

Key words: *Coffee robusta*, soil fertility, nutrition and soil management

INTRODUCTION

Coffee is an important worldwide cash crop that is cultivated on more than three million farm units most of which are small agricultural enterprises (CRIN Annual report, 2004). Coffee is of different species but only two (Arabica and Robusta) are widely cultivated. The two most important commercial species cultivated in Nigeria are the Arabica coffee which is cultivated in upland area, which accounts for only 4% and robusta that is common in lowland area accounts for over 94% of Nigeria coffee export (CRIN Annual report, 2009). Coffee robusta (C. robusta) is cultivated in the following states across the nation: Oyo, Osun, Ogun, Ekiti, Kwara, Ondo, Kogi, Edo, Delta, Abia, Cross River, (Williams 2008; Ibiremo et al., 2013). C. robusta was said to originate from central and western Sub-Sahara Africa (Dagoon, 2005). Its production on large scale started in Nigeria as far back as 1940s on a large scale, but gained momentum in the early to mid-1950s. C. robusta known scientifically as Coffea canephora (Pierre ex A. Froehner) is a flowering plant which belongs to order Gentianales and botanical family Rubiaceae. It is less susceptible to diseases (Penarredonda, 2017), more vigorous growth and productive cultivars than the Arabica coffee (Coste, 1992). Ibiremo et al., 2013 reported that coffee was a means of livelihood for more than 2, 800,000 farmers between 1960s and 1980s in Nigeria. It is a source of food, employment and foreign exchange for many developed and developing countries. Currently, over 20 million people are engaged directly in the production of coffee globally while the international coffee trade has about 500 million people in its management, from cultivation to the final product for consumption (Ayegboyin et al., 2015). ICO (2015), but they also reported that coffee world production is on decline from 27.2% in the 1970s to an average of 16% in the 1990s and 13.1% in the 2000s. to corroborate this, FAOSTAT (2018) as cited by Iloyanomon et al., (2020) stated that production of coffee in Nigeria has decreased from 1,849 tonnes of green beans in 2018 as against 5,340 metric tonnes in 2006. Declination in production was attributed to factors such as lack of land suitability assessment, poor farm management, poor market for coffee bean produced, old age of plantation, pests and diseases, weed competition among others. Presently, Nigeria is ranked 13th among coffee producers in Africa and 41st position in the world, producing just about 40,000 of 60kg bags, 2, 400 metric tons, 5,291,000 pounds (Szenthe Adriana, 2019).

Soil and Land Requirements

Soils are indispensable factor in the world growth issues in respect to food security, land degradation, poverty alleviation and general well-being of the citizens. It is a determinant factor for the wealth of any nation. Tropical soils consist mostly of Ultisols, Alfisols, Oxisols, Entisols, Aridisols and Inceptisols. These soils are prone to leaching and fast degradation (Amakiri 2004), they must therefore be carefully managed. Proper management of soil and other resources plays important role in their productivity. To improve soil health, the continuous soil management that is combined with other good management practices is very important. Coffee cultivation requires appropriate soil conditions, good agricultural practices, appropriate coffee cultivars, pest and diseases control (Ipinmoroti and Ogeh, 2012). On the overall, coffee can be cultivated on various types of soils but the ideal is a deep and sandy loam. A fertile, free draining, slightly acidic, well aerated, and deep soil with a minimum depth of 1-1.5 m is required for effective productivity. Hence, waterlogging, heavy clay or poor-draining soils should be avoided. MARDNAEC (2009) reported that a well aerated soil to allow root penetration, well structure and porous soil to assure quick penetration, stable soils to minimize erosion on steep slopes is suitable for coffee production.

Most soils under coffee production in Nigeria are moderate to marginally suitable in fertility status (Egbe *et al*., 1989), this is in agreement with the work of Ipinmoroti et al., (2019) with the report that farm sites evaluated for coffee production in two sub-urban communities in Ibadan, Nigeria were moderately suitable for coffee production. Ayegboyin et al., (2015) on a research that assess the performance of C. canephora seedlings raised on soil collected from different soil types, depth and amendments reported that top soils, whether from virgin forest or cultivated land without additional fertilizer have the same potential for raising C. robusta seedlings. It was however, suggested that cultivated land should be left fallow for some time before being used to raise coffee seedlings. Either organic fertilizer (Pacesetter grade B) of 60kgN ha^{-1}, 30kg$P_2 0_5$ ha^{-1} and 30kgK_2O or NPK 20:10:10 is recommended as early as 4 weeks after sowing to enhance seedling growth when top soil from heavily cultivated land is used. The performance of coffee seedlings on three nursery beds made of top soil, sawdust, top/sawdust mixture in equal proportion was studied at the central nursery of Cocoa Research Institute of Nigeria (CRIN), Ibadan with the objective of finding alternative growing medium for top soils in order to reduce sole dependency on top soil for seedlings production and at the same time to reduce cost. The result showed that top soil/sawdust medium will be suitable for raising of coffee seedlings in the nursery (CRIN Annual report, 2000). *C. robusta* requires temperature ranging from 22 - 28^{O}C. Phyiological problems such as poor fruit setting, flower abortion, development and premature ripening occur when temperature is greater than 30^{O}C. In addition, an altitude ranges of 900-1500 m above sea level and rainfall range of 1,200 mm to 1800 mm is required (UCDA, 2019).

Coffee Nutrition

Coffee plant requires adequate nutrients for optimum production. Both macro and micro nutrients are needed. Nitrogen (N), Phosphorus (P) and Potassium (K), Magnesium (Mg), Calcium (Ca), are required in large quantities while Zinc (Zn), Copper (Cu,) Boron (B), Iron (Fe), Manganese (Mn), Molybdenum (Mo), Sulphur (S) and chlorine (Cl) are required in small quantities. Quantities of these elements in the soil and plants are determined through soil and leaf sample analysis. Nutrients application is done to replenish those that are lost. Thus, fertilizers are needed to be applied in the necessary amount. UCDA, (2019) suggested that for proper and effective use of fertilizer, both soil and coffee leaves should be sampled and analyzed once in a year to determine the present status of nutrients and pH of such coffee plantation. This would make for proper understanding of the nutrient recycling and management of fertilizer for optimum production of coffee. Iloyanomon *et al*., 2011 reported on a research carried out in Ibadan, Nigeria on soil fertility evaluation of coffee (C. robusta) plantations of different ages and stated that N, P, Ca, Mg contents were adequate irrespective of age of the plantations but the soil K content was insufficient to meet the coffee plants nutrient requirements.

NITROGEN (N)

Nitrogen is an essential structural component of various compounds that are important for plant growth and development (Agbede, 2009). It is also important for carbohydrate utilization, growth and development. High N content in the soil and leaves of coffee plantation of different ages in Ibadan, Nigeria was reported by Iloyanomon et al., (2011). The values were above soil and foliar critical levels for coffee productivity (Tables 1 and 2). The N sufficiency could be ascribed to leaf litter produced under the plantations. Iloyanomon et al., (2020) reported 27.60 – 60.07 kgNha^{-1} yr^{-1} in coffee leaf litter. Medina et al., (2000) reported that leaves and branches from the coffee plant returned about 41 kgNha^{-1} yr^{-1}. Coffee leaves comprised of 53kgN/ha which was 47% of N uptake by coffee plant (Coffeeasean, 2008). On the other hand, N deficiency was reported by Iloyanomon et al., (2020) in some coffee plantations. Low N content of the soil was probably due to fast growing high yielding coffee cultivar which takes up to 135 kgNha^{-1} as reported by Mitchell 1988; and that the low quantity of leaf litter fall was insufficient to ensure buildup of the N removed by the harvested coffee berries. Therefore, good management practices that could replenish N in the soil is necessary.

PHOSPORUS (P)

ISSN: 2814-0508

P is a vital element in the establishment of new plantations due to its importance in cell division and root development (Akande et al., 2008). Ibiremo and Akanbi (2015) reported that soils under cultivation contain abundant P but most of which are fixed and unavailable to the plants. P sufficiency was recorded in the coffee plantations by Iloyanomon et al., (2011) since the soil P values were above the soil and foliar critical levels for coffee (Tables 1 and 2). The high value could be as a result of low P removal as reported by Nelliat, 1978 who reported 7kgP2O5 being removed by coffee berries from the field on harvesting. Likewise, one tonne of coffee has been stated to remove 7kg P_2O_5 (Jessy, 2011). Coffee leaves contain 11kg P/ha (Coffeeasean, 2008). P content of the soil and leaf from some coffee plantations of different ages has been reported to be low (Iloyanomon, 2020).

Table 1: Soil critical levels of nutrient elements of C. robusta

Nutrient Elements	Soil critical level
Soil pH	5.1-6.5
Soil texture (g/kg)	300-320
Organic carbon (g/kg)	9.00
N (g/kg)	0.9
P (mg/kg)	6.0
K (cmol/kg soil)	0.40
Ca (cmol/kg soil)	0.89
Mg (cmol/kg soil)	0.80
Ca : Mg	3-5
Zn (mg/kg)	2-10
Cu (mg/kg)	0.3-10
Mn (mg/kg)	<50
Fe (mg/kg)	2-20

Source: Iloyanomon et al. (2011).

Table 2: Foliar critical levels of nutrient elements of *C. robusta*

Nutrient Elements	Critical level (%)
N (g/kg)	1.10
P (mg/kg)	0.7 – 0.9
K (cmol/kg soil)	1.4
Ca (cmol/kg soil)	0.37
Mg (cmol/kg soil)	0.13
Ca : Mg	1.19
Zn (mg/kg)	0.002-0.003
Cu (mg/kg)	0.016-0.002
Mn (mg/kg)	0.005-0.01
Fe (mg/kg)	0.07-0.02

POTASIUM (K)

K is necessary for formation and translocation of carbohydrates, cell division, regulation of osmosis or control of water in the plants and increases the resistance of some plants to certain diseases and insects attack as well as activator of various enzymatic systems (Ibiremo and Akanbi 2015). Moyin-Jesu (2008), noted deficiency symptom of N, P, K as shown by yellow coloration, purple without application of fertilizer. Jessy (2011) stated that at the berry development stage, K requirement and absorption is highest with its peak at the ripening stage. Its uptake rises just after the main flowering at the last stage of fruit development and later as the plant recovers from fruit bearing where water is not limiting. Iloyanomon et al., (2011, 2020) reported very low K content in the soil and leaves of coffee plantation of different ages in Ibadan, Nigeria. This is similar to the findings of Carvajal (1985) who reported K insufficiency on a soil farmed with coffee for over 22 years. The low value of K was ascribed to loss of K during harvesting of coffee berries. A tonne of coffee beans has been reported to remove 35kg N, 7kg P_2O_5 and 50kg K_2O (Jessy, 2011). Therefore, harvesting of coffee berries with high concentration of K without replenishment of the lost through K fertilization could lead to deficiency of K from the coffee plantation. Functions of both macro and micro elements are summarized in Table 3.

Table 3: Macro and Micro Elements needed for coffee production and their functions

Elements	Functions
N	Essential for vegetative growth Enhances coffee bean size Helps in formation of chlorophyll (green colour) Helps in formation of hormones and enzymes It increases tree bearing capacity
P	Necessary for root development Promotion of early berry maturity It increases bean density Essential for flowering and ripening of berry Helps in formation of energy compounds
K	Essential for berry development and ripening Enhanced mucilage formation Helps in promotion of healing injured tissue especially after picking and pruning Necessary for photosynthesis and disease resistance Regulation of water uptake from the soil
Mg	It is a major constituent of chlorophyll Helps in seed germination Essential for photosynthesis It produces energy for the plants
B	Promotes shoot and root growth Essential for germination of pollen Facilitates flowering, fruit set and development Transport of sugar
Ca	Necessary for growth of terminal buds and flower formation Helps in bark formation (formation of cell wall) Facilitates root and apical growth
Zn	Enhances fruit set and leaf size Boost flower initiation and formation Sets the inter-nodal spacing on the branch and the stem
Fe	Helps in the production of chlorophyll Promotes bean colour Together with copper, it facilitates energy transfer during food manufacture
Cl	Helps in photosynthesis Gas exchange and water balance
Mn	Component for manufacture of enzymes Helps in photosynthesis
Mo	Helps in Nitrogen metabolism
Cu	Essential for chlorophyll and protein formation

S	Necessary for plant growth Helps in disease resistance, seed production and protein synthesis

Fertilizer Management

Nigerian soils are generally low in quite a number of essential nutrients due to various factors such as erosion, leaching, bush burning, low activity clay, and among others, hence, these must be provided to foster good and optimum coffee yield. Ibiremo *et al.,* (2011b) stated that most soils upon which coffee is cultivated are usually poor in nutrient contents such as nitrogen, phosphorus and potassium. Likewise, Iloyanomon *et al*., (2011) reported that coffee cultivation in Nigeria lacks good soil management systems as production gets little or no fertilizer applications in the hands of major producers who are small scale farmers. This has resulted into removal of nutrients through harvesting of coffee berries without replacement of lost nutrients. Application of appropriate fertilizer could increase C. robusta yield from average current of 1 metric tonne up to 3 metric tonnes of FAQ per hectare per year (UCDA, 2019).

Fertilizers are added to the soils to increase yields or improve crop productivity. The integrated use of organic and inorganic fertilizers is desirable to sustain coffee yield and maintain soil fertility. C. robusta responds well to application of both organic and inorganic fertilizers. Ojeniyi (1981) reported that application of NPK fertilizer in C. robusta enhanced uptake of some essential nutrients such as Mg, Ca, Mn, S and Cu in the soil therefore organic fertilizer is recommended in the production of coffee because of the vital roles they perform in the soil and plants. Application of organic and inorganic fertilizers depends on factors such as the history of the soil, soil condition, inherent soil fertility status (Ngaruiya, 1995). Various NPK formulations (liquid and solid) in Nigeria are used by farmers for some tree crops and arable crops production. Foliar spray is a well-established tool to enhance and improve plant nutrition. Liquid fertilizers are mostly foliar fertilizers that contain high purity NPK and trace elements. They are effective and quick by spraying on leaves and dissolve in water (Ibiremo et al., 2013). Ibiremo and Akanbi (2015) stated that the use of NPK fertilizer formulation especially liquid NPK provides another fertilizer options to farmers as ways of fostering coffee productivity. Likewise, liquid NPK fertilizer could simply be used in addition with other agro-chemicals like insecticides and fungicides for effective growth. In addition, Ibiremo et al., (2013) reported that the positive influence of NPK fertilizer formulations on the coffee seedlings growth mainly NUTRICO-1(NPK-liquid fertilizer) is a pointer and that there is need to explore other fertilizer formulations that will combine efficiency with cost effectiveness and ease of application in the production of coffee and other fruit trees.

Organic materials are natural source of major and micro nutrients. Coffee gains from organic manure in form of farmyard manure, compost, human faeces, human urine or composted household refuse (Adejobi et al., 2011). The use of cocoa pod husk has been reported by Obatolu (1995) as fertilizer for coffee. Cocoa pod husk ash (CPHA), organo-mineral fertilizer (OMF), their combinations and urea increased uptake of nutrient by coffee seedlings. Combination 15 t ha^{-1} + 5 t ha^{-1} CPHA gave highest soil OM, N, leaf K, Mg and K gave highest value for most growth and yield parameters signifying that availability of OM and N, K and Mg dictate strongly the performance of coffee. Aside from organic material (CPHA, OMF) urea alone increased P, K, Mg, Ca and Na concentration (Adejobi et al., 2011). Ojeniyi (1980; 1981), had observed that application of NPK fertilizer caused deficiency of Ca and Mg in leaves of C. robusta; although NPK at suitable combination enhanced the yield of coffee considerably. Yet in unfertilized plots, deficiency symptoms of N, P, K, and Mg were noted (Ojeniyi, 1980). Therefore, organic fertilizers such as CPHA and OMF would be effective in increasing coffee seedlings performance and nutrient uptake (Adejobi et al., 2011).

CONCLUSION

The study reviewed nutritional conditions and fertility status of soils for coffee robusta production in Nigeria. It was revealed that Nigerian soils are moderate to marginally suitable for coffee production and will require good management practices to obtain optimum productivity. Therefore, deficient nutrients should be supplied through the use of appropriate fertilizers which has been reported to increase coffee productivity.

ACKNOWLEDGEMENT

I sincerely appreciate Dr. R. R. Ipinmoroti for his support, guidance and correction in the course of this research.

SOIL AND FERTILIZER MANAGEMENT IN CASHEW (*ANACARDIUM OCCIDENTALE* L) PRODUCTION IN NIGERIA: A REVIEW

Ogbeide, C.E. and Ibiremo, O.S.

Soils and plant Nutrition, Cocoa Research Institute of Nigeria. P.M.B. 5244, Ibadan.

ABSTRACT

Research achievements in soil and fertilizer management in cashew production in Nigeria were reviewed, emphasizing historical antecedents, soil and fertilizer management among other things. Cashew thrives well in moderately deep soil of 1-1.5 m that is sandy loam with at least 60% sand and well drained that has capacity to supply continuous nutrients. Information on nutritional requirements showed that combination of urea at 120 kg/ha with MOP at 48 kg/ha gave the highest yield of 3.53 kg/tree for the first year, single application of SSP at 144 kg/ha significantly slightly increased yield during the second year, while NPK fertilizer when applied as urea at 60 kg/ha, SSP at 144 Kg/ha and MOP at 24 kg/ha gave the highest yield for the second year and significantly reduced the disease infection. Fertilizer application rates and other technical requirements of cashew cultivation are highlighted in this paper. Gaps for further research were identified which include the use of integrated nutrient management and site-specific fertilizer application for cashew cultivation were also proposed.

Keywords: *Nutrient, cashew, fertilizer, yield, Urea, Muriate of potash (MOP), Single super phosphate (SSP).*

INTRODUCTION

The history of cashew in Nigeria dates back to 15th century. As at that time, cashew was mainly used in afforestation schemes for the control of soil erosion in the former Eastern Nigeria. In Nigeria, commercial cashew plantations started in the early 1950s with the establishment of commercial plantation in different regions of Nigeria. Cocoa Research institute of Nigeria (CRIN) in 1975 commenced research on the cultivation, uses of cashew in Nigeria. Falade (1978) reported that its cultivation has spread to other agro-ecological zones of Nigeria. Cashew grows almost everywhere in Nigeria but is concentrated primarily in the southern and middle belt regions by small land holdings farmers. The majority of export of quality nuts comes from the Western and Eastern parts of the country. Industrial cashew processing in Nigeria began in the early 80's when the old Eastern Regional Government established the Premier Cashew Processing Factory, located in Oghe in Enugu State, primarily to process the harvest from the government owned 650ha cashew plantation as well as to serve other small land holding farmers in and around the States of Kogi and Benue.

Soil and climatic requirements

Cashew can be cultivated in a variety of soil types and in selecting suitable soil for cashew visual observation could be employed minimally to know the types of trees, weeds and presence of worm cast among other ecological indicators. The crop is predominantly found in all parts of the country. Falade, (1978) revealed that the wide spread coverage of the crop indicates that cashew grows on a variety of soil types. Suitable soils for cashew ranges from entisols in the South, ultisols in the West, ultisol or oxisol in the East to alfisols in the North (Obatolu, 1996). Most of the soils producing cashew are light in texture ranging from sandy to loamy sand. Cashew thrives well in moderately deep soil of 1-1.5 m that is sandy loam with at least 60% sand and well drained that has capacity to supply continuous nutrients. Excess of gravel and clay along profile retard cashew root growth and must be avoided. A well-drained friable deep and medium- textured soil that can retained enough moisture during climatic stress of a long dry season and an annual rainfall of 400-1,500mm is recommended for cashew production.

Soil fertility management

The soil type and the quality of the soil influence the growth and development of cashew plant. In Nigeria, soils on which cashew is grown is sandy loam in nature (Ayodele, 1993), which cannot hold nutrients for prolonged periods. It has been observed that most Nigerian cashew farmers do not use fertilizer and thus the nutrients being mined by the plants are not replenished. According to Ohler, (1979) reported that cashew flourishes in soils where most other crops do not perform better with nutritional assistance. Cashew respond well to fertilizer application, mostly during the vegetative growth stage (Hammed *et al*., 2011). The limited production may be as a result of nutrient deficiency in the soil. The use of organic fertilizer amended with phosphate fertilizer and Arbuscular mycorrhizal fungi (AMF) innoculation were found to have positive influence on the growth and chemical properties of the soil of cashew. Nigerian Sokoto rock phosphate (SRP) for cashew production also according to (Ibiremo,2010; Ibiremo *et al*..2012). Recent work by Adewale *et al.* (2013) also revealed that the trend of growth and development of cashew genotypes differed in response to varied combination of the soil nutrient. Cashew farmers in Nigeria use little or no fertilizer. Continuous harvest without appropriate nutrient replenishment, leads to nutrient mining. Cashew is responsive to nutrient supplementation as nutrients are lost through harvesting of nuts/apple. Most existing cashew plantation in Nigeria produce one-third of what obtained in other Countries. Research established soil and foliar critical levels for cashew below which fertilizer should be applied soil critical levels: Total N 1g/kg, Available P 3.7mg/kg soil, Exch. K 0.12 cmol/kg soil, Mg 0.08 cmol/kg soil, Ca 0.08 cmol/kg soil. The foliar critical level is N 1.24%, P 0.12%, K 0.34%, Ca 0.18%, Mg 0.88%. (Egbe *et al*., 1989). Below these soil and foliar critical levels, nutrient supplementation as fertilizer is necessary. Research established soil and foliar critical levels for cashew below which fertilizer should be applied: Soil critical levels: Total N 1g/kg, Available P 3.7mg/kg soil, Exch. K 0.12 cmol/kg soil, Mg 0.08 cmol/kg soil, Ca 0.08 cmol/kg soil. One kilogramme of cashew apple and nuts removed 64g N, 2g P, 25g K, 4g Ca, 2g S, 525mg Fe, 64mg Mn, 88 mg Zn and 27 mg. The deficiency symptoms of nutrients include yellowing of leaves and stunted growth due to N deficiency while P deficiency leads to leaves changes from leaf green to dark green, to bronze and yellowish shade. Leaves are small and K deficiency results in leaf chlorosis and firing of edges of the leaves.

Soil requirements for cashew

Falade (1978), reported that soils of the cashew in Ochaja, Kogi state, Nigeria have low levels of exchangeable bases, nitrogen and phosphorus indicating that possible response to fertilizer by cashew crop was possible. Adejumo (2010) reported that urea at 120 kg/ha when combined with MOP at 48 Kg/ha gave the highest yield of 3.53 kg/tree and lowest disease infection (90 inflorescence panicles infected) for the first year agree with the report of Katan (2009) that NO_3 nutrition stimulates K uptake and vice versa promoting the synthesis of organic N compounds. In the second year, NPK fertilizer when applied as urea at 60 kg/ha, SSP at 144 Kg/ha and MOP at 24 kg/ha gave the highest yield for the second year and reduced disease infection (125 inflorescence panicles infected) significantly. According to Adejumo, 2010, this might be attributed to a balanced NPK nutrition, especially SSP at high concentrations. The observation of increased yield and reduced disease infection of single application of urea at 60 and 120 kg/ha and SSP at 72 and 144 kg/ha observed for the second year was not surprising. Nitrogen is the most commonly used fertilizer and is essential for the production of many cellular components (Huber and Thompson, 2007). Yields of trees grown in this way are very much lower than the potential that could be gained if fertilizer was applied (FAO, 2004). Azam-Ali and Judge (2001) reported that potential yield of 10 to 15 kg per tree could be obtained under optimum conditions. The result is presented in Tables 1 and 2 below:

Table 1: Effect of fertilizer application on yield disease infection of cashew

Year	Type of fertilizer	Rate (kg/ha)	Result
First	SSP	144	Slight increase in yield and reduction in infection
Second	Urea+ MOP	120+48	Highest yield of 3.53kg/tree and lowest disease
Second	NPK+SSP+MOP	60+144+24	Highest yield and significantly reduced disease

Strategies to be adopted to increase cashew area in the states

a) Cultivable waste lands can be utilized for cashew plantations by different government agencies.

b) Awareness must be created among all the players (farmers, processors and entrepreneur) in cashew sectors through circulation of leaflets and booklets on improved cultivation practices.

c) Technology dissemination to the rural youth through training, demonstration and electronic media together with formation of farmer groups of common interest for holistic development.

Gaps in knowledge

Research effort should be made on the use of crop wastes as soil amendment alternative for cashew cultivation. These could also be integrated with inorganic fertilizers to improve their efficiency. Hence, the waste –to- wealth approach will reduce wastage within farming system.

Recommended research

Gaps for further research were identified which include the use of integrated nutrient management and site-specific fertilizer application for cashew cultivation are hereby also proposed.

CONCLUSION

Suitable soils for cashew cultivation are well drained soil, deep and medium texture soil that can retain enough moisture and nutrients for improve productivity. Use of unsuitable lands for cashew will not only lead to wastage of resources but also will reduce productivity. Hence, suitable soils with appropriate management practices will lead to high yield of cashew.

ABSTRACT

The nuts of kola (Cola species) are used in local and international trade as well as pharmaceutical, drug and wine production, religious, social and traditional functions. The results of fertilizer trails on common species of kola were discussed. Result on plant nutritional research, soil nutrient depletion due to nutrient mining as a result of yearly harvest and effect of fertilization on yield were reviewed. It was shown that poor soil fertility and nutrient element reduction lead to poor growth and establishment, decline in yield and quality. Boron deficiency was shown to reduce plant growth and number of nuts but significantly increased nuts weight. Major nutrient such as N, P, Ca, Mg and K were also reported to show deficiency symptoms which also affected growth and yield. The order of importance of essential nutrients was stated as boron>copper>zinc>phosphorus>calcium>potassium>magnesium. Nitrogen or any other element affect growth and yield only when it is significantly deficient. Loamy sand to clay soil with sand 65-70%, silt 14-19%, clay 15-20%, pH 5-6, N 0.14-0.18%, available P 6-8mg/kg, exchangeable cation 0.35-0.40, 0.32-0.35, 2.9-3.5 and 0.9-1.0 cmol/kg for K, Na, Ca, and Mg respectively are requirement for Kola production. Minimum NPK fertilizer recommended was 131kg N, 21kg P and 139kg K base on amount removed by yield per hectare per year. Critical soil and leaf nutrient level for N, P, K, Mg, Ca were reported as 0.1%, 3.87mg/kg, 0.12cmol/kg, 0.8cmol/kg, 0.8cmol/kg and 1.5%, 0.22%, 1.19%, 0.25%, 0.8% respectively and inclusion of micronutrient supplying fertilizer for kola production recommended. Significant increase in growth and yield was reported for sole application of organic fertilizer and also when combined with inorganic fertilizer. Inorganic fertilizer was said to be scarce, costly with adverse effect on soil acidity.

Keywords: Kola, Yield, Soil fertility, Nuts.

INTRODUCTION

There are more than forty species of Kola and the two most common and productive species of this crop used in Nigeria are *Cola nitida* and *Cola acumunata* (Adebowale 2015, Ndagi *et al.,* 2012). In Africa, especially West Africa where Kola originated, it is used to produce several pharmaceutical drugs, wine, liquors and confectionary in addition to its use as masticator and stimulant. Kola trade has increased over time since its inception as early as the nineteenth century raising the standard of living of the trader (Kanmegne, 2015). Presently, the demand of kola nut is far in excess of its production. Thus, there is a need to increase both its acreage as well as productivity (Ndagi 2012). The sustained increase in demand of kola nut has led to greater interest in it as tree crop. But it has been realized that fewer information existed on kola, particularly on soil fertility and plant nutrition. Also, the very few report that are available needed to be assembled for easier review as well as guide for further nutritional research on the crop. Therefore, the aim of this review is to focus attention on past work with view to know knowledge gap in order to recommend areas of further studies.

CHALLENGES OF SOIL NUTRIENT DEFICIENCY ON PRODUCTION

Soil fertility degradation is one of the most serious threats to kola production and effect of poor soil fertility lead to reduced growth, poor establishment, and decline in yield, poor kola nut quality and increase in disease and pest infestation. The production of kola nut is influenced by soil fertility. Nutrients are "mined" from the soil through kola pod yearly harvests but farmers hardly employ practices to ensure nutrient replacement through processes like fertilizer applications. This leads to non sustainable production of kola as the resulted low fertility status would at a point be no longer able to sustain production. Ipinmoroti *et al.* (2000) and Asogwa et al. (2012) reported falling kola yields due to old age and soil nutrient depletion and stated that ability of any soil to replace nutrients absorbed by crops depend mainly on the clay type, mineral composition of the fine fraction and soil fraction in toposequence. Also, Ajiboye *et al.* (2019) have shown that the decline in yield and soil physical and chemical degradation occur as result of mismanagement of agricultural land in the sub-Saharan Africa

According to Asogwa *et al,* (2012) there is an abundance of soils of high, medium, and low fertility that can be strategically exploited for kola nut cultivation in an effective land utilization policy and such suitable soils have long been identified in sub-Sahara Africa. These suitable soils should be utilized for new plantings of improved kola seedlings to ensure high production. Despite endowment in soil resources suitable for kola nut production, as well as long history of kola nut production particularly in Nigeria, the main challenge facing production is drop in yield of kola trees which result to low return from the stands (Ndagi, 2012). This has made farmers resolved at abandoning their farms for the production of annual crops like maize, cassava, guinea corn, and vegetables (pepper, tomatoes, etc.), among others (Ndagi, 2012). The need of the hour is to find a way for adequate nutrient replenishment to enhance the nutrient status of the soil above the critical nutrient level established for kola.

BORON- AN ESSENTIAL MICRONUTRIENT FOR KOLA

Effect of different rates and sources of boron on yield of kola between1968 and 1976 were reported by Egbe (1980). It was shown that non boron deficient tree consistently gave higher yield (nearly thrice) than the tree with boron deficient symptoms with a marked decline in yield. This confirmed Jacob *et al.,* (1972) and Egbe (1973) observation of wide spread of boron and copper deficiency in Kola plantations. The study on Kola clonal materials (AA 86 and some *C. nitida* tree) being screened for yield performance in Osogbo under old Oyo state and CRIN Gambari experimental station (1970) showed signs and symptoms of boron deficiency which include thickened shoots and broad leaves surface becoming uneven, less glossy as well as die back of the growing point with subsequent profuse bud break of many lateral shoots followed by necrotic spot on young leaves.

Abnormally short stem internodes of the branches were also observed with leaves showing various deficiency symptoms as well as production of parthecarpic fruits. The crop yield of *C. nitida* and its components such as branches (hands) per tree, pod per bunch, nut number per pod and mean nut weight were recorded for plant that were boron deficient and non boron deficient for six consecutive harvest seasons from 1971-76. It was observed that non boron deficient tree consistently gave higher yield than the tree with symptom. In 1973-1975 it was reported that boron deficient tree of clone AA86 in Gambari Experimental Station (GES) showed a marked decline in yield. The trees with visual boron deficiency symptoms produced less fruits per tree and pods per hand than the symptomless one. The boron deficient tree had a mean nut weight which was significantly higher than that of the normal tree. The higher mean nut weight of boron deficient tree (AA86) was believed to be as a result of the marked lower number of hands per tree as well as pods per hands. Eijnatten (1967) and Jacob (1973) had observed that higher number of pods per fruiting point had a decreasing effect on nut weight. From the yield data shown, it was concluded that *C. nitida* production, particularly in area where the soil was derived from basement complex rock in Nigeria suffered from inadequate boron supply. Through these reports it has been shown that boron deficiency in kola tree seems to contribute adversely to irregularity of bearing and has been discovered to depresses the yield of kola and that trees with visual B-deficiency symptoms produced less fruiting branches (hands) per tree as well as less pods per hands than symptomless one.

Joseph and Ipinmoroti (2013) examined soil and leaf micronutrient content of kola plantation in Uhomora, Edo State and found that Cu, Mn, Zn, and Fe level were 0.39, 0.03, 30.1, and 198 mg/kg soil compare to the critical level of 2.5, 0.1, 0.1 and 4.5mg/kg soil recommended for tree crop (McKenzie, 2001), while leaf micronutrient was found to be 2.11, 0.15, 20.92 and 27.85mg/kg dry weight for Cu, Mn, Zn, and Fe respectively. The leaf Cu, Mn and Zn content were far below critical level of 8.0, 20.0 and 25.0 mg/kg dry matter weight recommended for tree crops (McKenzie, 2001). They concluded that kola plantations nutrient management need inclusion of micronutrient supplying fertilizer for balanced nutrient supply.

MAJOR MACRONUTRIENT FOR KOLA

Egbe (1968) reported chlorosis as well as reduced growth in kola due to nitrogen deficiency and that phosphorus requirement was low at the beginning of growth but increase considerably with maturity. It was observed that calcium deficiency resulted in chlorosis from the tip and towards the base of the leaf. The rate of leaf production was notably reduced; new leaves were smaller than normal and attack by fungus accompanied deficiency. Magnesium and Potassium deficiency showed interveinal chlorotic spots in both sides of the midrib of the leaves extending to the base from the tip and development of puffy leaves with tissue between main lateral veins; papery texture as well as rounded leaves with drip trips pinched respectively.

Egbe and Ayodele (1981) stated that the order of importance of the essential nutrient for kola was boron>copper>zinc>phosphorus>calcium>potassium>magnesium and reported positive response of kola to PK (mineral fertilizer) application with more pod than P, K, or N alone or NP or NK and that N was observed to have depressive effect on production. It was concluded that the fertilizer N forced vegetative growth at the expense of fruiting and that all the fertilizers seem to have depressive effect on nut production when compared with the control tree and that this indicate that nutrient other than NPK are limiting yield of kola. Likewise, response of kola seedling tree to NPK was observed to be quite different from those of the ramet on the same soil type and climate. Ayodele (1983) reported that application of P, K, NK and PK resulted to higher average kola yield than the control while N, NP and NPK depressed yield. It has been confirmed that kola seedling would respond to fertilizer treatment because some moribund kola plot that were supplied with kola seedling showed some nutrient deficiency symptoms. NPK fertilizer was applied right to the plot from year of planting through maturity at mean application rate of 98, 98 and 58 kg/ha/annum of urea, superphosphate and potash respectively. The result indicated that at the rate of applied fertilizer on ramet, N and NP depressed yield at 5% level, indicating that the applied rate is probably too high. P, PK and NPK had no significant effect on yield, K and NK increase nut yield at 1% and 5% level of significance respectively. It was also found that treatments had no significant effect on nut yield of kola from seedlings.

Egbe and Ayodele (1984) reported that soil suitable for the growth of kola is formed from various parent materials and varied, ranging from loamy sand to clay. It was also reported that low nutrient was derived in soil from sandstone which is particularly low in exchangeable bases, nitrogen and phosphorus. Based on the result of physical and chemical analysis carried out, some of the textural and chemical properties considered favourable for the good growth of Kola were; sand 65-70%, silt 14-19%, clay 15-20%, pH 5-6, N 0.14-0.18%, available P (Bray 1) 6-8mg/kg, exchangeable cation 0.35-0.40, 0.32-0.35, 2.9-3.5 and 0.9-1.0 cmol/kg for K, Na, Ca and Mg respectively, organic carbon 1.6-2.0% as well as Carbon/Nitrogen ratio of 11:13.

In 1987 and 1988, Ayodele estimated the amount of nutrient (NPK) removed from the soil in harvested kola and found that the husk and the seed coat have higher content of N, P and K than the nut and suggested that the coat could be a good source of fertilizer. The calculated amount of N, P and K removed from the soil was estimated using 500-5000 nuts/hectare/year as 130.91kg, 10.34kg and 138.74 kg respectively. On the basis of this, minimum NPK fertilizer was recommended for kola production as 131kgN, 21kg P and 139kg K. Egbe *et al.* (1988) observed that kola plantation in Nigeria had low exchangeable K, total N and available P as well as widespread deficiency of boron and copper. In addition, critical soil and leaf nutrient level was established for kola productivity as 0.1% N, 3.7mg/kg P, 0.12cmol/kg K, 0.8cmol/kg Mg , 0.8 cmol/kg Ca and 1.09% N, 0.08% P, 1.2% K, 0.34% Mg , 0.47% Ca respectively (Egbe *et al.,* 1989).

Ayodele (1999) through studies on effect of NPK on the seedling of kola showed that it responded to additional element (e.g. NPK) only if the soil is deficient in such nutrient element. Likewise, Ipinmoriti *et al*., (2000) observed that some moribund kola plantation after decade without fertilizer application showed decline yield and too low soil N and K content while Ca was reported to be too high. Ayodele (1995) examined plantations of kola in Nigeria and found it to be generally acidic with pH value between 4.0 and 6.7, the N content was found to be below critical level of 0.1% though with no symptom of deficiency. The available P ranged between 1.0-8.5mg/kg and exchangeable base mean value for K, Ca and Mg in the study was 0.37cmol/kg, 3.13cmol/kg and 0.96cmol/kg higher than the 0.12cmol/kg, 0.8cmol/kg and 0.8cmol/kg reported critical values for soil. It was indicated from the study that moderate nutrient status of the soil with value of about 67% sand, 16% silt 17% clay, pH (H_2O) 6.0, 0.16% total N, 6.0 mg/kg available P, 0.37cmol/kg K, 0.3cmol/kg Na, 3.13cmol/kg Ca, 0.96cmol/kg Mg, 1.8% C and C/N of 13 support good growth of kola (*Cola nitida*) Adebowale *et al.,* (2015) discovered from five selected kola plantation in Ogun State pH range of between 5.29-7.57, sand, clay and silt content range between 49.95-73.57%, 17.57-35.81% and 2.64-14.72% respectively. The soil organic content was found adequate in almost all the soil while nitrogen was found to be below critical value of 0.1% and

ISSN: 2814-0508

available P was between 3.98-8.03mg/kg which was above the critical value of 3.7mg/kg soil. The exchangeable K was between 0.08-0.44cmol/kg, Ca content was found to be above critical value of 0.8cmol/kg while Mg was found to be below the critical level of 0.8cmol/kg.

ORGANIC AMENDMENT IN KOLA PRODUCTION

Egbe *et al.* (1988) found the use of animal as well as crop wastes in the form of farmyard manure or compost helpful in improving production. They observed that the use of chemical fertilizer on kola production had been hindered by its scarcity, high cost, incomplete nutrient supply as well as possible enhancement of soil acidity, low total N, available P and exchangeable K. Also, It is expected that young plant should be raised using top soil rich in organic matter. However, it is often difficult to obtain adequate suitable top soil due to deforestation.

Ajayi *et al.,* (2007) reported better growth performance and nutrient (N, P, Mg and Ca) uptake in kola seedlings (*Cola acuminata*) through application of cocoa pod husk in screen house. Ogunlade *et al.* (2008) also reported amendment of subsoil with 5ton /ha of either KPH or poultry droppings which consistently gave higher seedling height than 2.5 ton/ha and unamended top soil. Moyin-Jesu 2009 used amended organic fertilizer to raise kola seedling (*Cola acuminata*) and observed that the organic residues significantly increase growth and nutrient uptake of kola seedling, soil pH and organic matter content. Adejobi and Ayegboyin (2011) stated that urine has high nitrogenous fertilizer value than facea, contained up to 0.9%N, 0.12%P and 0.26% K and that human urine combined with cocoa pod husk releases more nutrient for kola production than faeces and cocoa pod husk separate application.

Kola testa has been suggested as a possible fertilizer ingredient (Olubamiwa, 2002). Adeosun *et al.,* (2013), used kola testa and NPK fertilizer as amendments and reported significant increase in growth performance, soil and leaf nutrient composition of kola seedling from sole and combined application compared to the control Adejobi (2015) stated that combined application of organic (human urine, Kola pod husk ash, goat dung) and inorganic fertilizer (urea) increased significantly the plant height, number of leaves, number of branches, shoot length, stem girth, leaf area, dry root weight and fresh shoot weight of kola seedling relative to urea treatment and the control. The leaf analysis of the kola seedling also showed that there was significant increase ($P<0.05$) in the leaf N, P, K, Ca, and Mg content for different organic fertilizer sources compared to control.

CONCLUSION

Kola is an important economic cash crop to a significant proportion of Nigeria population who are involved in kola farming, trading and industrial utilization. While the demand is rising, the production remains low because many of the trees in Nigeria are unfruitful or have very low yield due to inefficient pollination, old age, soil nutrient deficiency incompatibility, pests and diseases among others.

Work has not been done extensively on the effect of macro nutrient and micro nutrients. The positive and adverse effects of combination of these various elements (such as Ca and Mg, P and Zn, etc) on both seedlings and ramets growth and fruiting have not been evaluated.

RECOMMENDATION/ AREA OF RESEARCH IMPROVEMENT

The following are recommended to improve kola nut production:

(1) That attention should be given to soil fertility management of existing kola plantations and appropriate fertilization policy established to enhance productivity.

(2) Cocoa Research Institute of Nigeria (CRIN), particularly soil and plant nutrition section should be given necessary support in this regard.

(3) Farmers should be trained on the use of affordable, soil friendly and low cost organic amendment.

(4) Researchers should be as practical as possible in working with the farmers by setting up demonstration plots.

(5) Efforts should be geared toward organizing kola farmers into association and/or cooperative because this has the potentials of facilitating coordination and implementation of research findings.

ABSTRACT

Poor soil fertility status is one of the major factors responsible for decline growth and productivities of cashew in Nigeria. The study was conducted to evaluate some leaf nutrients contents of three cashew biotypes at different reproductive stages. The nut yield was also evaluated. The experiment was conducted at the cashew plot in Zone 3 and 4 (07° 10' N and 03° 52' E) of Cocoa Research Institute of Nigeria (CRIN) Ibadan. The cashew biotypes were established in blocks based on cashew biotypes of madras, small, medium, large and jumbo nuts size. The cashew trees sampled were randomly selected from three blocks (i.e. trees producing small nuts, medium nuts, and large biotypes and replicated three times). Leaf samples were collected on each selected tree at four different reproductive stages, processed and analysed chemically following standard procedures during the 2018/2019 production season. Soil samples were also collected, processed and analysed following standard procedures. Nuts from each sampled cashew tree were also collected every week as the fruit matured and dropped until the end of fruiting season. Nut yield data were subjected to Analysis of variance and treatments means were separated using Duncan Multiple Range Test (DMRT). Results indicated that nitrogen and phosphorous contents of the leaves were higher before flowering. The values of these two essential nutrients drastically reduced during flowering. Adequate supply of nitrogen and phosphorous is essential for efficient flowering and fruiting in cashew production. It is therefore recommended that farmers should apply fertilizers that are rich in nitrogen and phosphorus before the flowering stages to enhance cashew productivity. Cultivation of cashew biotypes with large and medium nut sizes is also recommended for farmers for higher nut yield.

INTRODUCTION

Cashew (*Anacardium occidentale* L.) is grown for it nuts and the pseudo- apple from which products, such as cashew juice wine, vinegar, jams, chocolate, cashew nut shell liquid (CNSL) and cooking oil are obtained. Cashew has a great potential as a foreign exchange earner and source of industrial raw material with the prospect of becoming a major commercial tree crop in Nigeria. The main focus of cashew farming/cultivation is the nut yield which is majorly determined by genetic potential of the variety planted and soil fertility, among other factors. Crop growers often attempt application of organic and inorganic fertilizers to boost soil nutrient and enhance their crop productivity. However, the foliar nutrient dynamics of cashew at different reproductive stages within the season vis-à-vis the nut yield has not been fully understood. Therefore, understanding nutrient concentration of cashew leaves at different reproductive stages within a season will guide on the appropriate soil fertility management options for enhancing cashew nut production. Therefore, the objective of this study was to evaluate some leaf nutrient contents of three cashew biotypes at different reproductive stages within the season. The nut yield was also evaluated.

MATERIALS AND METHODS

The experiment was conducted at the cashew germplasm plot in zone 3 and 4 (Latitude 07°10'N and Longitude 03°52'E) of Cocoa Research Institute of Nigeria (CRIN) Ibadan between November, 2018 and May 2019. The cashew plot was established in blocks based on cashew biotypes of madras, small, medium, large and jumbo nut sizes. The cashew trees tagged and labelled for this trial were randomly selected from 3 of the blocks - cashew trees producing small, medium and large nuts and replicated three times. Leaf samples were collected from cashew trees in each block representing each biotype- small, medium and large at four different reproductive stages (Before Flowering (Bf), During Flowering (DF), During Fruiting (DFT) and After Fruiting (AFT) in three replicates. The leaf samples were oven dried at 70^{oc} and grinded to powder for laboratory analysis following standard laboratory procedures. Nine core soil samples bulked together as a composite sample per biotype in each block were collected using soil auger at 0-20cm depth. The soil samples were air dried, sieved and analysed chemically following standard laboratory procedures. The nuts from each sampled cashew trees were also collected every week during fruiting season as the fruit matured and dropped. This continued till the end of fruiting season.

RESULTS AND DISCUSSION

The soil pH values ranged between 7.2 and 7.6 (Table 1), a little above the critical range of 4.5 to 6.5 (Egbe *et al*., 1989). The soil across the three blocks was sandy loam with sand and silt contents ranging from 838 to 898g/kg and 54 to 114g/kg respectively. The soil particle size composition affects its characteristic properties such as water holding capacity, permeability, porosity, infiltration and susceptibility to erosion and leaching (Aikpokpodion *et al.,* 2010). Soil and leaf nutrient status can give better indication of nutrients requirements (Rupa T.R et al., 2014). The soil test results indicated that the major nutrients were adequate for cashew production. The values of total nitrogen, available phosphorus and exchangeable cations were above the critical values recommended for cashew as reported by Egbe et al (1989). However, the organic carbon content was low in the three blocks of small, medium and large cashew nut sizes.

Table 1: Some properties of soils under cashew plantations with different biotypes

Soil properties	Cashew plantations with different biotypes		
	Small	Medium	Large
pH	7.6	7.4	7.2
Sand(g/kg)	878	838	898
Silt(g/kg)	74	114	54
Clay(g/kg)	48	48	48
Textural class	Sandy loam	Sandy loam	Sandy loam
Organic Carbon (%)	1.19	1.56	1.21
Total Nitrogen (%)	0.10	0.12	0.11
Available Phosphorus(mg/kg)	24.7	22.5	24.4
Exchangeable Potassium(cmol/kg)	0.46	0.42	0.28
Exchangeable Calcium(cmol/kg)	15.06	14.90	15.11
Exchangeable Magnesium(cmol/kg)	2.81	2.61	2.31
Exchangeable Sodium(cmol/kg)	0.72	0.65	0.64

The N contents of the cashew leaves for small, medium and large biotypes before flowering were adequate and above the foliar critical range for cashew (Egbe *et al*., 1989) which was similar to adequacy of soil N, P and K contents obtained before flowering. Ghosh and Bose (1986) reported that leaf N of 1.51% was optimum for high nuts yield and N content range of 2.4-2.58% indicated sufficient N and 0.98-1.38 % showed N defficiency (Haag et al., 1975). Similarly, Aikpokpodion et al., 2009 reported P range of 0.1-0.7%, this is also similar to results obtained by (Kumar et al., 1982) 0.06-0.18% and 0.08-1.35% obtained in this work. However, the N leaf contents declined during flowering and fruiting below the critical value (Table 2). Similarly, the P contents of the leaves were adequate before flowering but the values decreased for all biotypes during flowering and fruiting. Of all the macronutrients examined in the cashew leaves, the reduction of N and P during flowering and fruiting were more pronounced and this might be due to the need for more of N and P in flowers and fruits production in cashew. This implied that N and P are needed more during flowering and fruit formation for increase in yield. Gawankar et.al (2010) reported significantly higher number of flowers and nut yield of cashew over the control when urea (2%) foliar spray was applied on 10-year-old cashew plants. Cashew flowering is always preceded by new leaf and shoot (ie cashew flowers on the current season's growth) and nitrogen in particular as well as phosphorus will be required for new shoot growth (Mclaughlin et.al 2020). Therefore, adequate supply of nitrogen and phosphorus through organic or inorganic fertilizer source is essential before flowering for optimum flower and fruit formation which will ultimately enhance cashew nut yield.

Table 2: Macro Nutrient Contents of Cashew leaves of various biotypes at different reproductive stages

Reproductive stages	Cashew Biotype	Macro Nutrient Contents (%)				
		N	P	K	Ca	Mg
Before Flowering(BF)	Small	0.81	0.105	1.148	0.131	0.144
	Medium	1.06	0.128	1.175	0.216	0.168
	Large	1.03	0.135	1.227	0.221	0.173
During Flowering(DF)	Small	0.01	0.085	1.070	0.221	0.119
	Medium	0.02	0.089	1.175	0.250	0.182
	Large	0.64	0.092	1.070	0.263	0.163
During Fruiting(DFT)	Small	0.14	0.018	1.305	0.287	0.203
	Medium	0.60	0.099	1.096	0.281	0.166
	Large	0.31	0.094	1.357	0.230	0.119
After Fruiting(AFT)	Small	0.04	0.098	1.279	0.262	0.157
	Medium	1.69	0.116	1.148	0.320	0.247
	Large	1.25	0.078	1.044	0.210	0.087

The average number and weight of cashew nuts obtained for the different biotypes is shown in Table 3. The number of medium nuts was significantly higher than small and large nuts. However, small and large cashew biotypes were not significantly different in terms of nut count. Considering the weight of cashew nuts, medium and large nuts were not significantly different. Weight is normally considered by cashew buyers hence cultivation of cashew biotypes with large and medium nut sizes is recommended for higher nut yield.

Table 3: Average Nuts Yield from Three Cashew Biotypes

Biotype	Nut Counts		Nut Weight	
	Number/tree	Number/ha	(kg/tree)	(kg/ha)
Small	205b	56,990b	0.83b	147.74b
Medium	649a	180,422a	3.40a	945.2a
Large	252b	70,056b	3.05a	847.9a

Means with same alphabets on the same column are not significantly different

CONCLUSION

Adequate supply of nitrogen and phosphorous is essential for efficient flowering and fruiting in cashew production. It is therefore recommended that farmers should apply fertilizers that are rich in nitrogen and phosphorus before the flowering stages to enhance cashew productivity. Cultivation of cashew nut types with large and medium nut sizes is also recommended for farmers for higher nut yield.

ABSTRACT

Field experiments were conducted at Teaching and Research Farm of the Kebbi State University of Science and Technology (KSUSTA) Aliero located in Jega (lat. 12°12.99' N; long. 4° 21.90'E; Alt 197m) during 2019 and 2020 dry seasons. The aim of the experiment was to study the response of Watermelon (Citrullus lanatus) to planting density and fertilizer type. Treatments consisted of five (5) plant population densities 40,000, 26,667, 20,000, 17,778 and 13,333 plants/ha and two (2) fertilizer application (cow dung and NPK) plus the untreated control; each fertilizer type is designed to supply the recommended nitrogen dose of 120kg N ha^{-1}. Treatments were laid out in a Randomized Complete Block Design (RCBD) with three replications. Results revealed that vine length, number of leaves, crop growth rate, number of fruits per plant, fruits weight per plant and fresh fruit yield were higher with planting density of 40,000 pha^{-1} when combined with the application of NPK fertilizer. Based on the results, it could be concluded that, planting density of 40,000 pha^{-1} recorded the higher yield and NPK mineral fertilizer have relatively the superior performance on growth and yield of Watermelon.

Key words: Watermelon, Cow dung, NPK, Panting density, Fertilizer type, Growth, Yield

INTRODUCTION

Watermelon (*Citrullus lanatus*), a member of the Cucurbitaceae family, is widely cultivated for its fruit and vegetative parts (Schippers, 2002). The fruit is an important source of carotenoids and a precursor of vitamin A (Setiawan *et al*., 2001). According to National Watermelon Promotion Board (2008), It ranks among the top five most frequently purchased and cultivated fruits globally with a per capita annual consumption of 7 kg (NWPB, 2008). The fruit can be served fresh in fruit salads, cooked and used as confectionary, and is becoming an everyday fruit like bananas, apples, and oranges. Its seed is also considered an important dietary item and contains a high amount of minerals and other nutrients (Oyenuga and Fetuga, 1975). Its centre of origin has been traced to both the Kalahari and Sahara deserts in African (Janet *et al*., 1996) and these areas have been regarded as point of diversification to other part of the world (Schipper, 2002). In Nigeria, though there are no official figures recorded for the production, the crop has a wide distribution as a garden crop, while as a commercial vegetable production. It cultivation is confined to drier savanna region of Nigeria (Anon, 2006).

Plant spacing is an important agronomic attribute, since it is believed to have effects on light interception which affects the photosynthetic process. In watermelon, increasing planting density decreases the number of fruits per plant, but individual fruit size is mostly unaffected (Duthie *et al*., 1999). Also, it affects the photosphere and rhizosphere exploitation by the plants especially when spacing is inadequate and the plants suffer from clustering together (Talukder *et al*., 2003). The use of spacing in crop production is very important and good because it reduces competition between plants and weeds. When adequate spacing is done in plant production, it increases crop growth and yield. Generally, in Watermelon, the yield and number of fruits per unit area increased with increased crop density, whereas the yield and number of fruits per plant decreased. High planting density increased the number of fruits per area (NeSmith, 1993). However, some studies showed that average weight of fruits decreases with increase in plant density (Motsenbocker and Arancibia, 2002).

On the other hand, Fruits and vegetables production cuts across Nigeria's geo-political zones and generates income to the farmers. Low soil fertility has been recognized as a major and general problem of crop production in the Savannah areas of Nigeria (Saidu *et al*., 2011). This type of problem is solved through the use of either organic or inorganic fertilizer. Generally, excessive amounts of inorganic fertilizers are applied to vegetables in order to achieve a higher yield and maximum value of growth (Dauda *et al*., 2008). However, the use of inorganic fertilizers alone may cause problems for human health and the environment (Aisha *et al*., 2007). So also, the use of inorganic fertilizer by resource-poor farmers is limited by its scarcity, cost and untimely availability. Cultivation with persistent application of inorganic fertilizers increases soil acidity and soil physical degradation which may reduce crop yield (Saidu *et al*., 2011). On the other hand, organic manure can serve as alternative practice to inorganic fertilizers for improving soil productivity (Sarkar *et al*., 2003). The use of organic manure also has their limitations including high risk of infection, high cost of transportation and labour on account of its bulkiness as well as a slow release of nutrients for plant uptake (Adekiya *et al*., 2012). The aim of this study was to evaluate selected planting densities and their responses to different soil fertility sources in the study area.

MATERIALS AND METHODS

The experiment was conducted in Teaching and Research Farm of the Kebbi State University of Science and Technology (KSUSTA) Aliero located in Jega (lat. 12°12.99' N; long. 4° 21.90'E; Alt 197m) during 2019/20 and 2020/21 dry seasons. The area has a long dry season that is characterized by cool dry air (Harmattan) that prevails from November to February; and hot dry air extending from March to May. The locations were used for cultivation of vegetable and cereal crops. The treatments consisted of five (5) plant population densities 40,000, 26,667, 20,000, 17,778 and 13,333 plants/ha and two fertilizer application (cow dung and NPK) plus the untreated control. The land was ploughed and harrowed to a good tilt. Water channels were constructed to facilitate free and efficient irrigation. Plot size was 5m x 3m (15m^2). A space of 1.0m between the plots, and 1.5m between replicates will also be use as borders. Tube well was used as the source of water where water pump machine was used to draw water, with aid of delivery hoses, to the experimental plots. Irrigation was done at 3-5days' interval depending on the crop's need. Weeds were controlled manually using hand hoe at 3 and 6 weeks after sowing (WAS). Watermelon fruits were harvested before they were fully mature and was staggered at 3-4 days over 3weeks. Data were collected on Vine Length (cm), Number of Leaves, Shoot Dry Weight, Number of fruits per plant, Fruits weight per plant and Yield (t ha^{-1}). Data generated were analyzed following analysis of variance procedure, and treatment means were separated using Duncan's Multiple Range Test (DMRT).

RESULTS AND DISCUSSION

Soil Physical and Chemical Properties of Experimental Site: Physical and chemical properties of soils of study location prior to the experiments are presented in Table 1.

Response of Plant Density on the Growth and Yield of Watermelon

Vine length, Number of leaves and Shoot dry weight of Watermelon as affected by Planting Density during 2019/2020 dry season are presented in Table 3. Greater vine length and shoot dry weight was recorded by Planting density of 13,333 pha^{-1}. The influence of planting density in this study showed that vine length and shoot dry weight increased significantly as planting decreases. Decrease in plant density, increased the vine length and shoot dry weight which is a known vegetative components of watermelon which could be attributed to wide variability in crop performance caused by planting density as reported by Dantata (2008). Number of leaves was similar irrespective of planting density during 2019 dry trial but planting density of 13,333 pha^{-1} recorded the higher number leaves. This behavioural pattern of response in leaves number exhibited by watermelon in this study, agrees with the findings of Davis *et al.* (2008) who reported various differential growth behaviour among watermelons. The authors' report on the fact that growth of watermelon varied according to year has also found expression in the current study. Number of fruits per plant, Fruits weight per plant and Fruit yield of Watermelon as affected by Planting Density during 2019/2020 dry season are presented in Table 4 Higher number of fruits and fruit yield was recorded by planting density of 40,000 pha^{-1}. This result was in agreement with those reported by Maynard and Scott (1998) who stated that in the wider spaced plants, the area allotted for development of the single plant is larger and hence provide a possibility for more lush growth and development of fruit bearing branches. For high densities, plants compete with each other for nutrients, water and light and, therefore, develop less fruiting branches.

Response of Fertilizer on the Growth and Yield of Watermelon

Vine length, Number of leaves and Shoot dry weight of Watermelon as affected by Fertilizer type during 2019/2020 dry season are presented in Table 3. Greater Vine length, Number of leaves and Shoot dry weight were recorded by the application of NPK fertilizer followed by the application Cow dung while the lowest data were recorded by the untreated control. This could be attributed to the role of applied NPK in enhancing production of assimilates during growth and consequent partitioning of these assimilates to fruits which enhanced vegetative growth. Similar result was reported by Bairwa *et al.* (2009).

Number of fruits per plant, Fruits weight per plant and Fruit yield of Watermelon as affected by Fertilizer type during 2019/2020 dry season are presented in Table 4. Greater Number of fruits per plant, Fruits weight per plant and Fruit yield was obtained from the application of NPK fertilizer This could be attributed to the significant role played by NPK in the improvement of soil fertility, nutrient uptake and enhancement of crop yields. NPK fertilizers have been reported to cause significant effects on fruit weight, fruit number and fruit yield (Sarkar *et al*., 2003).

Interaction

The significant interaction between planting density and fertilizer type on Fruit yield (Table 5). Have clearly indicated the interdependence and complimentary role of planting density and fertilizer type in influencing the manifestation of the potentials of watermelon in terms of growth, development and yield as reported by Motsenbocker and Arancibia (2002).

CONCLUSION

Based on the results, it could be concluded that, planting density of 40,000 pha^{-1} recorded the higher yield and NPK mineral fertilizer have relatively the superior performance on growth and yield of Watermelon.

RECOMMENDATION

From the findings of this study, the following recommendations could be made:

1. Planting density of 40,000 pha^{-1} could be adopted for higher Cucumber fruit yield in the study area.

2. Application of NPK fertilizer could also be considered since it recorded superior performance among the fertilizer types tested in the study area.

ABSTRACT

Musk melons (Cucumis melo) are fruits which are rich in nutrients especially vitamins and minerals. They can be used for weight loss, healthy skin and heart, improved immunity and eye vision. They are particularly rich in vitamins A and C. In order to determine the effect of poultry manure and intra row spacing on the percentage brix, Vitamin A and Vitamin C contents of musk melon field trial was carried out at Samaru, in the Northern Guinea Savanna of Nigeria during the 2019 rainy season. The treatments consisted of four poultry manure rates (0, 3.5, 7 and 10 t ha^{-1}) and three intra row spacing of 30, 50 and 70 cm with an inter row spacing of 75 cm. The treatments were factorially combined, laid out in a randomized complete block design and replicated three times. The variety used was a local one named X- Jaja. Three fruits were collected as per treatment from the net plots for yield and nutrient analysis. The sugar content (% brix) was determined using a Refractometer while the vitamin A and C contents of the musk melon were determined in the analytical laboratory using a UV Spectrophotometer 2550 model. The data were recorded for each treatment with the average computed and then subjected to analysis of variance and treatment means were separated using the New Duncan multiple range test. The results show that application 3.5 t ha^{-1} of poultry manure significantly produced the highest percentage brix, Vitamin A and C. The vitamin A and C values obtained were observed to be significantly higher with 70 and 50 cm intra row spacing respectively. However, spacing at the different levels used in the trial did not significantly influence the percentage brix. Based on the result of this trial, it can be concluded that application of 3.5 t ha^{-1} of poultry manure with 50 cm spacing gave the optimum amounts of sugars, vitamin A and C in musk melons production at Samaru.

Key words: Muskmelon, Poultry Manure, Brix, Vitamins

INTRODUCTION

Musk melon (*Cucumis melon* L.) belongs to the family Cucurbitaceae. It is a specie of melon that has been developed into many cultivated varieties. These include smoothly skinned varieties such as honey dew, Crenshaw and Casaba and different netted cultivars (Cantaloupe, Persian melon and Santa class melon). Musk melon is grown commercially to a limited extent in several countries of Europe, Asia, Africa, South and Central America. The United States leads in commercial production (Kroll, 2013). However, the crop is gaining recognition in drier savannah part of Nigeria such as kano, katsina, Jigawa, Gombe and Borno states.

When ripe, musk melon can be eaten raw as snacks, a fruit side dish or tossed with other fruits in a salad. Musk melon is featured in several beverages especially in India, where pureed musk melon and water are combined in a simple drink and touted for its numerous health benefits. Pureed musk melon is also used to flavour sorbets and ice cream. In China, Japan and Korea, Kwaci and Kwatji, (dried salted melon seeds) are sold as snacks. The seeds also are sometimes pressed to produce melon oil and or ground into powder and taken as a natural remedy for certain ailments. Strips of musk melon flesh are dried for fruit leather. Fewer dishes call for cooked musk melon, but winter melon varieties with Crips cucumber or squash like flavours, are used in stews and curries or stir fried with vegetables or other fruits. Sweeter musk melon types can be blended in to jam (Kroll, 2013). Muskmelon is rich in nutrients and can be used for weight loss, healthy skin, healthy heart, improved immunity and eye vision. It helps to cure kidney stone and prevents complications or problems during pregnancy. It also eases menstrual cramps. Per 100 gram serving, cantaloupe melons provide 34 calories and are a rich source (20% or more the Daily Value, DV) of vitamin A (68% DV) and vitamin C (61% DV), with other nutrients at a negligible level.

In spite of the increasing relevance of muskmelon in Nigeria, low yields are obtained in farmers' fields because of declining soil fertility due to continuous cropping and disregard for soil amendment materials Adekiya and Ojeniyi, (2002). Application of poultry manure is one of the ways of improving soil fertility which is cheap than inorganic fertilizer and effective in supplying nutrient for crop growth and also essential for establishing and maintaining the optimum soil physical conditions by reducing soil temperature, bulk density and increasing the total porosity for plant growth and yield (Enujeke *et al.*, 2013).

Plant spacing helps to ensure that each crop has an equal chance to grow and also to simplify execution of field operations. The rate at which field operations are carried out, weed-crop competition and yield are influenced by the spatial arrangement on the field (Celac, 2011). Despite the importance of musk melon its production and productivity is low in Nigeria and this can be improved by determining the appropriate spacing and optimum use of organic manure as part of good cultural practices. To satisfy the ever increasing need for the production of Musk melon for the Nigerian populace, there is need for extensive research to be carried out so as to maximize farmers' yields by varying the application rate of poultry manure and plant spacing for the production of Musk melon in Samaru Zaria and its environment.

MATERIALS AND METHODS

The experiment was conducted at the Horticultural garden of the Institute for Agricultural Research (I A R), Samaru (Lat. 11º17'N Long. 09º38'E and 686m above sea level), in Northern Guinea Savannah ecological Zone of Nigeria, during the 2019 wet season. The treatments consisted of four poultry manure rates (0, 3.5, 7 and 10 t ha^{-1}) and three spacing rates (75$cm \ x \ 30cm$, 75$cm \ x \ 50,$ 75cm x 70cm). The treatments were laid out in a randomized complete block design (RCBD) and replicated three times. The variety used was collected from local farmers in Jaja village, Kudan local government of Kaduna states. It has a maturity period of 80 days with potential yield of 10 t ha^{-1} and becomes yellow in colour when mature. The poultry manure was collected from Animal Science farm IAR/ABU and was analysed to test for the macro nutrients which was 16.95g/kg N, 5.89g/kg $P_2 0_5$, 4.15g/kg K_20. Soil sample of the experimental site was taken randomly at various locations at the depth of 30 cm using soil auger. The sample was bulked to form a composite sample mixture, air dried and thoroughly mixed, then ground and sieved with 2mm mesh before laboratory analysis for its physical and chemical properties. The field which is 0.15 hectare was harrowed and ridged at 75cm apart and then divided in to plot according to the treatments. The gross plots consisted of 3 m length and 3 m width while the net plot consisted of two inner ridges of 3 $x \ 1.5m$. Seeds were sown on the 10th June, 2019 at different spacing rate of 75 x 30cm, 75 $x \ 50cm,$ 75 x 70cm inter and intra row three seeds were sown which was later thinned to two plants per stand at 2WAS. Poultry manure was applied and incorporated in to the ridges by opening the crest and burying the manure as per treatment (0, 3.5, 7, 10 t ha^{-1}) two weeks before sowing. Weeds were controlled manually by hoe weeding at 3 and 6 WAS. Cypermethrin was applied against the incidence of insect pests at the rate of 4 L ha^{-1}, at one-week interval when the crop started flowering. There was no disease incidence noticed during the course of the experiment.

Harvesting was done by hand picking when the fruits attained physiological maturity (when the fruits turn from green to yellow colour). Data was collected from the 3 tagged plants in the net plot. The sugar content of the crop was determined using refracto meter and the average was recorded. The vitamin A and C content of the muskmelon were determined using UV-spectrophotometer 2550 model to test the vitamin A and C content of the fruit. The data collected were subjected to statistical analysis of variance (ANOVA) as described by Little and Hills (1978). The treatment means were separated using New Duncan Multiple Range Test (DMRT), (Duncan, 1995).

RESULTS AND DISCUSSION

The effect of poultry manure and intra row spacing on brix percentage of musk melon is presented in Table 1. The result showed that, application 3.5 t ha^{-1} of poultry manure significantly gave the highest percentage brix while the control rate gave the least. However, application of 10 t ha^{-1} gave comparable sugar content with the application of 3.5 and 7 t ha^{-1}. There were no significant differences in the percentage brix of musk melon with the different intra row spacing. However significant interaction of poultry manure and plant spacing on percentage Brix of musk melon was observed as shown in Table 2. The results show that combination of poultry manure and 50 percentage intra row spacing gave the least percentage brix while the combination of 3.5 t ha^{-1} of poultry manure with 50cm or 70cm significantly produced the highest percentage brix. Similarly, Table1 shows the effect of poultry manure and intra row spacing on the vitamin A content of musk melon. Application of poultry manure significantly influence the vitamin A content of musk melon.

ISSN: 2814-0508

Where there was corresponding decrease in vitamin A content when poultry manure was increase from 3.5 to 10 t ha^{-1} while the control gave the least amount of vitamin A. significant respond was obtained with intra row spacing on the vitamin A content of musk melon where increasing the intra row spacing from 30 to 70cm increase the vitamin A content of musk melon. There was no significant interaction observed between the factors on the vitamin A content.

Table 1: The effect of poultry manure and intra row spacing on the percentage brix, vitamin A and C of musk melon at Samaru

Treatment	Brix (%)	Vitamin A (mg l^{-1})	Vitamin C (mg l^{-1})	Yield (kg ha^{-1})
Poultry manure (P) t ha^{-1}				
0	4.29c	1.15d	0.24b	1252
3.5	7.71a	1.73a	0.26a	6914

Means followed by the same letter(s) in a column are not significantly different from each other using Duncan Multiple Range Test (DMRT). * : Significant at 0.05; ** : Highly Significant at 0.01; NS : Not Significant

The effect of poultry manure and intra row spacing on vitamin C content of musk melon is presented in Table2. Significant differences where observed on the vitamin C content when poultry manure was applied. Increasing poultry manure from 0 to 3.5 t ha^{-1} significantly increase the vitamin C content however further increase from 3.5 to 10 t ha^{-1} significantly reduce the vitamin C content. Significant response was recorded with intra row spacing. Increasing the intra row spacing from 30 to 50cm significantly increase the vitamin C content however further increase to 70cm significantly decrease the vitamin C content. There was no significant interaction between the factors on the vitamin C content. The fruit yield and quality of musk melon increased significantly with the application of poultry manure when compared to the control. This could be due to the fact that more nutrients were made available to the plants when the organic manure was applied. Similar results were reported by (Dunsin *et al*., 2019, Antonios *et al*., 2019 and Hassan *et al*., 2012). The Vitamins A, C and fruit yield which was significantly increased with increased spacing could be due to reduced competition among plants as a result of wider spacing and available nutrients.

Table 2: Interaction of poultry manure and intra row spacing on percentage brix of musk melon at Samaru.

	Poultry manure (t ha^{-1})			
Spacing (cm)	**0**	**3.5**	**7.0**	**10.0**
30	4.36i	7.90a	6.36g	7.13e

ABSTRACT

The productivity of onion in Nigeria despite being a crop of commercial crop is adversely affected partly by poor agronomic practices of farmers some of which include suboptimal nutrient application and plant population per unit area. In order to overcome the challenge and meet demand, a trial was carried out in 2018 at the Institute for Agricultural Research Orchard to determine the effect of Poultry manure and intra row spacing on the productivity of onion in Samaru located at the Northern Guinea Savanna of Nigeria. Treatments consisted of four poultry manure rates (0, 1.5, 3 and 4.5 tha^{-1}) and intra row spacing (15, 20 and 25cm) laid out in a randomized complete block design with three replications. Data were collected on plant height, crop growth rate, bulb diameter and bulb yield. Results showed significant increases with poultry manure application except on bulb diameter while varying the intra row spacing had no significant effect on the parameters taken. Highest yield (6tha^{-1}) was recorded at 4.5tha^{-1} of poultry manure and could therefore be adopted for onion production using 20 cm intra row spacing in the Northern Guinea Savanna of Nigeria.

INTRODUCTION

Onion is a vegetable crop of the family Allium which are known for their characteristic pungent flavours and medicinal properties. It can be consumed raw or used as spices in various local delicacies and soups. The crop is rich in nutrients (Vitamin C 9%, Vitamin B6 9%, Mg 3%, Ca 2%, Fe2% etc.), helps reduce risk from cancers and lower blood pressure (Anon, 2021a). Nigeria is one of the largest producers of onions in the world with over 2million tonnes annually bulk of which are cultivated in the northern part with the red type being the most commonly cultivated for commercial purposes (Anon, 2021b). There is a high demand for onion in Nigeria which farmers are often not able to meet often due to poor agronomic such as suboptimal nutrient application and plant population among others. Nitrogen, Phosphorus and Potassium are some of the critical nutrients required by onion as nitrogen and potassium enhance strong and early growth while phosphorus enhances root development (Anon, 2021a). Supply of these nutrients is therefore needful for good growth, development and high yields. These nutrients can be supplied through the application of which in addition to nutrient supply serve as soil amendment. Additionally, manures pose very little to man and his environment compared to synthetic or chemical fertilizers. Failure of farmers to plant at optimum intra row spacing further reduces plant population and consequently total yield and supply as such demands not met. A trial was therefore conducted to determine the effect of poultry manure and intra row spacing on onion in Samaru Northern Guinea Savanna.

MATERIALS AND METHODS

The trial was carried out at the orchard of the institute for Agricultural Research, Ahmadu Bello University Zaria in the Northern Guinea Savanna. Treatments consisted of four poultry manure rates (0, 1.5, 3 and 4.5tha-1) and three intra row spacing (15, 20 and 25cm) laid out in a randomized complete block design with three replications. Seeds (red creole) were broadcasted in the nursery on the 18th January, 2018 and mulched with dry straw for 10 days after which it was removed to enhance sunlight uptake and hardening of seedlings. Transplanting of the seedlings was done on the 18th March when the seedlings were 8weeks old. Poultry manure was incorporated two (2) weeks prior to transplanting. Transplanting and manure incorporation was done according to the treatments. Data was collected on plant height and crop growth rate at 6 and 9 weeks after transplanting (WAT), bulb diameter and bulb yield at harvest. Data collected was subjected to analysis of variance as described by Snedecor and Cochran (1967), using the general linear model (GLM) procedure of the statistical analysis system (SAS) package (SAS, 1990) version 9.1. Treatment means were separated using Duncan Multiple Range Test (Duncan, 1955).

RESULTS AND DISCUSSION

The result of soil analysis of the experimental site (Table 1) showed that the soil was loam, moderately acidic, had low nitrogen, phosphorus and potassium. The organic matter content was also moderate. Poor nutrient status of the soil could be due to continuous cultivation and the addition of fertilizers rather results in further soil degradation which might have been the reason for the moderate acidity recorded. This is in agreement with Belay, 2015 who stated that loss in soil fertility is aggravated by continuous cultivation which leads to nutrient mining of the soils.

Results of poultry manure analysis (Table 2) also showed that the total nitrogen (1.57%), phosphorus (0.27) and potassium (0.11) content of the manure were low.

Table 3 showed significant increases in plant height and crop growth rate (CGR) with poultry manure application. Results on plant height showed that at 6WAT, poultry manure application up to 3tha^{-1} increased height of onion beyond which similar increases were recorded. At 9WAT however, poultry manure application increased height of onion up to 4.5tha^{-1} manure applied. Similarly, the CGR at 6WAT showed that at 4.5tha^{-1} poultry manure, CGR was higher than the control but comparable to 1.5 and 3tha^{-1}. At 9WAT however, application of 3.0tha^{-1} and 4.5tha^{-1} poultry manure significantly increased CGR than the control but comparable to 1.5tha^{-1}. The bulb diameter and yield of onion is shown on table 4. Results showed that bulb diameter was not significantly affected by both poultry manure application and varying of intra row spacing. However, yield was significantly affected by poultry manure only where increase in poultry manure rates applied resulted in significant increase in yield up to the highest manure rate (4.5tha^{-1}). The increases due to poultry manure application could be attributed to nutrients supplied by the manure especially as the fertility status of the soil of the experimental site was poor. Ehizogie 2018 recorded similar results where onion yield among other parameters increased with poultry manure application when compared with the control. Additionally, poultry manure improves soil organic matter content which consequently affect aggregate stability thereby improving aeration, buffering of soil reaction, water holding capacity, cation exchange capacity and microbial activity thus resulting in the positive responses observed with poultry manure application Adeyemo *et al.,* 2019.

CONCLUSION

Based on the result of the trial it can be concluded that 4.5tha^{-1} of poultry manure and 20cm intra row spacing could therefore be adopted for onion production in the Northern Guinea Savanna of the Nigeria.

ABSTRACT

Field trials were conducted to determine the effect of intra row spacing and NPK fertilizer on the growth and yield of Bird's eye chilli pepper (Capsicum frutescens L.). The trials were carried out during the 2017 wet season at the Institute for Agricultural Research farm Samaru, ($11^{0}11^{1}$N;$07^{0}38^{1}$E and 686m attitude), Kaduna State and at IRS/ IAR Kadawa Station ($11^{0}39^{1}$N;$08^{0}02^{1}$E and 500m attitude), Kano State. The treatments evaluated were three intra row spacings (20 cm, 30 cm and 40 cm) and four levels of NPK 20:10:10 (0, 300, 600 and 900kgNPKha^{-1}) which were factorially combined and laid out in a randomized complete block design (RCBD) and replicated three times. Data were collected on growth, yield and yield components. Plant height, CGR and RGR were not significantly affected by intra row spacing but were significant on NAR, fresh fruit weight per plant and fresh fruit yield per hectare. Application of NPK fertilizer significantly increases only the fruit yield per plant and fruit yield per hectare. Significant interaction between intra row spacing and NPK fertilizer was observed from fresh fruit yield per plant and fruit yield per hectare. Highest fruit yield/ha was obtained at a spacing of 20cm and NPK of 300kg/ha.

Key words: Intra row spacing, NPK fertilizer, chilli pepper, Growth and Yield.

INTRODUCTION

The bird's eye chilli pepper is one of the most widely used spicy that generate high income to farmers compared to the other varieties because of it purgency, nutritional and industrial use, it is a major vegetable after tomato and onion. In recent years the production of chilli pepper in Nigeria has once been reported as an exporting commodity (Adigun2001). Production constraints such as cost, poor method of fertilizer applications, method of drying, poor planting arrangement (spacing) and search for crude oil (fuel) has drastically reduced the value, quality and yield of chilli pepper production in Nigeria.*Capsicum annuum* and *Capsicum frutescens* are the most common dry species used in Nigeria, the crop is widely cultivated because of its spicy property and nutritional value which accounts for a large portion of vitamins A and C in many Nigerian diets. Most vegetable crops have been reported to do well under appropriate plant spacing and fertilizer application which leads to Maximum plant growth and fruit yield whereas too high or low fertilizer and poor plant arrangement could result to poor fruit quality and yield (Paththinige *et al*. 2008). However, there is still Paucity information on the Effect of intra row spacing and NPK fertilizer on growth and yield of bird's eye chilli pepper. In some other place, using intra row spacing have been proved to significantly increase the yield of bird eye's chilli pepper (Aliyu 2002, Shiral and Hagimon, 2004) who reported that narrower spacing which is synonymous to high plant densities have been found to bring about higher fruit yield per unit planting area in Hot pepper, while the application of NPK fertilizer significantly increase the Growth and Yield component of chilli pepper (Yasuor, 2013). Because of reduction in value, quality and poor management practice resulting into low yield of these crop, the scope of this study was to find out the appropriate intra row spacing and NPK fertilizer that will give maximum growth and yield of bird eye's chilli pepper.

MATERIALS AND METHODS

Field experiments were conducted on a loamy soil during 2017 rainy season at the Research farm of Institute for Agricultural Research, Ahmadu Bello University, Samaru ($11^0$11'N; 7^0 38'E and 686 m above sea level) Zaria in the Northern Guinea Savannah Ecological Zone, Kaduna State and at Irrigation Research Station (IRS/IAR) research farm Kadawa ($11^0$39'N; 08^0 02'E and 500 m above sea level) in the Sudan Savannah Kano State of Nigeria. The treatments consisted of four levels (0, 300, 600 and 900kgha^1) of NPK fertilizer 20:10:10 equivalent to 0:0:0, 60:30:30, 120:60:60, 180:90:90 and three intra row spacings (20 cm, 30 cm and 40 cm). Treatment were factorially combined and arranged in a Randomized Complete Block Design (RCBD) and replicated three times. The gross plot was 2.4 x 4.5 m (10.8 m^2) while the net plot size was 1.5 x 2.4m (3.6 m^2) and inter row spacing of 75 cm respectively was adopted. Data were collected on growth (plant height, CGR, RGR and NAR) and yield component (fresh fruit yield per plant and fresh fruit yield per hectare).

RESULTS

The result shows no significant effect on plant height, CGR and RGR using intra row spacing all through the sampling period, but shows significant effect on NAR at 10 WAT at Samaru and Kadawa. Using 40 cm intra row spacing produced significantly higher NAR than the closer spacings 20 and 30cm which were statistically at par Table1. Application of NPK fertilizer had no significant effect on plant height, CGR, RGR and NAR at 10 WAT at both locations. Table 2. Effect of intra row spacing and NPK fertilizer on fresh yield of chilli pepper. Fresh fruit yield g/plant and fruit yield kg/ha were significantly affected by the intra spacing at Samaru and Kadawa Combined each decrease in the intra row spacing from 40cm to 20cm resulted in significant decrease in fresh fruit yield per plant, while for the fruit yield kg/ha the reverse is the case, Spacing of 20cm gave more fruit yield per hectare than 30 and 40 cm intra row spacing which were statistically at par at Kadawa while at Samaru and the combined each increase in spacing from 20 to 40cm significantly decrease the yield. The fruit yield of pepper increased significantly when NPK fertilizer was applied at both locations. At Samaru, application of 300 and 600kg NPK fertilizer produced higher fruit yield per plant than 900kg NPK and the control while at Kadawa and combined applying 300kg NPK out yielded the other levels while for fruit yield kg/ha, the Application of 300kg NPK fertilizer was significantly better than 600 and 900kg and higher than the control at Samaru while at Kadawa all the applied NPK fertilizer were statistically at par and higher than the control in fruit yield. Table 3. Shows the interactions between fresh fruit yield per plant and fresh fruit yield kg/ha at Samaru and Kadawa Combined. It was observed that application of 300kgNPK/ha in combination with 30cm intra row spacing resulted in the highest fresh fruit yield per plant (g) while for the combined analysis of the fruit yield kg/ha indicates that all the three intra row spacings were statistically similar in fresh fruit yield when 0 and 300kgNPKha^{-1} were considered, however 20 cm significantly out yielded 30 and 40 cm intra row spacing when 600 and 900kgNPKha^{-1} were applied.

DISCUSSION

Response to intra row spacing

Plant height, CGR and RGR were not significantly influenced by the intra row spacing ranging from 20 cm to 40 cm at both locations. This might be due to the fact that the plants have the same genotypes which gave each plant equal advantages to perform at the same past irrespective of their individual spacing. This agrees with the findings of Salau *et al*. (2008) who reported non significant response with intra row spacing of hot pepper in some growth and yield components during his trials in 2009 and 2010. The significant increase in the Net assimilation rate as observed by the intra row spacing could attribute to the fact that wider spaced plants (40 cm) tend to have higher photosynthetic potential (NAR) as intra row spacing increased because of less plant and its broad leaves which allows it to access light and water source for photosynthesis within the canopy. This only improved the individual performance but could not compensate for the low leaf area per unit area of land as a result of sparse plant population (Russo 2003). The increase in fruit yield per plant observed from the wider spacing when comparing with other individual plants could be that plant accommodating the wider spacing has more space to develop properly with less inter and intra plant competition for utilizing the available resources resulting in higher fruit yield per plant. This result is in conformity with the findings of Aminifard *et al*. (2010) who reported that the performance of hot pepper was enhanced by wider spacing as the number of fruits per plant and fruit size were reduced at closer spacing. The highest and lowest fruit yield per hectare was observed in 20 cm and 40 cm. This could contribute to the fact that the increase in the plant number as a result of using the closer spacing per unit area might have contributed to the extra yield per unit area leading to high yield. This result is in conformity with the findings of Law-Ogbmo and Eghareuba (2009), Aminifard (2010) and Islam *et al*. (2011) who reported that highest fruit yield per hectare of sweet pepper and other plants were obtained from plants grown at closer spacing with in Row spacing of 20 cm and 30 cm respectively and also the yield advantage due to narrow spacing could be attributed to the development of a full canopy in early development stages (Fukai *et al.* 2004).

Response to NPK fertilizer

The application of NPK fertilizer differed significantly among the yield parameters. The non significant response exhibited by the growth component to the application of NPK fertilizer could be due to the inherent character that are genetically controlled rather than being influenced by management practice (Nielson 1979). Application of NPK fertilizer significantly increases the fruit yield per plant and fruit yield per hectare due to plant nutrient absorption. This report is in conformity with Suge *et al*. (2011) who reported that increasing NPK rates from 50% to 100% of the recommended rates encouraged the fruit quality. The significant interaction between intra row spacing and NPK fertilizer application observed on fruit yield of chilli pepper shows that intra row spacing and NPK fertilizer plays a major role in the growth and yield of bird eye's chilli pepper in other to attain a higher yield per hectare. The Plant spacing ensures the proper use of land for growth and development of the plant for good yield while fertilizer application is very much essential for good plant establishment and expected growth. This agrees with the finding of Abdel Mawgoud *et al*. (2007) who reported that two management practice which greatly influence growth and fruit yield are spacing and fertilizer application.

CONCLUSIONS

The growth (NAR) and yield component of bird eye's chilli pepper were significantly affected by intra row spacing and NPK fertilizer. Plant height, CGR and RGR were not significantly affected by intra row spacing and NPK fertilizer. Intra row spacing and NPK fertilizer significantly increases the fresh fruit yield per plant and fruit yield per hectare. Therefore, from the above study it can be deduce that the use of intra row spacing and NPK fertilizer in pepper production cannot be underestimated for its growth and development. Application of 300kgNPK/ha gave 7254.30kg/ha fresh fruit yield per hectare and a spacing of 20 cm gave higher fruit yield of 6913.10kg/ha which could be recommended by farmers for bird eye's chilli pepper production in the Northern Guinea and Sudan Savannah of Nigeria.

ABSTRACT

The present investigation was conducted during the 2020 dry seasons under irrigation at Gwallaga- mayaka Fadama Farm site, Bauchi (Latitude 10^0-17" N. Longitude 9^0-49" E, 609.3m above sea level) in the Northern Guinea Savannah zone of Nigeria. Cabbage (Brassica oleraceae L. var. savoy) was planted on soils treated with control, Poultry manure-based compost (6.0 t/ha), Cow dung manure (6.0 t/ha), Sheep manure (6.0 t/ha) and Vermicompost (6.0 t/ha) arranged in factorial combination and laid out in Randomized Complete Block Design replicated thrice. All organic manure applied significantly affect plant height, number of leaves per plant, root length at harvest, head diameter at harvest, weight per head, yield per hectare, pH, organic matter, P and K levels. Poultry manure-based compost gave the tallest height, highest number of leaves, longest root, heaviest weight per head, largest head diameter, highest yield, increased in pH, highest organic matter, N, P and K levels than other treatments and control. However, there was a consistent compatibility of cabbage with poultry manure-based compost as a suitable soil improvement input for sustainable cabbage production. Further studies using poultry manure-based compost rate of 6.0t/ha in combination with cabbage variety savoy be conducted to ascertain its superiority over other organic manure sources for soils improvement and sustainable cabbage production in the study area.

Key words: Fertility, Input, Management, Restoration, Sustainability, Yield

INTRODUCTION

Cabbage (*Brassica oleraceae* L. var. savoy) is considered a high value vegetable due to its relative importance to human health and the economy of farmers involved in its production (Jahangir *et al*., 2009). The crop is a leafy green vegetable closely related to other high value Cole crops such as broccoli, cauliflower and Brussels sprout which are good sources of vitamins A, C and E, minerals and contain antioxidants which are important for good health, being rich in calcium, folic acid, selenium, potassium, sulphur, magnesium and help in restoring vitality, fitness, calming nerves and promote relaxation and sleep (Jahangir *et al*., 2009). It also contains an anticarcinogenic properties, aid in bowel cleansing due to the presence of glucosinolates and photochemical products that offer an extra protection against heart disease (Rosa and Rodrigues, 2001). There is an increasing scenario in production failing to keep up with daily demand and this has stimulated interest in the greater utilization of organic manure for restoring, rejuvenating soil fertility and fertilizing vegetable crops in order to achieve an increased in yield. Organically grown high value vegetables occupy a major part of the fresh produce industry that has experienced strong growth in the 1990s (Olusola, 2002).

There is a considerable potential to maintained, increased and improved the quality and yield of high value vegetable crops such as cabbage through improved cultural practices like the use of organic manure (Batt *et al.,* 2008). Organic manures are any organic material added and mixed with the soil in order to increase and maintain the soil fertility by improving the chemical and physical properties of the soil (Arancon *et al.,* 2006). Organic farming preserves and enhances fertility of the soil (Abdel *et al*., 2004). Building up or nourishing the soil with the use of organic compost is the major concept of organic farming which is highly sustainable strategy (Stephens and Kostewicz, 2009). The production of high value vegetable crops such as cabbage through the use of organic manure is one among the many cultural practices that would improve quality of produce and at the same time improve the soil fertility. However, adopting organic vegetable crop production systems with low inputs will provide greater food security for rural and urban dwellers

(Altieri, 2002). The present study intend to determine the response of cabbage variety savoy to different rates of organic manure and to identify the best rate amongst the applied organic manure on growth and yield of cabbage, and, on soil pH, soil organic matter content, phosphorus (p) and potassium (k).

MATERIALS AND METHODS

The Study Area: Field experiment was conducted under irrigation at Gwallaga-Mayaka Fadama farm, Bauchi (10^0 17" N, 9^0 49" E and 609.3m above sea level) located in the Northern Guinea Savannah ecological zone of Nigeria (Kowal and Knabe, 1972) during the 2020 dry season.

Sampling Design: Total field size was 100 square meters, total bed size was 1 x 6 meters spaced 30 x 40 cm under the double row planting method replicated thrice in a randomized complete block design (RCBD). Organic manure applied were incorporated in a single dose into the prepared beds according to the design two weeks before transplanting. Cabbage *(Brassica oleraceae* var. savoy) was sown into nursery beds and transplanted when at three-to-four leaves stages to already prepared permanent growing beds. Soil samples of each replicate were collected and bulked before applying the organic manure and after termination of the study from a depth of 0-30 cm. Samples were analysed for pH, organic matter, percent nitrogen, phosphorus and potassium, all important cultural and management practices such as weeding, watering and hilling-up were carried out when necessary. Azadirachta indica seed extract was used to control the mild pest attack noticed.

Analytical Techniques: Measurements were conducted for cabbage plant height (cm**),** number of leaves per plant, root length at harvest (cm), head diameter at harvest (cm), weight per head (kg), yields (kg/ha), pH, organic matter, P and K levels. All data collected were analyzed using the equation of Chapman and Ayrey (1981) in variance of randomized complete block design in three replicates. Mean difference were determined using Duncan's Multiple Range Test (DMRT).

RESULTS AND DISCUSSIONS

The initial physico-chemical properties of the top indicated that the soils are mostly clay-loam with low organic matter (Kowal and Knabe, 1972). However, Tab le 1 showed the chemical composition of the various organic manure applied, where poultry manure-based compost and sheep manure gave the highest and lowest value in all the chemical properties analyzed, respectively.

Table 1. Nutrient status of the various organic manure used.

Chemical properties	PMBC	CDM	SM	VMC
OC %	18.15	15.45	12.15	16.49

PMBC = Poultry manure-based compost, CDM = Cowdung manure, SM = Sheep manure, VMC= Vermicompost.

Plant height, Head Diameter and Weight per head

Table 2 showed that there were significant differences among the different organic manure applied and the control. However, poultry manure-based compost had a higher plant height than the other organic manure and control. Similar trend was obtained in head diameter and head weight per head where significant differences occur between the various organic manure rates and control, poultry manure-based compost significant, gave the largest and heaviest head than the other organic manure, Control generally had the lowest and lighter weight per head**.**

The use of organic manure in vegetable crop production such as cabbage is on the increase in view of the high price of inorganic fertilizers and the difficulty in procuring it at the required time Snyder, (2009). Furthermore, organic manure is the most valuable of all soil enriching elements that historically had been used as a source of plant nutrients for soil fertility restoration and for vegetable crop production (Ingrid (2004) and that, nutrient contents of decompose chicken manure is among the highest of all animal manures, its use as organic soil amendment will provide appreciable quantities of all important plant nutrients.

Table 2: Cabbage Plant height, Head Diameter and Weight per head as influenced by various organic manure rates

Treatment	Plant height (cm) 2020	Mean	Head Diameter (cm) 2020	Mean	Weight per head (g) 2020	Mean
Control	12.45d	16.06d	18.68d	15.13e	99.10e	109.58e

PMBC = Poultry manure-based compost, CDM = Cowdung manure, SM = Sheep manure, VMC= Vermicompost, LS = Level of significance, LS = Level of significance. Means with the same letter (s) in a column are not significantly different at 5% level by DMRT.

The significant effect of the different organic manure applied on cabbage plant height, head diameter and weight per head could be attributed to adequate amount of nutrients elements present in the various organic manure applied particularly the macro element of nitrogen, phosphorus and potassium whose released add more of these nutrients elements to the soil as reported by Bulluck *et al*. (2002).

Number of leaves, root length and yield t/ha

Table 3 showed a significant difference among the various organic manure rates and control on cabbage number of leaves, root length and yield per hectare. Poultry manure-based compost produced the highest means followed by vermicompost and control. The significant differences obtained indicated a more efficient use of nutrients released by the various organic manure applied by cabbage root owing to their availability within the root zone for timely absorption and utilization. Organic manure is a supplier of N, P and K to the soil which also increases the phosphate solubilizing bacteria in the rhizosphere (Khan *et al*., 2008). Wang *et al.* (2001) reported that organic manure improves the structure of the soil directly through their action as bulky diluents in compacted soils or indirectly when the waste products of animals or micro-organisms cement soil particles together thereby improving the soil structure and increases the amount of water available to the crops root. When decompose chicken manure was applied under field conditions at 8.2 t/ha organic carbon mineralization of 50% was obtained (Abdel *et al.,* 2004, Zahid, 2001) and that further increase beyond 8.25t/ha is not advisable and may lead to unnecessary monetary losses.

Table 3. Cabbage Number of leaves, Root length and Yield as influenced by various organic manure rates

PMBC = Poultry manure-based compost, CDM = Cowdung manure, SM = Sheep manure, VMC= Vermicompost, LS = Level of significance. Means with the same letter (s) in a column are not significantly different at 5% level by DMRT.

Organic matter, P and K levels

Table 4 present the results of analysis of initial soil properties of the experimental site before and after the experimentation. The soil is clay loam and slightly acidic, low in organic matter, phosphorus and potassium. However, after application of all the organic manure, soil values obtained indicated that pH level was changed to neutral (increase), there was a significant increase in phosphorus and potassium content of the soil and poultry manure-based compost significantly produced the highest means. This might be ascribed to the flocculating, aggregating and conditioning role of the applied organic manure, because Ammonium-N (NH_4-N) is a significant part of total N in decompose organic manure, which additionally contains uric acid which metabolizes rapidly to NH_4-N in most soils (Dixon, 2006). Meanwhile, availability of these organic elements to cabbage will enable the crop absorbed much of phosphorus and potassium for root, leave and head development considering the initial pH, organic matter, phosphorus and potassium content of the soil. Furthermore, decompose poultry manure is especially suitable for acid soils as it has strong liming effect as it reduces the acidity of the soils thereby protects crops from aluminum toxicity (Manivannam *et al.,* 2009). Organic manure has the potential to supply most of the nitrogen and sulphur and half of the phosphorous taken up by crops root from the soil and also supply most of the cation exchange capacity (CEC) of acidic and highly weathered soils (Manivannam *et al.,*2009).

Table 4: pH Level, Organic matter, Phosphorus and Potassium contents of the soil of experimental site as influenced by various organic manure rates

Treatment	pH 2020	OM (g/kg) 2020	P (g/kg) 2020	K (Cmol/kg) 2020

ISSN: 2814-0508

Benefits derivable from organic manure application to soil are improved soil physical properties when applied to heavy or sandy soils and the fibrous portion of the organic manure having high carbon content promotes soil aggregation which in turn improved the permeability and aeration of clay soils and the ability to absorb moisture which also helps in the granulation of sandy soils and consequently improves the soil water holding capacity (Wang *et al.,* 2001). Treating sandy soil with organic manure decreased macro pores which increased micro ones and as a result hydraulic conductivity decreased and more reduction was obtained by increasing the application rates (Sunassee, 2001). Vermicompost contains more organic matter, nitrogen, phosphorous, sulphur, calcium and magnesium (Zahid, 2001).

CONCLUSION AND RECOMMENDATIONS

It was established that the organic manure treatments had a statistically significantly and positive impact on all agronomic variables of cabbage crop study. All the organic manure has a high impact on the growth, yield of cabbage and soil organic matter, soil pH, P and K levels. Poultry manure-based compost gave the highest growth and yield value, soil organic matter, soil pH, P and K levels. Furthermore, the response of cabbage under organic manure at 6 t/ha was better and higher under poultry manure-based compost compared to other organic manure treatments and control. The use of poultry manure-based compost at 6 t/ha in combination with cabbage variety should be examined again in the study site in order to further ascertain its superiority in terms of cabbage yield, soil fertility restoration and soil reclamation over other organic manure rates used.

ABSTRACT

In an attempt to encourage farmers in Ibadan North local government areas of Oyo State, Aquacrop model was used in simulating the appropriate irrigation water requirements that will produce optimal yield of tomato for drip, sprinkler and furrow irrigation in the investigated environment. Dry biomass yield of 8.1, 7.9 and 7.5 ton/ha were simulated for drip, sprinkler, and furrow irrigation respectively. These will provide a guide to farmers in the area on the likely yield to expect, provided they follow the guideline provided regarding other farm operations (weed and nutrient management etc.). Other factors that will guide the choice of appropriate irrigation system for individual farmers are provided in the write up.

INTRODUCTION

Ibadan North is a Local Government Area in Oyo State, Nigeria. Its headquarters is located at Agodi in Ibadan. Several households in Ibadan North Local Government area depend on agriculture (Wahab and Abiodun 2018). They are mostly smallholder farmers (< 2 ha land) due to the traditional land tenure system that denied them access to large acreage of land (Nyambo et al, 2019). Major crops produced in the area are horticultural crops which helps to augment family needs like feeding, rent and payment of school fees. Unfortunately, they largely depend on rainfed cultivation partly due to their low level of income. Most never bother to find out the cost of irrigation but they depend on the assumption that "it is very expensive" and beyond their reach (Takeshima 2016).

Because most farmers produce in the raining season, they hardly break even. The price of their commodities is usually low due to high supply, relative to demand which leads to discouragement amongst them. Consequently, it is increasing difficult to the youths to show interest in agriculture (Adesina and Favour 2016). They youths would rather migrate to the city in search of "white collar jobs" or engage in petty trading, and lately, in commercial motorcycling. If they could be encouraged to produce their crops also in dry seasons, they will likely make enough profit to compensate for losses they might have incurred in raining season. Hence, their livelihood will be enhanced. We therefore used Aquacrop model in simulating the appropriate irrigation schedule that will produce optimum yield of tomato (our test crop) in the investigated area.

Fortunately, Ibadan north local government is blessed with some perennial streams and rivers (Ajibade et al 2010, Agboola et al., 2012). It also enjoys bi-modal annual rainfall of approximately 1420 mm. It usually starts March – early November, with a short dry spell in August, referred to as August break. The months of November to March are normally dry with cold harmattan weather. We simulated for three types of irrigation *viz* drip, sprinkler, and furrow irrigation. It is expected that that farmers in the area will take advantage of the simulation result and pick the most appropriate irrigation method for their locations.

MATERIALS AND METHODS

Brief information and assumptions:

Investigated area: Ibadan North Local Government area of Oyo State, Nigeria (Latitude 7.3621 Longitude 3.9372, Altitude 139.85 meters above sea level).

Crop investigated: Tomato (high density)

Weed management: Assumed to be Perfect

Other assumptions, based on some known facts in the area: No mulch, Moderate soil fertility

Irrigation Water Quality: Excellent.

Simulation period: 1st December, 2016 to 20th March, 2017 (110 days)

Weather data used: 1st January, 2015 to 31st December, 2018, downloaded from https://power.larc.nasa.gov/data-access-viewer/

Details of the steps taken, including weather and soil information of the study area are provided in Figure 1. For drip irrigation, ten (10) mm of irrigation water was applied at transplanting. This was repeated at 3 days' interval up until 75 days after transplanting (DAT), slightly beyond the flowering period. It was thereafter reduced to 5 mm untill 95 DAT after which irrigation ceased. By this stage, the fruits were already matured. Excess moisture will only lead to increase in water content of the fruit, thereby encouraging pest build up and spoilage.

Thirty (30) mm of irrigation water was applied *via* sprinkler method at transplanting at 7 days' interval. This was increased to 40 mm at 40 DAT when the plant was matured and the roots are well developed. It was later reduced to 25 mm at 70 DAT up until 90th DAT when irrigation ceased after full maturation of fruits.

Forty (40) mm of irrigation water was supplied by furrow irrigation method at transplanting. This continue at 10 days' interval until 40th DAT when the depth of irrigation water was increased to 60 mm. This we maintained until 80th DAT when it was further reduced to 50 mm and we stopped irrigating at 90th DAT when the fruits were already matured.

Several options were tried but the best options are reported. In choosing the best option, consideration was not given to yield alone, but also we tried to minimize runoff and drainage to the bearest minimum (so as to minimize waste of resources). Consideration was also given to water use efficienty and evappotranspiration (ET) water productivity. During the simulation process, we tried as much as possible to avoid stomata closure or any other forms of water stress, most especially at the critical period of its morphological development like flowering and fruitng. In spite of our efforts, we ended up with some level of stress but they were limited to towards the end of the growing cycle, when the stress will have minimal effects on the crop. At best, the stomata closure at this stage will only improve the shelf life of tomato thereby preventing losses.

RESULTS AND DISCUSSION

Drip Irrigation

Dry yield and biomass yield of 8.1 and 12.8 ton/ha respectively were simulated (Figure 2). ET water productivity was 2.51 kg yield per m^3 water evapotranspired. Rainfall and drip irrigation supplied 69.8 and 275.0 mm of water respectively. None of the supplied irrigation water was drained but 74.9 mm, largely from the rain component, was evaporated. Water use efficiency (considering the rainfall and supplementary irrigation) was about 71.5%. It turned out to be 89.7% when irrigation water alone was considered.

Sprinkler Irrigation

The plant experienced a little stress close to the onset of flowering but the increased moisture around this period provided the needed stability effects such that we were able to save cost *via* water management and at the same time, the yield and quality were not compromised. Rainfall supplied 69.8 mm while 385 mm was supplied by sprinkler irrigation (Figure 3). None of these components were drained and 119.7 mm was lost to evaporation thus bringing water use efficiency to 53.7% (supplementary implication) and 63.4% when irrigation water alone was considered. Biomass and dry yield were 12.6 and 7.9 ton/ha respectively; ET water productivity was 2.18 kg yield per m^3 water evaporated.

Furrow Irrigation

Biomass and dry yields were 12 and 7.5 ton/ha respectively (Figure 4). Rain and irrigation water by furrow irrigation method contributed 69.8 and 410 mm respectively. Out of these, 79.5 and 78.9 mm were lost to drainage and evaporation respectively. Hence, water use efficiencies were 48.3 and 56.5% respectively for supplementary and full irrigation.

CONCLUSIONS

We have provided three (3) alternatives for farmers in Ibadan North local government area, Oyo State, Nigeria. Each farmer is at liberty to pick the options that is best suited for him based on certain considerations: Although, dry biomass yield of 8.1, 7.9 and 7.5 ton/ha were simulated for drip, sprinkler, and furrow irrigation respectively, we will require the services of agricultural economists so we may be able to decide the cost of inputs, relative to income (benefit cost ratio *etc*). For example, the depth of irrigation water, hence the cubic meters of water used are not the same. Also, while weeding will be required for up to three times for both sprinkler and furrow irrigation, drip irrigation will likely not require weeding as water will only be delivered to the root zone of the crop whereas weeds will not be able to survive. Other considerations by farmers in the area will include:

1. The source of water to be used for irrigation. A perennial stream / river, or groundwater?

2. Location of their farm relative to water source. For example, if the farm is downstream of the water source, water can be delivered by gravity. Hence, cost of pumping the water from water source to the field will be eliminated.

3. Financial status of the farmer. Is he able to raise the startup capital for such systems as drip or sprinkler irrigation etc.

ABSTRACT

As available water resources and plant nutrients are becoming less by the day, there is a pressing need to give more emphasis to efficient use of irrigation water as well as plant nutrients for maximum economic return and resources sustainability. As such, field experiments were conducted to determine Growth and Yield of Lettuce as Influence by Irrigation frequency and Poultry Manure at Irrigation and Demonstration Farm (lat. 12°27'13"N; long. 4°12'01"E; 197m above sea level), Waziri Umaru Federal Polytechnic Birnin kebbi during 2020/2021 dry season. The aim of the experiment was to study the response of Lettuce to irrigation frequency and poultry manure. Treatments consisted of three (3) Irrigation intervals which are; Daily application of water, 1day interval application of water and 2days interval application of water which denoted as A, B and C; and three (3) levels of nutrients which are; 2tonnes/ha, 4tonnes/ha and 6tonnes/ha denoted as N1, N2, N3 and the untreated control respectively. Treatments were laid out in a Randomized Complete Block Design (RCBD) with three replications. Result revealed that; Daily application of water or One-day interval applications of water are most suitable for Lettuce production in Birnin Kebbi. Similarly, Application of 4t/ha of poultry manure gives greater yield advantage. The result of the research concluded by recommending Daily application of water or One-day interval application of water as well as application of 4t/ha of poultry manure could be adopted for higher yield of Lettuce.

Key words: Lettuce, Irrigation, Poultry manure, Growth, and Yield

INTRODUCTION

Lettuce (*Lactuca sativa* L.) is one of the important leafy vegetable used as salad and also marketed as fresh vegetable. Genus Lactuca has more than 100 species and six types. Different types of lettuce are Romaine (Cos), Crisp head (Ice berg), Butter head, Stem (Asparagus), Leaf (Cutting) and Oil-seed lettuce (Moreira *et al*., 2014). It is commercially grown in Asia, North and Central America, Europe as well as Africa. The major lettuce growing countries in the world are China, US, Spain, Italy, India and Japan. Most lettuce varieties are eaten fresh and are commonly served as the base of green salads. It ranges in colour from yellow to dark green depending on the variety. Lettuce plant can vary greatly in size, shape and leaf type but generally, the leaves of the plant form a dense head or loose rosette. The stem of the plant is short, with a larger leaves arranged at the bottom and becoming progressively smaller further up the stem. Leave can be smooth or curly. The lettuce plant can grow to a height of 20-100cm in height depending of variety and it typically grown as annual, harvested after only one growing season (Villas Boas *et al*., 2004). Lettuce probably originated from Asia, where it was grown for centuries and its early forms were used in Egypt around 4500 BC. The Romans grew types of lettuce resembling the present romaine cultivars as early as the beginning of the Christian era. The crop was also used in China by the 7th century A.D. lettuce now one of the world's most important salad crops and is grown worldwide (Maboko and Plooy, 2008).

According to FAOSTAT (2018), annual global production for lettuce approximately stands at 27.86 million tonnes. The major producing countries include China (12,855,211 tonnes), United state (3,827,390 tonnes), India (927,349 tonnes), Spain (875,000 tonnes) and Italy (844,976 tonnes) as at 2018 (FAOSTAT, 2018). Nigeria's annual lettuce output is less than 200,000 tonnes and can be grown across most state, Plateau state has the highest. Lettuce is one of healthiest food put on this planet. The green leafy vegetable contains many health benefits, such as maintaining normal blood sugar levels, fighting off inflammation, reducing the risk of heart disease and helping people lose weight. It is rich in vitamin A and C and minerals like calcium, iron, magnesium, potassium and sodium. However, Vitamin-C is lost if it is over cooked. It is grown for its tender leaves and head, which are chopped and used as salad with salt and vinegar and it is gaining popularity with the change in food habit and health consciousness among the people (Brito *et al.*, 2012).

Lettuce is a cool season crop that grows best within a temperature range of 12°C to 20°C. It does not suffer from light frosts and winter cold except near maturity. Severe frost before harvest can scorch leaves and heads. Temperatures above 27°C affect head development and plant edible quality and also promote premature seed stalk development. High temperatures also inhibit germination and can cause a high incidence of tip burn. The crop has high moisture requirements and not more than 50 % of the available water in the root zone should be depleted before irrigation. The plant grows well on a wide variety of soils ranging from light sand to heavy clay, whoever, best results are obtained on fertile loams that are rich in organic matter. A pH between 5.5 and 7 is optimum. Lettuce should be grown on soils with a high water-holding capacity and proper drainage for good root growth and plant performance (Brito *et al.*, 2012).

Insufficient water supply (rainfall or irrigation) and Low soil fertility are among the most important factors that limit vegetables production in any region in Nigeria are. The period of harmattan (Shining sunlight, dry and dusty wind blowing over West Africa between the November and middle of March) in the lowland northern states such as Kebbi and Sokoto, majority of farmers lacks basic knowledge of irrigation scheduling and this affect the productivity of the system, as the crops are either over or under irrigated, leading to wastage of the little available water. On the other hand Low soil fertility has also been recognized as a major and general problem of crop production in the Savanna areas of Nigeria (Adekiya *et al.,* 2012). Lettuce is more susceptible to nutrient deficiencies than most crop plants because of their shallow root system it becomes necessary to provide adequate level of soil fertility through the use of organic manure (Akanbi *et al.,* 2010).

Irrigation scheduling is a critical management input to ensure optimum soil moisture status for proper plant growth and development as well as for optimum yield. Therefore, it is essential to develop irrigation scheduling strategies under local climatic conditions to utilize scarce water resources efficiently and effectively. Fertility of most soils has already declined due to continuous cropping and reduced the use of organic manure (Nweke *et al.*, 2013). Farmers in these areas have low knowledge of timely and optimum application of irrigation. In addition, the cultivation of lettuce requires proper supply of plant nutrient, hence it is necessary to evaluate the effect organic manure on growth and yield performance of lettuce. The main aim of this research is to determine the effects of irrigation frequency and Poultry manure on the growth and yield lettuce (*Lactuca sativa* L).

MATERIALS AND METHODS

Experimental Site

The research was carried out in a dry season of 2020/2021 at Irrigation and Demonstration Farm (lat. 12°27'13"N; long. 4°12'01"E; 197m above sea level), Waziri Umaru Federal Polytechnic Birnin kebbi. The area has a long dry season that is characterized by cool dry air (harmattan) that prevails from November to February/March; and hot dry air extending from March to May. The location was used for cultivation of vegetable and cereal crops.

Treatments and Experimental Design

The treatments consist of three (3) Irrigation intervals (A, B and C) and three (3) levels of nutrients (N1, N2 and N3). The treatments are; Daily water, 1day interval and 2days interval denoted as A, B and C; the levels of nutrients are; 2tonnes/ha, 4tonnes/ha and 6tonnes/ha denoted as N1, N2 and N3 respectively. The experiments were laid out in a Randomized Complete Block Design (RCBD) with three replications.

Cultural Practices.

The land was leveled and constructed into seed beds. The plot size was 2 x 2m (4m^2). Space measuring 1m was left between blocks and 0.5m between plots. Seeds were broadcasted across seed bed. Watering can was used to apply water. Irrigation was scheduled according to the treatments. Manure was applied before planting and the amounts were applied according to treatments. Weeds were controlled manually using hand hoe at 2 and 4WAP and occasional hand pulling when necessary to ensure weed free plots.

Data Collection

Data were collected on the following growth and yield parameters.

Growth parameters

- Plant height (cm), Plant heights of 5 tagged plants were recorded at 4 and 6WAP. This will be achieved by measuring the plant from ground level

ISSN: 2814-0508

to the tip of plant using a measuring tape/ruler. The mean will be calculated and recorded

- Number of leaves per plant: Number of leaves of 5 tagged plants was counted and the mean number per stand will be recorded for each plot at 4 and 6WAP

Yield parameters

- Fresh Yield Plot^{-1} (kg/plot): Fresh yield per plot was obtained from all the harvested plant within the plot using a weighing balance.

- Fresh Plant yield (t ha^{-1}): Fresh yield per plot were extrapolated to per hectare in tonnes.

Data Analysis

The data collected were subjected to analysis of variance (ANOVA) and means were separated using Least Significant Difference (LSD) and Duncan's Multiple Range Test (DMRT).

RESULTS AND DISCUSSION

Soil Physical and Chemical Properties of Experimental Site

Physical and chemical properties of soil of study location prior to the experiments are presented in Table 1. The result indicated that particle size distribution at both 2020 and 2021 was dominated by sand, with values of 63.3 and 61.7%, respectively. For silt particles, it was 24.9 and 28.2%, respectively. Least particle size distribution was observed with clay having recorded 11.8% for 2020 and 10.1% for 2021. The soil was found to be sandy loam. This suggests that the soil in both locations has high macro porosity and low ability to retain water. Soil pH at 2020 (7.46) and 2021 (6.11) indicated that the soil at 2020 was slightly alkaline while that at 2021 was slightly acidic. Organic carbon, total N, available P and Ca were observed to be low in both locations. Exchangeable Mg was moderate, while exchangeable K and Na were higher in both 2020 and 2021 locations.

Table 1. Physical and chemical properties of soil of the experimental site during 2020/2021 dry session

Particles size analysis	2020	2021
	0–30cm depth	
P^{H}	6.60	6.11
Organic Carbon %	1.04	0.87
Organic Matter %	1.79	2.01
Total N %	0.084	0.093
P mg/kg	0.93	1.05
Ca Cmol/kg	0.50	0.78
Na Cmol/kg	0.52	0.62
Mg Cmol/kg	0.80	0.74
K Cmol/kg	1.95	2.56
CEC Cmol/kg	8.40	8.94
Sand %	63.3	61.7
Silt %	24.9	28.2
Clay %	11.8	10.1

Chemical Composition of Poultry Manure (PM)

Chemical compositions of manure prior to the experiments are presented in Table 2. The result indicated that, poultry manure contained organic manure carbon (g kg^{-1}) with values of 3.31 at 2020 and 3.25 at 2021. Poultry manure pH values of 6.10 and 6.20 indicated that, the manure was slightly acidic. However, the result indicated that poultry manure contained high amount of total N in 2021 (1.94 mg kg^{-1}) than in 2020 (1.71 mg kg^{-1}). The result shows an indication of the poultry manure capability of improving the soil nutrient status.

Table 2. Chemical composition of Poultry Manure (PM) during 2020/2021 dry Season

Character	Poultry manure	
	2020	2021
Organic carbon (gkg^{-1})	3.31	3.25
P^{H}	6.10	6.20

Total N (mg kg^{-1})	1.71	1.94
Na (mg kg^{-1})	135	142
K (mg kg^{-1})	2500	2500
Ca (mg kg^{-1})	0.45	0.60
P (mg kg^{-1})	7.63	8.24

Plant Height (cm)

Plant Height of Lettuce as Influenced by Irrigation frequency and Poultry manure rate in Birnin Kebbi during 2020/2021 dry season is presented in Table 3. Plant height of lettuce was significantly ($p<0.05$) affected by irrigation frequency in both seasons. Daily application of water produced significant taller plants followed by One-day interval application of water. Shortest plants were recorded by two days interval application of water. This trend could be linked to adequate supply of the photosynthetic raw material (water), which controls most of the plant physiological processes including height development. According to Brown (1984), high temperatures reduce the rate of photosynthesis in most plants. With the characteristic high temperatures of the experimental site, the rate of evapotranspiration was very high. Therefore, keeping irrigation interval above one day has greatly deprived the plant the available water for optimum photosynthesis, hence less dry matter was partitioned, which might have resulted in reduced size of plant (Samson and Ketema, 2007). Soil moisture and nutrient conditions were directly affected by the irrigation regime, when irrigation water can be used in a timely manner to offset the water consumption of crops, the crops can grow and develop rapidly. However, too much water can lead to extended oversaturation of soil moisture in the root zone, resulting in the inability of the root system to respire normally, thus inhibiting the growth of the plants, whereas insufficient water cannot meet the normal water requirements of the crops, resulting in slow growth (Yu *et al.,* 2016).

Poultry manure had significantly ($p<0.05$) affected plant height in both trials (Table 3). Application of 4t/ha of poultry manure gave significant taller plants followed by the application of 3t/ha of poultry manure while the untreated control gave significant shortest plants. This finding was buttressed the report of Bairwa *et al.* (2009) that, mineralization of manures aids in soil nutrient buildup that in turn leads to improved nutrient availability to the growing crop. Moreover, the organic manures are also significant sources of major and micronutrients much needed by plants (Tyagi *et al*., 2016). Similar results have been reported by Sharma *et al*. (2015). The better performance of crops with poultry manure in all the growth characters observed infers that the plant response to poultry manure which agrees with earlier finding of Olatunji and Oboh (2012). Significant interaction was not recorded between the irrigation frequency and poultry manure (Table 3).

Table 3: Plant Height of Lettuce as Influenced by Irrigation frequency and Poultry manure rate in Birnin Kebbi during 2020/2021 dry season.

Number of Leaves

Number of Leaves of Lettuce as Influenced by Irrigation frequency and Poultry manure rate in Birnin Kebbi during 2020/2021 dry season is presented in Table 4. Number of leaves of lettuce was significantly ($p<0.05$) affected by irrigation frequency in both seasons. Daily application of water gave significant higher number of leaves followed by One-day interval application of water while the lowest number of leaves was recorded with two days' interval application of water. As explained earlier, high irrigation frequency ensures production of more photosynthate, by supplying enough water to compensate for the high evapotranspiration that resulted due to high temperatures of the experimental area. This ensures concentration of more solutes in high irrigation frequency leaves than low irrigation frequency leaves (Yu *et al.,* 2016).

On the other hand, poultry manure showed significant ($p<0.05$) effect with respect to number of leaves. Application of 4t/ha of poultry manure gave significant higher number of leaves followed by the application of 3t/ha of poultry manure while the untreated control gave significant fewest number of leaves. Organic manure differs from chemical fertilizers due to the fact that they provide plants with the needed nutrients and at the same time build the soil structure (Akanbi *et al*., 2004 and Charoenpakdee, 2014). Soils with lots of poultry manure remain loose and airy, hold moisture and nutrients better, stimulate growth of soil organisms, and promote healthier root development. Organic fertilizers are made from plant and animal sources or from rock powders (Ogunlade *et. al*., 2009). Poultry manure has been reported to have a great ability to conserve nitrogen and improve plant nutrient uptake by acting as a buffering agent against undesirable pH fluctuations and by improving soil water availability through retention and aeration which ultimately contributes to better nutrients utilization by the crop (Adediran, 2015). There was no significant interaction between the irrigation frequency and poultry manure.

Fresh Yield

Total Yield (kg/plot) and Total Yield (t/ha)

Total Yield (kg/plot) of Lettuce as Influenced by Irrigation frequency and Poultry manure rates in Birnin Kebbi during 2020/2021 dry season is presented in Table 5. Total yield of lettuce per plot was significantly ($p<0.05$) affected by irrigation frequency in both seasons. Daily application of water and One-day interval application of water produced significantly higher yield per plot while the lowest yield per plot was recorded with two days' application of water. The frequent irrigation at Daily application of water or One-day interval application of water made water available at the root zone and this enhanced uptake of nutrients from the soil, transport these nutrients as well, and translocation of assimilates to shoots. Similar findings were reported by Wang *et al*. (2004) and Islam *et al*. (2009) who independently noted significant increase in dry matter production, plant height, number of leaves per plant and yield with frequent irrigation interval than with wider intervals. As a result, the moisture enhanced efficient uptake and utilization of nutrients for photosynthesis and leaf formation leads to higher plant weight, size and yield (Kang *et al*., 2004 and Slamet, 2017). The result showed that different levels of irrigation responded differently to yield of lettuce. Data from the experiment indicate that both Daily application of water and One-day interval application of water had highest total yield. The effect of irrigation frequency on yield has been investigated and similar results reported by Jordan *et al*. (2003).

However, poultry manure showed significant ($p<0.05$) effect with respect to fresh yield of lettuce (Table 5). Application of 4t/ha of poultry manure gave significant higher yield followed by the application of 3t/ha of poultry manure which in turn was higher than the application of 2t/ha of poultry manure. The untreated control produced significantly lowest yield. Maximum fresh yield was found with 4t/ha of poultry manure. This might be due to the availability of nutrients at the critical stages of the crop growth resulted early establishment, vigorous growth and development of plants leading to longer and wider leaves (Mal *et al*., 2013 and Slamet, 2017) and resulted into adequate slow but steady supply of nutrients which favored increased production of photosynthesis during the growth stages and consequently partitioning and allocation of the dry matter at the developmental stages of okra (Slamet, 2017). There was significant interaction between the irrigation frequency and poultry manure with respect to yield of lettuce in 2020 dry season. The interaction between irrigation frequency and poultry manure with respect to yield of lettuce (Table 6), the highest yield was recorded at Daily application of water, coupled with the application of 4t ha^{-1} of poultry manure. The lowest yield was recorded when irrigation frequency was kept at 2 days' interval coupled with the application of 2t ha^{-1} of poultry manure.

INTERACTION

The significant interaction between irrigation frequency and poultry manure on Fresh yield (Table 6). Have clearly indicated the interdependence and complimentary role of irrigation frequency and poultry manure in influencing the manifestation of the potentials of lettuce in terms of growth, development and yield as reported by Slamet (2017). Application of 4tha^{-1} attained higher yield when combined with Daily application of water or One-day interval application of water (Table 6). This might be due to adequate water available for efficient dissolving of the added manure as well as quickly mineralized and higher nitrogen content of Poultry manure (Table 2) that enhanced the growth and development of lettuce by increasing the rate of plant metabolic processes like photosynthesis and respiration which in turn helped to build the plant tissue (Slamet, 2017).

CONCLUSION

From the findings of this research, it may be concluded that Daily application of water or One-day interval application of water are most suitable for Lettuce production in Birnin Kebbi. Similarly, Application of 4t/ha of poultry manure gives greater yield advantage.

RECOMMENDATION

From the findings of this study, the following recommendations could be made:

1. Daily application of water or One-day interval application of water could be adopted for higher lettuce yield in the study area.

2. Application of 4tha^{-1} of poultry manure could also be considered since it recorded superior performance among the levels of manure tested in the study area.

INFLUENCE OF UREA RATE AND GIBBERALLIC ACID CONCENTRATIONS ON BIOCHEMICAL CONTENT OF FLUTED PUMPKIN (*TELFAIRIA OCCIDENATLIS* HOOK F.) UNDER DIFFERENT IRRIGATION REGIMES

Ahmad, A.M.

Department of Biological Sciences Federal College of Education, Kano

Corresponding author's e-mail: aminamusabio@gmail.com

ABSTRACT

Nitrogen rate, Irrigation regimes and growth hormones were among the major constraints concerning the production of Fluted Pumpkin in the north. Fluted Pumpkin is a leafy vegetable used as food, blood tonic and in managing diseases such as hypercholesterolemia, hyperglycaemia, anaemia, chronic fatigue, diabetes among others. Experiment was therefore conducted to investigate the inspiration of Nitrogen rate and Gibberallic concentration on biochemical content of Telfairia occidentalis in the Teaching and Research Farm of Faculty of Agriculture, Bayero University, Kano. The treatments consisted of 3 nitrogen levels (0,45 and 60kgN/ha), 3 irrigation regimes (3, 5 and 7days intervals) and 3 Gibberallic acid at (0ppm, 500ppm and 1000ppm). The experimental design was split-plot with nitrogen rate and irrigation regime in the main plot while GA_3 concentrations in the sub-plot treatment. Samples from each treatment combinations were determined for proximate content and mean values were presented as the means of triplicate samples in mg/100g. Proximate content (Tables 1-2) were inclined by irrigation regimes, nitrogen rate and gibberellic acid concentrations. The nutrient content gives the result as carbohydrate, crude protein and total ash to be higher; 31.25±3.1, 17.66±2.7 and 22.31±1.8 mg/100g respectively at 5 days' irrigation regime. Urea at the rate of 60kgN/ha recorded to have high content of carbohydrate (28.46±3.7 mg/100g). Gibberellic acid at 500ppm recorded higher mineral content of Na (29.34±1.7), Ca (57.42±2.9) and Fe (35.89±4.8) mg/100g.It is therefore recommended that Telfairia occidentalis soil should be supplemented with 60kgN/ha and 3days irrigation regime in combination of 500ppm GA_3 concentration. Similar research can be conducted on other crops by either increasing or decreasing the rate or concentrations of growth promoting compounds to determine the influence on proximate content.

Key words: Fluted pumpkin, Nitrogen rate, GA_3, Irrigation regime, Biochemical content, split-plot.

INTRODUCTION

Vegetables are good source of fibre, which lowers the body cholesterol level, consequently decreases the risk of cardiovascular diseases. Fluted pumpkin (*Telfairia occidentalis* Hook F) is a tropical vine grown in West Africa as a leaf vegetable and its edible seeds. The term fluted refers to the shape of the female flowers which resemble a flute. The crop is a member of cucurbitaceous (Akoroda, 1990a).

MATERIALS AND METHODS

The experiment was conducted in 2017 and 2018 dry season, at the teaching and research farm of the faculty of Agriculture Bayero University Kano. The seeds were planted one seed per hole at the depth of 5cm with the hilum facing downward (Musa, 2010). The treatments consisted of a factorial combination of Nitrogen rates (0 kg N/ ha, 45kg N/ha and 60kg N/ha), irrigation regimes (3days, 5days, and 7days) and Gibberallic acid concentrations (0ppm, 500ppm and 1000ppm). The treatments were laid out in Randomised split arrangement with irrigation intervals and nitrogen rate assigned to the main plots while Gibberallic acid concentrations was assigned to the sub-plot. The treatments were replicated three times. Nitrogen in the form of urea was applied in split, at planting and at 12 weeks after planting. 0kgN/ha (control), 45kgN/h and 60kgN/ha according to the treatment combination. Gibberallic acid at a concentration of 0ppm, 500ppm and 1000ppm was prepared using standard procedure described by John (1987). The whole experimental plots received uniform irrigation at 3 days' interval for 3weeks for the plant to establish, after which the irrigation treatment was introduced at 3, 5 and 7days interval. Pest and weed were controlled as described by (Olaniyi and Akanbi, 2007).

Determination of proximate Content of *T. occidentalis* Leaves

Telfairia occidentalis leaves were detached from six tagged plant from each treatment combination. Twenty gram (20g) was measured at 18 $WAGA_3A$. The samples were packed in envelopes with their label and gathered in oven and dried at 75°C until properly dried (Akanbi *et al*., 2007). The powdered samples were used for Biochemical analysis. All parameters for proximate content were obtained in triplicate and the mean values were recorded as 100ml/g (AOAC, 1990).

RESULTS AND DISCUSSION

Leaf Biochemical Content at Harvest at 18 WAGA$_3$A

Table 1 shows the effect of irrigation regime, nitrogen rate and Gibberellic acid concentration on leaf proximate content of *Telfairia occidentalis* at 18WAGA$_3$A final harvest in 2017 season. Irrigation regime influenced leaf carbohydrate content, Crude fibre content and total ash content. Irrigation at 5days interval had the highest carbohydrate content, crude fibre, crude protein and total ash, 31.25±3.2, 15.42±1.4, 15.42±1.4, 17.66±2.7 respectively while 3days irrigation had the lowest. Irrigation at 3 days' regime had the highest crude fat content 1.8±0.9.

Nitrogen at the rate of 60kg/ha had the highest carbohydrate content while the control had the least value. The untreated control recorded the lowest crude fibre content while nitrogen at 60kg/ha had the highest. However, nitrogen at 45kg/ha had the highest crude protein while the lowest protein content was observed from plots without nitrogen application. Nitrogen at the rate of 60kg/ha had the highest total ash content and crude fat content while the control had the least.

Applying GA$_3$ at the rate of 500ppm supported the highest carbohydrate content and the control had the least. Similar trends were observed on crude fibre and crude protein content. Highest total ash content was observed from plot treated with 1000ppm of GA$_3$ while the control had the lowest. The highest fat content was recorded from plots with 500ppm GA$_3$, while no GA$_3$ concentration recorded the lowest fat content.

Table 1. Effect of Irrigation Regime, Urea Rate (N) and GA$_3$ Concentrations on Biochemical content (mg/100g) of *Telfairi aoccidentalis* Dry Leaf Matter at 18WAGA$_3$A

	Proximate content				
Treatment	Carbohydrate	Crude fibre	Crude protein	Total ash	Crude fat
Irrigation Regime					
3days	27.46±3.4	16.26±1.6	13.52±4.6	19.61±1.3	1.83±0.9
5days	31.25±3.1	15.42±1.4.	17.66±2.7	22.31±1.8	1.75±0.7
7days	17.44±0.1	13.11±0.3	11.72±1.4	18.33±0.1	1.41±0.3
N(kg/ha)					
0	17.41±0.1	24.62±0.2	9.31±1.3	9.26±0.2	1.04±0.1
45	26.59±1.6	13.49±1.4	13.19±1.6	12.27±1.7	1.13±0.2
60	28.46±3.7	15.44±2.6	12.57±0.4	10.68±1.2	1.55±0.9
GA$_3$ (ppm)					
0	25.29±0.8	11.40±0.2	14.50±0.3	8.42±0.2	1.02±0.2
500	34.22±1.9	21.38±1.7	20.53±1.7	11.46±1.3	1.32±0.6
1000	28.52±1.8	18.40±1.4	16.51±1.5	15.31±1.5	1.02±0.3

Values are given as means of three replicates ± SD, WAGA$_3$A= Weeks after Gibberellic Acid Application.

Leaf Mineral Content at Harvest 18 WAGA$_3$ A

Table 2 shows the effect of irrigation regime, nitrogen rate and Gibberellic acid concentrations on leaf mineral content of *Telfairia occidentalis* at 18 WAGA$_3$A final harvests in 2017 season. Irrigation at 5 days' interval recorded the highest Sodium content while 3 days recorded the least. Similar observation was with Potassium (P), calcium (Ca), iron (Fe) and magnesium (Mg).

Applying nitrogen at the rate of 60kgN/ha recorded the highest value of sodium content (34.22±2.7) while the control had the lowest value. Similar trends were observed in Potassium, iron and calcium contents. However, applying 45kgN/ha of N had the highest value of Magnesium content (77.13±2.0) while the lowest magnesium content was observed where no nitrogen was applied 39.48±1.5).

Gibberellic acid concentration influence leaf mineral content. Spraying the crop with 500ppm GA$_3$ had the highest sodium (29.34±1.7) than the control, while the control recorded the lowest potassium content (12.21±1.8). Similar trends were observed for potassium (K) and Iron (Fe). Applying 1000ppm of GA_3 supported the highest Magnesium (Mg) content (64.29±3.1) while the control had the least value (49.3.7±2.9).

Table 2. Effect of Irrigation Regime, Urea Rate (N) and GA_3 Concentrations on Mineral Content (mg/100g) of *Telfairia occidentalis* Dry Leaf Matter at 18 $WAGA_3A$

		Mineral content			
Treatment	Sodium (Na)	Potassium (K)	Calcium (Ca)	Iron (Fe)	Magnesium (Mg)
Irrigation Regime					
3days	27.85±2.4	10.21±3.7	23.77±2.6	28.70±4.6	48.99±2.7
5days	33.19±2.6	13.38±2.8	28.34±2.7	38.31±3.9	66.79±3.6

1000	27.37±2.4	14.69±2.8	46.82±2.5	27.48±4.5	64.29±3.1

Values are given as means of three replicates ± SD, $WAGA_3A$= Weeks after Gibberellic Acid Application.

Effect of Irrigation Regime on Biochemical Content of Fluted Pumpkin (*T. occidenatlis* Hook F)

Nutritional content of *T. occidentalis* leaves were significantly affected by watering regime. High carbohydrate content in *T. occidentalis* (31.25mg/g) gave rise to high energy value of about 293.13kcal/1000g. In line to this study is the report of Idris, (2011) that *T. occidentalis* leaves recorded high carbohydrate content.

Results of proximate analysis revealed that Irrigation interval of 5days yield higher contents of Mg, Ca, P, K and Fe. Prolonged watering regimes had a profound negative effect on concentrations of these mineral elements. This corroborated with the findings of Moftah and Al-Humaid, (2006) that concentration of N, P, K and Ca in tuberose plant leaves were substantially decreased by severe water deficit condition.

Effect of Urea (N) Rate on Biochemical Content of Fluted Pumpkin (*T. occidenatlis* Hook F)

Fertilizer rate affect the shoot nutritional content of *T. occidentalis*. In all the nitrogen level 0kgN/ha recorded the lowest values of nutritional and mineral content of the crop. The proximate content of *T. occidentalis* was high as the N rate increased, even though there was no significant difference observed between 45 and 60kgN/ha, which were higher than control. Crude protein content was observed to be higher as the N rate increased from 0kg to 60kg.

This result agreed with the findings of Olaniyi and Akanbi (2007), that the integration of N-fertilizer and organic fertilizer; and their sole application relatively improved moisture, fibre, crude protein, dry matter, fat and Ca contents of fluted pumpkin. This could be attributed to the successive increase in nitrogen level in response to urea fertilizer. The finding was contrary to that of Zakaria *et al*., (2006) that N fertilizer at the rate above 60kgN/ha was found to play no significant effect on protein content of leafy vegetables. Olsen *et al*., (1993) observed similar effect on pepper.

Split applications of nitrogen fertilizer at appropriate time corresponding to plant need, may increase Fe content of vegetables and crops nutritional value this agrees with the finding of Fei *et al*., (2008). Similarly, Fe content in different parts of the plant may be affected by nitrogen fertilizer.

Effect of Gibberellic Acid Concentrations on Biochemical Content of Fluted pumpkin (*T. occidentalis* Hook F)

Proximate content of *T. occidentalis* leaves was found to be affected by GA_3 concentrations. The edible portion of *T. occidentalis* had higher percentage Carbohydrate, crude protein, and crude fat at a 500ppm of GA (mg/100g). Total ash and crude fat were found to be higher at 1000ppm concentration. This agrees with the findings of Dybing and Lay, (1982) who observed the quality of plants with respect to oil latex, sucrose and protein content of *Datura innoxia* plants at high concentrations of growth hormones. Kadiri *et al.,* (1997) reported similar increase in vitamin A, B6 and C content of *Abelmoschus esculentus* and *Solanum gilo* following foliar spraying with IAA, GA_3 and coconut milk at various concentrations. The low percentage of crude fat in *T. occidentalis* leaves showed that vegetables are low in fat content; as such they are good source of dietary fibre. The high percentage of crude fat in the control treatment (1.32mg/100g) could be attributed to the inherent fertility of the soil.

The composition of Phosphorus, Potassium, Calcium, Iron and Magnesium were higher at 500ppm concentration. This finding could be attributed to the fact that GA_3 stimulates growth and nutritional content of vegetable crops when applied at right time and correct proportion. This agrees with the report of Ouzounidou *et al*., (2008); and Ashraf, (2010) that moderate concentration of GA_3 or Etherel had superior effect on various total yield and nutrient content of onion plant. Similarly, Mukhtar, (2008) reported higher increase in biochemical and some mineral content of *H. sabdariffa* at various concentrations of growth regulators.

ABSTRACT

A field trial was carried out for two years (2018 and 2019 rainy seasons) to study the performance of Amara (Tacca leontopetaloides(L) Kuntze under different row spacings in Lafia Nasarawa State Nigeria. Three different intra row spacings (30; 45 and 60cm) with a uniform inter row of 30cm were used. The three row spacings were replicated three times and all the nine plots were laid in a randomised complete block design (RCBD). In both years of the study; the investigation revealed that the use of 30cm x 30cm row spacing produced larger tubers and higher yield per hectare than the rest of the spacings used.

Keywords; Amara, Spacing, Fertilizer Rate, Domestication, Performance.

INTRODUCTION

Amara (Tacca leontopetaloides (L) Kuntze) is a wild plant commonly called Amara in Plateau and Nasarawa States of Central Nigeria. At present, the crop plant is harvested from the wild and eaten as food derived from tubers that are similar to those of Irish potatoes. Amara tubers can be processed into flour which is made into a Gel meal prepared first by boiling water and making a soup sauce. The flour is added to make a fine gel and allowed to settle into a semi-solid tasty delicacy. Such a dish is highly cherished by the Taroh and Goemai people of Plateau state and the Alago people of Nasarawa state. Tacca leontopetaloides (L)Kuntze has up to 47 synonyms. The Basionym, Leontice leontopetaloides (L) appeared in species Plantarum. The common synonyms today are Tacca pinnatifida and Tacca involacurata. The local names are also many and varied with some related to the local communities in which they are found. They include; Bat flower, Polynesian arrowroot, Yabio, Fiji arrowroot, Kabusa, Masao and many more (NDB, 2004). Amara is a plant mostly found along the fringes of the Middle Belt of Nigeria, notably Plateau and Nasarawa states. Although the plant possesses such tremendous qualities in terms of food and medicine, it is yet to be domesticated in Nigeria and no literature has so far reported its production under conventional agronomic practices (e.g. spacing) as applied to crops such Irish potato, cassava and yam.

Considering its food values, gelling qualities and its medicinal qualities, Amara is worth a plant to be recognised as more than a wild collection. Thus, it should be cultivated under field conditions in addition to other similar tuber crops such as Irish potato, cocoyam, cassava and yam in order to provide additional food source to feed the ever-growing population of Nigeria.

MATERIALS AND METHODS:

A field trial was carried out at the Teaching and Research Farm of College of Agriculture, Lafia, Nasarawa State during the wet seasons of 2018 and 2019. Lafia is located at latitude 08.33 N and longitude 08 .32E in the southern guinea savannah of Nigeria. Data on rainfall distribution, maximum and minimum temperatures and relative humidity of the study area for the two years were obtained from the Nigeria Meteorological Agency (NIMET) of the Federal Ministry of Aviation, Lafia office. The site for the research was under maize production for three consecutive years. The soil of the area is sandy loam which is characterised by low N, P, and K as shown in the soil textural and chemical analyses table 1.

Table 1: Physical and chemical analyses of soil before planting

Soil properties at 0 – 3cm depth	
Physical composition	
Clay (g/kg)	8.64
Silt	11.14
Sand	80.22
Textural classification (USDA)	Sandy loam
Chemical composition	
pH (H_2O)	5.18
pH (0.01M$CaCl_2$)	5.04
TN%	0.13
Avail. P (ppm)	18.08
K (mg/kg)	0.16
OC (mg/kg)	0.42
C/N_c	3.23

Mg (Mol/kg)	1.45
Ca (Mol/kg)	2.21
Na (Mol/kg)	0.85
CEC (Mol/kg)	4.67

The treatments consisted of only one factor (spacing) with three intra row levels: 30cm, 45 cm and 60cm and a uniform inter row spacing of 30cm.

The three inter row spacings were replicated three times and all the plots were laid out in a randomised complete block design (RCBD). The experimental site in each of the two years under investigation was first harrowed twice at the onset of the rainy season. The area was then mapped out into plots of $9m^2$ each. The plots were then arranged side by side in rows of three blocks with each row having 3 plots. The space between blocks was 1m apart while the space between plots within a block was 50cm. Amara seedlings for transplanting were collected from the wild around college of Agriculture Lafia. The seedlings were then planted at a depth of 3-5cm. Weed control and other agronomic practices were applied at 2 weeks after transplanting.

Data collection:

Ten sampled plants were randomly chosen from each plot and tagged for data collection. From the ten tagged plants, growth parameters such as plant height and stem diameter were taken forthnightly while yield parameters such as tuber size, and tuber yield (weight) were obtained by harvesting, measuring and weighing tubers in $1m^2$ area of each plot.

Data analysis:

Analysis of variance (ANOVA) was carried out to test for the level of significance among treatments using F-test as described by Snedecor and Cochran (1967). Where the F test was significant, Duncan's Multiple Range Test(DMRT) was used to separate the means of the treatments.

RESULTS AND DISCUSSION

Plant height: Effect of row spacing on plant height of amara during the wet seasons of 2018 and 2019 is presented in table 2. Intra row spacing showed a significant effect on the growth height of amara in both years. In 2018, amara plants sown at 30cm x 30cm exhibited the highest growth rate throughout the sampling dates followed by plants sown at 30cm x 45cm. Amara plants sown at 30cm x 60cm were the least in growth rate throughout the study period. In 2019 wet season however, except at 12 weeks after planting, 30cm x 30cm and 30cm x 45cm were at par with each other on growth height while 30cm x 45cm produced taller plants (32.80cm) followed by 30cm x 30cm (29.00cm) with 30cm x 60cm having shorter plants throughout the study period (25.60cm). It should however be noted that during the study period, growth heights of plants sown at 30cm x 30cm and 30cm x 45cm were not significantly different from each other but both were significantly different from the heights of plants sown at 30cm x 60cm.

Stem diameter: The effects of row spacing on amara stem diameter grown during the 2018 and 2019 wet seasons are presented in table 3. In both years, Amara plants sown at a spacing of 30cm x 60cm produced higher stem diameter than those sown at 30cm x 45cm. Plants sown at 30cm x 30cm on the other hand, had the least stem diameter. In both years, plants sown at 30cm x 45cm and 30cm x 60cm had significantly greater stem diameter than those sown at 30cm x 30cm. This, by implication shows that with wider spacing, the plants on the field are less populated and hence there is little or no etiolation experienced by the plants on such plots. This result does not agree with that got by O-Sage Katanka *et al.* (1984) who reported that Xanthomonas and Colocasia spp sown at three different spacings: 1m x 1m, 1m x 0.75m and 1m x 0.5m and evaluated for leaf area index, number of leaves and dry weight of different parts determined were not statistically different.

Table 2: Effect of spacing on plant height (cm) of Amara plant at Lafia, Nasarawa State during 2018 and 2019 wet seasons

Tuber size (cm). The effects of row spacing on tuber size at harvest observed during the wet seasons of 2018 and 2019 are shown in table 4. In both years, the use of 30cm x 30cm row spacing produced tubers with larger sizes (22.71) cm while the use of 30cm x 60cm row spacing produced the least tuber size (17.03cm).

Tuber yield (t/ha): The effect of row spacing on tuber yield observed during the 2018 and 2019 wet seasons is presented in table 5. It could be observed that in both years of the study, row spacing 30cm x 30cm produced higher mean yields of 6.93t/ha and 6.47t/ha that are significantly ($p < 0.05$) higher than that of 30cm x 60cm spacing which had the least tuber yield of 3.16 and 2.65t/ha. This result shows that amara plants would likely give higher yield when sown at close spacing of 30cm x 30cm or even less. This result tends to tally with that got by Arene et al (1984), when they evaluated the effects of spacing (10, 20, and 30cm), land preparation (ridges and flats) and mulch on two varieties of ginger in 1982 and 1983, the highest yields were obtained under mulch for both ridges and flats at 10cm spacing. Sulikeri et al (1977), also reported that the highest yield of egg plant cultivar 'malapur' were obtained at closer spacing with FYM at 10t/ha and NPK fertilizer.

SUMMARY

During the study period, it was observed that spacing of 30cm x 30cm led to the production of taller plants than 30cm x 45cm and 30cm x 60cm used. However, stems of the plants were thicker with spacing of 30cm x 60cm than the other spacings used. On the other hand, production of larger tubers was observed with spacing of 30cm x 30cm. Similarly, spacing of 30cm x 30cm led to higher tuber yield than the wider spacing used.

CONCLUSION

From the foregoing results, it has become evident that amara plant requires close spacing, may be closer than 30cm x 30cm to give higher yield.

RECOMMENDATION

From the results obtained, it can now be recommended that amara seedlings should be transplanted onto the field at a spacing of 30cm x 30cm or even less in order to obtain higher yield.

ABSTRACT

The use of inappropriate sett size and plant population has deprived farmers of ginger suitable yield. A field trial on the effect of sett size and population density on the growth and yield of ginger (Zingiber officinale Koswe) was conducted between April to October, 2018 and 2019 at Experimental farm of the Department of Crop Science, Faculty of Agriculture, University of Benin, Benin City, Nigeria. The field trial involved three sett sizes of 10, 15 and 20 g and four plant populations of 1,000,000, 333,333, 500,000 and 250,000 plants per hectare. The trial was laid out in a 3 × 4 factorial arrangement fitted into randomized completely block design with three replicates. Data were collected on growth variables (plant height and number of leaves) and yield variables (rhizome length, rhizome weight and rhizome yield) at harvest. Plant height and number of leaves (m^{-2}) were significantly influenced by sett size and plant population. Plant height and number of leaves per unit area increased with increase in sett size and plant population. Sett size and plant bpopulation had no effect on rhizome length. Rhizome weight increased with increase in sett size and decreased with increase in plant population. Plants which grown from 20 g sett had the highest rhizome yield while a population of 1,000,000 plants per hectare had the highest yield which was comparable with the rhizome yield obtained from 500,000 plants per hectare. Therefore, it is suggested that ginger farmers in the humid agro ecological zone of Nigeria should adopt sett size of 20 g and 500,000 plant per hectare.

Key words: Growth, plant height, plant population, sett size, yield components.

INTRODUCTION

Ginger (*Zingiber officinale* Rosc.) is an herbaceous perennial plant belonging to the order Zingiberales and the family Zingiberaceae. Ginger is used throughout the world as a spice or fresh herb for cooking and varieties of other value added products (Bartley and Jacobs, 2000). It is available in the form of oil, oleoresins, grind and fresh ginger.

Nigeria's annual total production is 117,000 tonnes (FAOSTAT, 2012), 10 % of which is locally consumed as fresh ginger and 90 % dried primarily for the export markets (Ajav and Ogunlade, 2014). The average crop yield per hectare is 3.52 t ha^{-1} (National Root Crop Research Institute, 2009). This present productivity level is quite low indicating the need to increases the yield level of this crop. The major problems responsible its low productivity among others were low soil native fertility, scarcity of planting material, suboptimal plant population, non-use of fertilizer inputs among other factors.

Plant population plays an important role in contributing to good growth and high yield, because very high plant population will create opportunity for plants to have a proper light interception for photosynthesis and may lead to high level of disease incidences. On the other hand, very low population will also reduce the expected yield per unit area. Inter and intra-row spacing is one of the major factor that influence the growth and development of ginger.

Limited availability and cost of planting materials is a major constrain to ginger production in Africa. Panting materials can account for about 50 % of the cost of the production. Large quantity of materials of seed ginger is needed to plant one hectare. If farmers do not purchase seed ginger, they may set aside 30 % of their harvest for planting the next year. Appropriate sett size should be determined to boost its production. Hence, this study was conducted to evaluate the effect of sett seizes and plant population on the growth and yield of ginger.

MATERIALS AND METHODS

Experimental Site

The experiment was conducted between April and October, 2018 and 2019 at The Experimental Farm of Faculty of Agriculture, University of Benin, Benin City, Edo State, Nigeria. The study area lied approximately on longitude 5^0 and $6^{\,0}$ 30 E; and latitude 5^0 and $6^{\,0}$ 30 N with elevation of 162m above the sea level. The climate is tropical rain forest with rainfall occurring between March and October with average temperature of 27 ^{0}C. The existing vegetation on the site were Guinea grass (*Panicum* maximum) and sensitive plant (*Mimosa* *pudica)*. The soil was characterized by well drained sandy loam soil and a moderately flat topography. The soil type was a typical ultisols which developed from a coastal plain sand.

Composite soil samples were taken from the site in both years of cropping and analyzed for their physical and chemical properties using standard laboratory procedures as outlined by Mylavarapus and Kennelley (2002).

Experimental design and treatment

The treatments were three sett sizes (2, 4 and 6 cm) and four plant population (250000, 333333, 500000 and 1000000 plants per hectare) laid out in a 3 × 4 factorial agreement fitted into a randomized complete block design with three replications. Each plot had a dimension of 1.0 × 1.0 m with 0.5 m between plot and 1.0 between blocks. Each replicate had 12 plots and total of 36 plots made up the experimental site. Experimental site occupied area of 1800m^2.

Cultural practices

The land was normally cleared, marked out into blocks and plots and beds constructed manually using hoe and spade. After which cured poultry manure was applied on marked out plots as basal at 15 t ha^{-1} four weeks prior to planting for equilibrium. Three seed setts (10, 15 and 20 g) of rhizome were sown on April 28, 2018 and 2019 according to the design of the experiment. The setts were planted in-situ at a spacing of 5× 20 cm, 10 × 20 cm, 15 × 20 cm and 20 × 20 cm corresponding to 1000000, 500000, 333333 and 250000 plants per hectare (pph) as per treatment. The planting depth was 3 cm and placement orientation was horizontal. Watering was done the following day by supplying equal quantity to every plot with watering can. The plots were weed-free, rain-fed, rouging of disease plants and land picking of pests were done when required. Rhizomes were harvested at 150 days (24 September 2017) from planting when the leaves and shoots have dried off.

Data Collection and analysis

Plant growth were monitored in-situ from four randomly selected inner row plants per plot using conventional growth indices which include plant height and number of leaves at 19 weeks after planting (WAP). Plant height were measured from the base of the plant to the apical meristem of the randomly selected plants with a calibrated metre rule and the mean computed. The fully extended leaves in all the sampled plants were counted, recorded and average computed.

For the yield variables, the tagged plants in each plot were harvested and data were collected on rhizome length, weight and yield. All harvested rhizomes from all sampled plants were measured using a metre rule and total sum divided by the number of rhizome to obtain the average rhizome length. Rhizome weight was measured by weighing all harvested rhizomes from sampled plants using digital weighing balance. Rhizome yield was estimated from rhizome weight as;

$$\text{Rhizomes yield} = \frac{\textit{Rhizomes weight}}{\textit{Plant spacing}} \times \frac{10000}{1000 \times 1000}\ \text{t ha}^{-1}$$

Year-wise data were analyzed using analysis of variance, followed by combined analysis over two yearss with Genestat Statistical Programme, Version 8.1 and significantly differences among treatment means were compared using Least Significant Difference (LSD) at 0.05 level of probability.

RESULTS

Properties of soils of the experimental site

The physical and chemical properties of the soil prior to cropping with ginger is presented in Table 1. Soils of both years were sandy loam textually, moderately acidic and organic carbon. Total nitrogen, available phosphorus and exchangeable cations were low.

Growth of ginger

The height and number of leaves of ginger as influenced by sett size and plant population is presented in Table 2. Sett size had significant ($P<0.05$) effect on plant height and number of leaves. Plant height and number of leaves increased with increase in sett size. Sett size of 20 g had the tallest and the leafiest plants.

Plant height number of leaves per m^2 varied among plant populations. Plants produced grown at 500,000 pph had the tallest but only significantly taller than plants grown at 250,000 pph. Plant grown at a plant population of 1,000,000 pph had the highest number of leaves.

Yield components of ginger

Yield components as influenced by sett size and plant population are presented in Table 3. Yield components varied significantly (P<0.05) among sett size and plant population except rhizome length. Plants grown with 20 g sett had the highest rhizome weight and yield. Rhizome weight decreased with increase in plant population. The lightest and heaviest rhizomes were produced from plants grown with 1,000,000 and 500,000 pph, respectively. However, rhizome yield increased with increased in plant population. The highest yield was observed with plant grown in 1,000,000 pph plot but at par with plant grown in 500,000 pph plot.

DISCUSSION

The soil of the experimental site was an acidic sand, a typical ultisols developed from coastal plain sand. The soil had low fertility status. This necessitated the need for poultry manure application to improve the supplement nutrients that are deficient in the soil.

This field trial demonstrated that sett size and plant population had ample effects on the productivity of ginger. With sound agronomic practices coupled with appropriate sett size and plant population, ginger production can be successfully enhanced in the humid ultisols environment. The productivity of ginger in Nigeria is relatively low, about 10 t ha^{-1} (FAO, 2008). This low productivity was due to inadequate sett size as well as inappropriate plant population among other factors. Trial showed that plant growth arisen from the larger sett size grown more vigorous than the smaller sett size. This was in agreement with Sambo (1992) who reported higher growth rate was observed with largest sett compared with smaller setts. This finding was also in agreement with the observation of Misra and Neduchezhezhiyam (2004) in yam who found out that the sizes of tuber significantly affected the vine length. The higher growth accrued to plants grown with larger sett could be attributed to the availability of sufficient food reserves which probably encourage vigorous growth.

Plant height decreased with lower plant population (250,000 pph) and highest at 500,000 pph and comparable with 1,000,000 pph. This observation was in agreement with the findings of Desta (2008) in onion, who reported the decrease of plant height at very high population which could probably be due to intense competition for growth resources (physical space, water, nutrient and light) as a result of overcrowding resulting in decreased plant height. At 500,000 pph, plant attained highest height which might have adjusted its canopy in the vertical spacing by increasing inter-nodal length as a result of proper horizontal space (Yadav *et al*., 2013). Increasing plant population resulted in higher number of leaves up to 500,000 pph indication proper plant population with less competition for limited available growth resources. 1,000,000 pph exhibited similar number of leaves with 500,000 pph due to intense completion resulting in overshading and premature drying up of lower leaves.

Rhizome weight and yield increased with increase in sett size. This result is in conformity with Ravindran and Bacu (2005) on ginger in which larger setts produced higher yield than smaller sett. The yield variation between smaller and larger setts could be due to the fact that plants arising from the larger sett have more available nutrients to initiate vigorous and rapid growth and producing maximum yield and yield attributes than smaller sett size (Sengupta and Dasguta, 2011).

The rhizome weight decreased with higher plant population observed in this trial was in agreement with the finding of Sen *et al* (1990) who reported that yield per unit area was higher where cuttings are densely planted. The higher rhizome weight produced from lower plant population might be due to better availability of nutrients, water, physical space and light for the enlargement of rhizomes (Yadav *et al*., 2013). Competition for growth resources is less as the population maximum has not be attain and growth resources are high for plants, which results in a greater weight per plant. The highest rhizome yield accrued to 500,000 pph might be due to higher number of plants per unit area together with efficient utilization of nutrients by the growing plants (Yadav *et al*., 2013).

CONCLUSION AND RECOMMENDATIONS

Sett size and plant population have profound effect on the overall performance of ginger production in the humid forest environment. This study showed that rhizome yield was increased to ensure sustainability through the use of larger sett and appropriate plant population. Sett size of 20 g produced plant which had the tallest and leafiest in addition to having the heaviest and highest rhizome yield. 500,000 pph witnessed highest plant height and rhizome yield. Sett sizes of 20 g cropped at 500,000 pph had the most vigorous plants and rhizome yield. Based on these facts, the farmers should adopt sett size of 6 cm and 500,000 pph for optimum production of ginger in the ultisols environment

ABSTRACT

Experiments were conducted at the National Horticultural Research Institute (NIHORT), Ibadan, Nigeria in 2018 and 2019 cropping seasons to determine the effects of plant population and soil amendments on the physiological plant growth and yield of two varieties of grain amaranth. The treatments consisted of two varieties of grain amaranth (TE81/28 and CEN18/97), three plant populations (100,000; 60,000 and 40,000 plants ha^{-1}) and five levels of organic fertilizer (0, 25, 50, 75 and 100 kg N ha^{-1}) and 100 kg N ha^{-1} of inorganic fertilizer (NPK) to make up six levels of soil amendments. The treatments were laid out as split split plot in a randomized complete block design replicated three times. The main plot consisted of Amaranth varieties, while plant population and soil amendments were in the sub-plot and sub-sub plot respectively. Data on physiological plant growth parameters collected includes - crop growth rate, relative leaf growth rate, net assimilation rate, leaf area ratio and grain yield and were analyzed using the analysis of variance and treatment means differences were separated by the use of least significant difference at 5% probability level. The results showed that the organic fertilizer gave a progressive increase in the parameters measured with an increase in application rates, however, the in-organic fertilizer (100 kg N ha^{-1} NPK) significantly increased both the physiological plant growth indices compared to the organic fertilizer rates, while plant population was optimum in yield parameters at 60,000 plants ha^{-1} with CEN18/97 amaranth variety.

Key words: Amaranth, Variety, Soil amendment, physiological, analysis and Yield.

INTRODUCTION

Vegetables are valuable in maintaining the alkaline reserve of the body because of their high carbohydrate, fiber, vitamins and minerals contents and this makes each vegetable group contributes to diet in their own way (Robinson, 1990). Nutritionally, vegetables play key roles in alleviating food insecurity and ill health in developing counties. Studies have shown the potential synergetic effects of vegetables as neutraceuticals (Micro-nutrient dense and medicinal) (Kimiywe, *et al.,* 2007).

Like many other vegetables, grain amaranth is a widely cultivated plant which produces grain as well as leaves for human and animal utilization. Nutritionally, grain amaranth is valuable, and it is an economically important crop that all efforts should be put towards its increased production as food for man, animal and for commerce. Vegetables play valuable roles in alleviating food insecurity and ill health in man. Like many other vegetables, grain amaranth cultivated for the grain as well as leaves for man and animal utilization. It is a high protein pseudo-cereal plant with an upright growth habit with both the grain and leaves often being utilized for both man and animals as food (Saunders and Becker, 1984). Grain amaranth has the potential to substitute for expensive animal protein because of its comparable protein quality.

Soil fertility needs for grain amaranth production varies significantly depending on rainfall amounts and distribution (Mposi, 1999). Akiri, (2019) described soil fertility degradation as the second most serious constraint to food security in Africa. Sanchez (2002), and Akinrinde (2006) attributed the low soil fertility to nutrient leaching, fast mineralization of organic matter, erosion of the top soil by intensive rainfall, bush burning, over grazing, clearing and continuous farming activity thus, severely reducing the soil productivity and results in low economic returns from farming activities. Mafongoya *et al.* (2006) attributed the low productivity of tropical African soils to their low nutrient holding capacities, high acidity, low organic matter, poor soil structure and low water-holding capacity. The heavy use of inorganic nitrogenous fertilizers is known to be inimical to the activities of symbiotic nitrogen fixing organisms, such as *Rhizobium spp* (Akinrinde, 2006). Indeed, fear is being expressed about the contribution of N fertilizers to the environmental problems arising from N pollution of the earth's atmosphere with its oxides resulting in the greenhouse effect (FAO, 1994). Health issues and environmental concerns had drawn attention to organic agriculture aims at maintaining balance of nature and to produce crops without damaging the environment, besides its nutritional qualities.

Plant population studies conducted with grain amaranth often resulted in conflicting reports (Weber, 1987); with environmental factors being pinned as the most likely factors responsible for a greater part of the differences observed. Henderson *et al.* (2000) reported significant environment and plant population effects on grain yield and suggested that different plant population should be adopted in different environment.

Despite the nutritional and industrial value of grain amaranth, little attention has been given to it in Nigeria. The crop has not been extensively studied in the area of fertilization, plant population, varietal effects and responses to classical growth indices, hence the need for this study. The study was to produce appropriate production package for optimum grain yield with a view to encouraging the production of the novel species in Nigeria and to determine the appropriate soil amendment level, with the optimum plant population, varietal effects on grain amaranth growth and yield.

MATERIALS AND METHODS

Site description

The study was conducted in 2018 and 2019 cropping seasons on an Inceptisoil at the experimental farm of the National Horticultural Research Institute (NIHORT) Jericho, Idi-Ishin, Ibadan (7^0 30'N, 3^0 50'E); with altitude of 168 m above sea level and average annual rainfall of 1200.25 mm and 1320.00 mm (2018 and 2019) in the Rain forest zone of Nigeria.

Treatments and experimental design

Two varieties (TE81/28 and CEN18/97), three plant populations (100,000, 60,000 and 40,000 plants ha^{-1}) and six fertilizer levels (0, 25, 50, 75, 100 kg N ha^{-1} organic fertilizer and 100 kg N ha^{-1} in-organic fertilizer (NPK 15 15 15) were evaluated. Varieties were in the main plot while plant population and fertilizer rates were in the sub and sub-sub plots respectively. The experimental design was a 2 x 3 x 6 factorial arrangement fitted into split split plot and replicated three times. The area of each plot was 4m^2, well labeled and in correspondent to each treatement and separated by alley ways of 1m between plots. Ridges were constructed around each plot to prevent erosion. Mechanical land preparation was adopted using tractor drawn disc plough and harrow. The land was ploughed once and harrowed twice to give a well pulverized soil. Thereafter the field layout was carried out to mark out the appropriate number of treatment plots.

Seeds of the Amaranth species were planted directly on the prepared and labeled in the plots on the 5th and 7th of July in 2018 and 2019 respectively. Seeds were planted to obtain the population density of 100,000, 60,000 and 40,000 plants ha^{-1}. Properly cured organic fertilizer to supply 0, 25, 50,75 and 100 kg N/ha and in-organic fertilizer (NPK 15:15:15) to supply 100 kg N/ha were applied two weeks after planting by deep side placement at about 8-10 cm away from the base of the plants. Manual hand weeding was done two weeks after planting followed by weekly hand picking of weeds. After 40 days of planting, two plants were randomly selected, harvested per plot, the leaves carefully removed and the leaf area determined in the laboratory using leaf area meter model ATMK 2; Detal-T Device LTD. The whole plant's parts (leaves and stems) were then put inside separate envelopes and oven dried for 84 hours at 80^{0}C. The samples were allowed to cool, weighed to determine the dry matter per plot. At 54days after planting the same procedures above were repeated. The leaf area (size of assimilatory system) and dry matter (plant weight) obtained at 40 and 54 days after planting were then used to calculate the following components of classical growth analysis according to Beadle (1987).

Crop growth rate (CGR)

This is expressed in terms of the weight per unit area and time (kg m^{-1} S^1).

$$CGR = \frac{(W_2 - W_1)}{\quad} ;$$

W_2 = Final dry matter weight

W_1 = Initial dry matter weight

t_2 = final time

t_1 = Initial time

Relative leaf growth rate (RLGR)

This is expressed in terms of the growth of the leaf and the expansion in area.

RLGR = $\dfrac{}{t_2 - t_1}$;

A_2 = Final leaf area

A_1 = Initial leaf area

t_2 = final time

Net assimilation rate (NAR)

Net assimilation rate is defined as the increase of plant material per unit of assimilatory material per unit time.

NAR = $\dfrac{(W_2 - W_1)(\ln A_2 - \ln A_1)}{(A_2 - A_1)\cancel{(t_2 - t_1)}}$;

W_2 = Final dry matter weight

W_1 = Initial dry matter weight

A_2 = Final leaf area

A_1 = Initial leaf area

Leaf area ratio (LAR)

Leaf area ratio (LAR) is the ratio of the assimilatory material p

LAR = $\dfrac{(A_2 - A_1)(\ln W_2 - \text{Ln } W_1)}{(W_2 - W_1)\cancel{(\ln A_2 - \text{Ln } A_1)}}$;

W_2 = Final dry matter weight

W_1 = Initial dry matter weight

A_2 = final leaf area

Determination of yield:

The seed head of 10 randomly selected plants used for biological yield were harvested, sundried for five days and weighed to obtain the unthreshed seed weight per plot. The dried seed head obtained from the unthreshed seed weight was threshed manually by the use of club to get the seeds which were sundried for three days, and weighed to get the seed yield**.** The obtained data were subjected to analysis of variance **(ANOVA**) using Genstat Discovery 4 statistical package (2019) and mean differences were separated using LSD $_{0.05}$.

RESULTS

Effects on Physiological growth parameters

The results obtained shows that grain Amaranth growth rate increased significantly with increased rates of the organic fertilizer, however the use of the inorganic fertilizer resulted in significantly higher CGR values than the organic fertilizer for the two years of assessment (Table 1). The results also showed that planting grain Amaranth at low population rate of 60,000 plants per ha resulted in optimum crop growth rate than other rates for both years of assessment, while. variety CE18/97 was significantly superior to variety TE81/28 in both 2018 and 2019 cropping seasons. In similar trend, the relative leaf growth rate increased significantly with increased rate of the organic fertilizer while, the inorganic fertilizer resulted in significantly higher RLGR than organic fertilizer (Table 2) with variety TE81/28 producing significantly higher relative leaf growth rate than variety CEN18/97.

Results on Table 3 showed that application of different forms and rates of soil amendment, increased net assimilation rate (NAR)with increased rates of the soil amendments. The population of 60,000 plants per hectares resulted in significantly higher NAR than for other population density. The results further showed that variety TE81/28 had significantly better NAR than CEN18/97. The results on effects on leaf area ratio (LAR) showed same trend as obtained above for NAR (Table 4). However, none of the organic fertilizer rates performed better than the inorganic fertilizer. The lower population resulted in significantly higher leaf area ratio than the higher populations, with variety CEN18/97 producing significantly higher leaf area ratio than TE81/28. Seed yield trend indicated that the soil amendments resulted to higher seed production while, it was lower for the control treatment (Table 5). There were no significant mean differences resulting from plant variety but the seed yield was higher at the lower plant population.

DISCUSSION

Results of the present study showed that physiological growth indices including crop growth rate (CGR), relative leaf growth rate (RLGR), net assimilation rate (NAR) and leaf area ratio (LAR) of grain amaranth increased significantly with increased application of organic soil amendments. Nevertheless, the values were significantly inferior to inorganic fertilizer applied at 100 kg N ha^{-1}. The results were in line with the findings of Ogboma et al., (2009) who reported that crop growth rate increased significantly as the soil amendment increases and at low plant population. Abidin and Yassdar (1986) had earlier reported that N application encourages crop growth rate, while nitrogen fertilizer 50kg N/ha significantly increased crop growth rate compared with the control (Anika *et al.*, 2009). Similarly, Makinde *et al* (2009) reported that crop growth rate was significantly enhanced by N application to grain amaranth.

This study showed that net assimilation rate increased significantly with increase in soil amendments. The result was in line with the findings of Abidin and Yassdar (1986) who reported that N application increased net assimilation rate significantly over the control (no fertilizer). Similarly, NAR increased with decrease in plant population. Low plant population lead to less competition for light and moisture with resultant improved plant growth. Watson (1952) attributed variation in CGR to variation in leaf area index (LAI) and or NAR. The increase in CGR and NAR with increased N application observed in this study was in conformity with observations by Akintoye (1995) and Abayomi and Fagbenja (2005). The trends of the RLGR were similar to those of CGR. This was also similar to the observation of Abayomi and Fagbenja (2005) on maize. Pawar and Chetti (1996) had earlier reported positive relationship between grain yield and leaf area ratio in sorghum. In similar vein, agronomic practice that would minimize high leaf area ratio such as the use of optimum population density need to be given high priority for profitable commercial crop production. In this study, leaf area ratio was significantly increased by increase in soil amendment application, while plant population of 60,000 stands per hectares gave the highest leaf area ratio.

Results of this study showed that seed yield of grain amaranth increased with increased application of organic soil amendments, but the optimal values were obtained with inorganic fertilizer at 100 kg N/ha. Total seed yield showed that increased soil amendments resulted in significant increase in seed yields. The application of 100kg N/ha of inorganic fertilizer resulted to the highest seed yield. The results were in consonance with the findings of Elbehri et al, (1993), Myers (1998) and Bruce and Philip (2008) who reported a linear response of grain amaranth yield to N fertilization. The increase in grain yield as fertilizer application rates increased could have been due to increase in plant growth. This responsiveness of grain amaranth yield to nitrogen fertilization was also consonant with reports (Mahyers, 1996; Jefferson Institute, 1999; Bruce and Philipe, 2008). Kauffman and Weber (1990) also found grain yield to increase when nitrogen was applied at rates up to 90kg N/ha, to double at 100kg N and reduce at higher rates. Apaza-Gutierrez et al (2002) reported that grain amaranth yield showed a linear response to chemical and organic fertilizers. Manga et al. (2001) reported that the application of nitrogen fertilizer at the rate of 50kg N/ha was optimum for yield of grain amaranth in the Savanna ecological zones of Nigeria. Richard et al (2018) reported that the rate of increase in grain amaranth yield rose steadily as the rates of organic and inorganic N was raised from 0 to 100kg N/ha. Law Ogboma et al. (2009) reported that increase in organic soil amendment decreased the seed yield of grain amaranth agreed with the findings of Adediran and Banjoko (2002), who reported that the application of manure resulted in the enhancement of yield in the crop.

The results of this study on seed yield were in trend with reports on other crops. The 60,000 plants per hectares resulted to highest seed yield which was significantly higher than at 100,000 and 40,000 plants per hectare respectively. The results of the present study were at variance with the findings of Anon (1990) in a multi locational AICR trials conducted at Gujarat and Delhi who revealed that narrow spacing of 30cm resulted in higher yield over the wider row spacing of 75cm in grain amaranth. Seed yield responded similarly to the soil amendment and plant spacing in the two evaluated amaranth varieties. This was in line with Gutierrez et al (2002) who reported that grain yield in grain amaranth varieties responded similarly to variations in plant density.

CONCLUSION

Grain amaranth is a vegetable crop with high protein content that has great potential for sustainable food security if properly managed. The results revealed that plant height, number of leaves, stem girth as well as the grain yield of grain amaranth varied significantly with variety, plant population and soil amendments. Application of organic soil amendment at the rate of 100 kg N/ha gave the highest grain yield. Planting at 60,000 plants/ha produced optimum grain yield of the grain amaranth, compared to 100,000 and 40,000 plants/ha while CEN18/97 variety gave the highest grain yield which was not significantly higher than TE81/28 variety. In conclusion, application of 100kg N/ha of organic fertilizer was the best soil amendment for the grain amaranth production, while 60,000 plants per hectare was the most appropriate using CEN18/97 variety.

ABSTRACT

A nursery experiment was carried out to determine the response of oil palm (Elaeis guineensis) seedlings to selected plant residues in the nursery in the dry season. A Completely Randomnized Design (CRD) involved four treatments viz: pigeon pea shell, cowpea shell, NPK fertilizer with control experiment. The four treatments were replicated three times. Plant residues were applied at the rate of 0.03 kg/pot while N.P.K. 15-15-15 at 0.0005kg/pot four weeks after emergence (WAE) to single seedlings grown in polythene bags. The following parameters were recorded at bi-weekly intervals after seedling emergence: plant height, leaf area, stem girth, and number of leaves. Soil and plant analysis were carried out to determine nutrient contents. The lowest response was recorded for the control treatment, followed by N.P.K 15-15-15 while the highest was recorded for the pigeon pea husk followed by cowpea husk.

INTRODUCTION

Most of the nutrients in the soils of the Western part of Nigeria has depleted in nutrients status due to continuous agricultural uses and pressure from population explosion. Also, oil palm seedlings required much nutrients in their nursery stage due to this the soil must be amended with nutrients in order to support oil palm seedlings in the nursery. (Imogie *et al.,* 2016). Crop residues such as parts of leguminous plants (leaves and husk) can be used as mulching material which when degraded will increase the nutrient status of soil. Mulching with plant residues has been shown to be beneficial to crops (Agbona et al, 2020) and mulched seedlings subsequently grow better in the nursery (Gunn et al, 1961). Mulching shows significant improvements on other crops in the nursery. (Agbona *et al*, 2020, Agele et al, 2013, Agele *et al*, 2008). Agele *et al*., 2013 opined that plant residues improve crop growth and also stated that soil containing plenty of organic matter makes for better performance of crops and provides the best condition for seed to germinate. Similarly, Agele *et al*, 2013 and Agbona *et al* 2020 confirmed that organic matter helps in binding the soil aggregates and increases microbial activities. Iwueke, (1987) pointed out that the use of organic matter such as plant residues is not injurious to plants but rather improve their yields. This was also supported by Adebisi *et al*., 2020, Agbona *et al*, 2020 and Agele et al, 2013. Ayeni et al, 2020 pointed out that the major elements present in plant residues are nitrogen, phosphorus, magnesium and potassium. Similarly, Agbona *et al*., 2020 stated that nutrients supplied by plant residues are very important in the development and growth of seedlings in the nursery. The applications of plant residues inform of manure will no doubt produce healthy seedlings and reduce cost of production.

MATERIALS AND METHODS

The experiment was carried out at the nursery site of Teaching and Research Farm, Federal Polytechnic, Ile-Oluji during the dry season of 2020. The climate of the site can be described as sub-humid tropics with distinct dry and wet season. The annual rainfall ranges from 1100-1300 mm with moderately high temperature (24.4-28^{0}C). the relative humidity is moderately high all the year round. The organic materials used were collected from Farm Settlement Village, Ile-Oluji.

Experimental Design and Treatment

The experimental design used was randomized completely block design (CRD). In each plot there were 15 seedlings and the design was made up of 3 blocks with each block containing 60 seedlings. Making a total number of 180 oil palm seedlings for the experiments.

The polybags used for the experiment were filled with topsoil adequately watered and allowed to settle for 5 days to promote microbial activities. The polybags were arranged on a raised platform to prevent insect (termites) attack. Karate and Basudin were used to control termites and other insects at recommended rates. The germinated oil palm nuts were purchased from National Institute for Oil Palm Research (NIFOR) Benin and they were planted on 20th of March, 1999. Over 99% of the planted nuts emerged. There were four treatments replicated three times. The treatments were: Cowpea husks, Pigeon pea husks, N.P.K 15-15-15 and Control

0.003kg of the plant residues and 0.0005kg of NPK were applied. The plant residues were applied around the base of the plant while the ring method was adopted for NPK when the seedlings were 4-5 weeks old.

The following parameters were taken from random sample of five seedlings per treatment per plot fortnightly: plant height, stem girth, number of leaves and leaf area. Plant height was taken from the surface of the soil in the polybags to the tip of each seedlings, number of leaves per plant was counted while stem girth was determined by using a string tied round the stem and later spread on a metre rule. The leaf area was calculated by spreading the leaf on a big graph sheet and measurement taken in cm.

The soil samples connected from the area where the topsoil was collected for nursery planting were analysed for pH in water and 0.1M of $CaCl_2$. Soil organic matter was determined by using wet dichromate oxidation method. The sand, silt and clay contents were determined from the "particle size analysis" (Crockford and Nowell, 1956).

The exchangeable bases (cations K^+, Ca^{++} and Mg^{++}) were determined by extraction with 1M of NH4OAC and the extracts were determined on flame photometer. The available phosphorus was extractants by Bray P extrants and the filtrates were developed into blue colouration using Murphy reagent.

Plant residues analysis was done to determine % ash, % phosphorus % nitrogen and % magnesium. Nutrients analysis of the leaves of the seedlings was also carried out to determine % ash, % calcium and % magnesium to evaluate the uptake of nutrients by the plants.

Data Collection and Statistical Analysis

All the data collected were subjected to the analysis of variance (ANOVA). The least significance difference (L.S.D) was used to separate the means.

RESULTS

Soil Analysis

Table 1 shows the physio chemical properties of the soil used. The pH value was 6.90 in (H_2O) and 6.60 in ($CaCl_2$) indicating that the soil is slightly acidic. The percentage organic matter was 4.32, which is greater than the 3% recommended for oil palm. Nitrogen value is also 0.28% which is greater than 0.15% recommended for the production of oil palm. The value of other elements and cation exchange capacity of K, Ca and Mg are also shown in the table below.

Table 1. Soil Analysis before the Experiment

PH		%Organic Carbon	%Organic Matter	%Organic Nitrogen	Available Phosphorous (PPM)	Exchange Cations (mg/kg)		
1.1 H20 Suspension	2.1CaCl2 Suspension							
		2.51	4.32	0.28	18.69	K	Ca	Mg
6.90	6.60					17.89	125.40	80.95

Table 2 shows the soil analysis after the experiment. The result shows that the pH of the soil was reduced making a little more acidic except in the control experiment where the value increased by 0.5. the corresponding percentage of organic carbon, organic matter, nitrogen, available phosphorus and exchangeable of K, Ca, Mg of cowpea husks, pigeon husks and NPK (15-15-15) show slight increase, in their content. However, the soil analysis shows reduction in the corresponding values of the control experiment in relation to the soil test before the experiment.

Table 2: Soil Analysis after the Experiment

Treatments	pH (suspension)		% organic carbon	% organic matter	% Nitrogen	Available phosphorous In (ppm)	Exchangeable cation (mg/kg)		
	1.1 H_20	2.1 $CaCl_2$					K	Ca	Mg
Cowpea husk	6.80	6.40	2.57	4.43	0.35	28.70	10.89	127.40	85.40
Pigeon husk	6.70	6.00	2.66	4.58	0.37	26.69	32.89	126.42	82.29
N.P.K (15-15-15)	6.0	5.50	2.54	4.38	4.58	29.01	27.90	125.09	81.98
Control	6.85	6.50	2.30	3.97	0.10	15.70	15.75	120.20	80.06

Plant Analysis

Table 3 shows the result of plant analysis of pigeon pea and cowpea husk. The analysis clearly indicates that cowpea had more nutrients considering its ash, nitrogen, phosphorous, potassium, calcium and magnesium before the experiment.

Table 3: Plant Nutrient Analysis (%) of Cowpea and Pigeon Pea Husks

Sample	Ash	Nitrogen	Phosphorous	Potassium	Calcium	Magnesium
Cowpea husks	8.49	4.03	1.19	1.74	1.59	0.62
Pigeon pea husks	4.78	3.38	0.30	0.96	0.54	0.20

Leaf Analysis

Table 4 shows the result of leaf analysis after the experiment. The result indicates that NPK fertilized plants had the highest nutrient in its leaves.

Plant Height

At 2 WAE, plant height (Table 5) differed significantly as a result of the application of different plant residues and inorganic fertilizer. The effect of pigeon pea husks was significantly different from other treatments. NPK and the control were not significantly different in their effects. The pattern was similar for all other weeks.

Table 4: Leaf Analysis of Plants Fertilized with NPK and Crop Residues

Sample	Ash	Nitrogen	Phosphorous	Potassium	Calcium	Magnesium
Cowpea husks	11.75	4.24	2.20	1.18	0.10	0.02
Pigeon pea husks	11.01	4.15	1.88	0.66	0.09	0.02
NPK 15-15-15	11.97	4.77	2.06	1.14	0.11	0.03
Control	11.62	3.69	0.92	1.85	0.11	0.02

Control	18.96c	22.95c	28.56b	31.80c
LSD (0.05)	2.5	3.23	2.73	1.96

WAE= Weeks after emergence

Leaf Area

The differences in the leaf area (Table 6) were significant at 2 and 8 WAE. At 8 WAE, the leaf area recorded for seedling treated with pigeon pea husks was significantly different from that recorded for cowpea. However, the two treatments were not significantly different from the control.

Number of Leaves

The analysis of variance (Appendix) shows that the number of leaves (Table 7) at 4,6 and 8 WAE was not significantly influenced by the number of leaves as a result of the treatment applied. At 8 WAE, number of leaves for cowpea and pigeon pea were the same statistically. The number of leaves for NPK (15-15-15) and the control were also the same. The two pairs were significantly different from each other.

Stem Girth

The analysis of variance showed that there were significant differences in the stem girth (Table 8) at 2 and 8 WAE due to the treatments applied. At 8 WAE, the stem girth for cowpea and pigeon pea were the same statistically. The stem girth for NPK and the control were also the same. The two pairs were significantly different from each other.

DISCUSSION

From the results of the project, the effect of pigeon pea husks on oil palm seedlings was found to be better than other treatments in most of the parameters examined. It was closely followed by cowpea husks. Plants treated with cowpea husks compared favorably well with those treated with pigeon pea husks. This has evident in parameters such as number of leaves, stem girth and plant height. Although results from plant analysis confirmed that cowpea husks contain more nutrients than pigeon pea husks. Its better performance might be due to the rate of decomposition of the two plant residues. This confirmed the work of James (1999) who concluded that organic fertilizer takes time to decompose in their nature. According to him, the finer the particle sizes and the fresher the plant residues the faster will be the rate of decomposition.

Soil analysis before and after the experiment revealed that soil was rich in nutrients. Thus, small addition of nutrients from pigeon pea husks may have increase soil nutrient contents to meet the requirement of the seedlings.

The effect of NPK 15-15-15 was more pronounced than that of the control, experiment and this confirms previous report on the plant response to mineral fertilizer (Yaro *et al.,* 1989). They noted that fertilizer produces plant foods which readily dissolve into the soil for plant uptake.

The control plants competed very closely with the NPK fertilized plants due to initial high nutrient content of the soil. The soil analysis before the experiment confirms that the soil had 0.28% nitrogen and 4.32% organic matter while the final leaf analysis for the control plants gave 3.69% of nitrogen. The latter probably arose from the high organic matter content of the soil before experiment.

Pigeon pea husks increased the carbon content nitrogen, organic matter content, available phosphorous and exchangeable K, Ca and Mg of the soil. This was closely followed by cowpea husks. The NPK showed little increase in the soil nutrient value but it cannot be compared with the organic materials. This was in accordance with the work of Nyle, (1984) who reported that most dry matter of plant residues are mostly carbon and hydrogen and essential elements in such residues are mostly carbon and hydrogen and essential elements in such residues which helps in soil aggregation and also improve microbial activities. Similarly, Agbona *et al*. (2020) reported that plant materials decomposed easily if irrigation is maintained, thus nutrients are released subsequently to the plant rooting zones. Also, Adebisi *et al*. (2020) and Ayeni *et al*. (2020) reported same results in using plant waste and residues as organic materials in raising crops.

Generally, economic analysis would most likely indicate the superiority of pigeon pea husks to the remaining treatments. Although one would expect that NPK (15-15-15) might perform better as a result of its high percentage of Nitrogen uptake in the plant leaves (leaf analysis). Its effect is not significant due to its initial toxicity on the seedlings earlier at the beginning of the experiment. Before the seedlings picked up, other treatment had outgrown it. This clearly supports the previous work of Rajaratnam (1973) who stated that inorganic fertilizers can be toxic to oil palm seedlings in nursery.

CONCLUSION AND RECOMMENDATION

Oil Palm (*Elaeis guineensis*) responded positively to the organic materials (plant residues) used as a result of easy release of its nutrients for plant uptake and it improvement of microbial activities. Plant residues increased the organic matter content and exchangeable cations of the soils. Based on the result obtained from this experiment, I hereby recommend leguminous plant residues most especially pigeon pea husks for raising oil palm seedlings in the nursery.

ABSTRACT

To investigate the efficacy of different concentrations of Gibberellic Acid (Ga_3) and Coconut Milk on the performance of Bell pepper (Capsicum annuum l), a field trial was conducted at the nursery site of Shelterbelt Research Station Kano Latitude 12^0 1' 42.20" to 12^0 1' 43.65" N and Longitude 8^0 30', 9.06" to 8^0 30' 29.07" E), during the rainy season of 2020. The aim of the research was to determine the effect of gibberellic acid (GA_3) and coconut milk on growth and yield of Red bell pepper (Capsicum annuum). The experiment was laid on complete Randomized Block Design (CRBD). The treatments consist of Gibberallic acid (GA_3) at three concentrations (100ppm, 200ppm and 300ppm) and Coconut milk at three levels (4%, 5% and 6%). The experiment was replicated three times and the parameters measured were the growth and yield characters. The data collected were subjected to analysis of variance (ANOVA) using and means were separated using Duncan Multiple Range Test (DMRT) at 5%. From the result obtained 300ppm Gibberallic acid shows a significant effect on plant height at 4WAT, all the GA_3 concentrations had a significant effect ($p<0.05$) on Number of Fruits plant^{-1} and fruits weight plant^{-1} whereby more number of fruits plant^{-1} (12.66) and highest fruit weight plant^{-1} (68.00g) were recorded with 200 ppm gibberellic acid. However, number of leaves plant^{-1}, number of branches plant^{-1}, and number of flowers plant^{-1} were not affected by the application of GA_3 on Capsicum annuum. Coconut Milk also shows significant effect on vegetative growth and yield components of Capsicum annuum where by significantly more Number of flowers (15.02 and 14.35), fruits plant^{-1} (13.68 and 12.35) and fruit weight plant^{-1} (70.11.00g and 70.01g) were recorded with 6% and 5% Coconut milk respectively. The findings of the research revealed that application of GA_3 have more effect on yield than the vegetative growth whereby Coconut milk have significant effect on both vegetative growth and yield of Capsicum annuum.

Key words: *Capsicum annuum;* Gibberellic Acid; Coconut Milk

INTRODUCTION

Red bell pepper (*Capsicum annuum L*), also known as sweet pepper, green pepper, or pimento, belong to the family Solanaceae. The crop is native of tropical South America especially Brazil which is thought to be the original home of pepper (Islam *et al*., 2010). It is a warm season annual crop when grown in temperate regions and a herbaceous perennial when cultivated in tropical areas. It is an important vegetable crop all over the world which ranks second in the vegetable cycle after tomato (Anonymous, 1989). Red bell pepper is a delicious vegetable that can be enjoyed either raw or cooked and it is an excellent source of antioxidants, vitamin A and C as well as nerve-supportive vitamin B6, it is also a very good source of heart-healthy fiber, vitamin E, folate, potassium, vitamin K as well as the enzyme-supportive molybdenum.

Nigeria still imports pepper, thus indicating that there is high demand for pepper locally despite the good weather, soil and numerous potential of pepper in Nigeria not to talk of the export, pepper yield in Nigeria have been very low compare to Western Europe, the low yield of pepper could be attributed to some production challenges which include diseases, pests and poor management practices (Jaliya, 2006).

Currently, growth enhancing substances are commonly used in agriculture to enhance productivity (King and Evans, 2003). Plants growth enhancing substance can be regarded as any material or substance which when apply to growing plant either by foliar spray, injection or by drilling into soil in low concentration would influence the plant growth rate above or below normal process and result to more productivity of the crop (Anonymous, 2016). Gibberellic acid is one of the most important growth stimulating substances used for promoting cell elongation, cell division and thus promotes growth and development of many plant species (Anonymous, 2003). Gibberellic acids are used in Agriculture as plant regulators to stimulate both cell division and cell elongation that affect leaves as well as stems (eventually affecting fruit development and fruit set) (Bhaskar and Rao 1998).

Many research has been done over the years to determine the chemical composition of coconut milk and in particular the active growth promoting factors , Among the known components reported by Raghavan (1977), are inorganic ions such as phosphorus (P), magnesium, potassium, and sodium, amino acids including glutamic acid, asparagine, proline, and glycine, organic acids particularly malic acid, vitamins, sugars, auxins, cytokinins, and giberrellins and other miscellaneous substances that help to promote plant growth and yield (Raghavan, 1977).

As earlier reported that Nigeria do still imports peppers because of their high demand, as such there is need to find a way of increasing peppers production and yield locally. Many studies have shown that foliar application of Gibberellic acid with optimum concentration increased yield of many crops compared to traditional farming (Paroussi *et al*., 2002), also Coconut milk is an organic plant growth enhancer which contains many components that help plant growth and yield. Therefore, the aim of this research is evaluate the effect Gibberellic acid and Coconut milk on the growth and yield of Red bell pepper (*Capsicum annuum L).*

MATERIALS AND METHODS

Experimental Site

The Research was Conducted during the rainy season of 2020 at the Nursery site of Shelterbelt Research Station Kano Latitude 12^0 1' 42.20" to 12^0 1' 43.65" N and Longitude 8^0 30', 9.06" to 8^0 30' 29.07" E), which is in Sudan savannah ecological zone of Nigeria.

Planting Media

The planting media consisted of four different components (Cow dung, River sand, Top soil and Saw dust) mixed in the ratio of 1:1:1:1. 42 rubber pots of 25cm width and 15cm depth were filled to serve as growing media. The seedlings of *Capsicum annuum* were sourced from sub-station of National Horticultural Research Institute (NIHORT) research farm, Kadawa irrigation site Kura local government area, Kano.

Treatments and Experimental Design

The treatments consisted of gibberellic acid at three levels, 100ppm, 200ppm and 300ppm and coconut milk at three levels, 4%, 5% and 6% and distilled water as control. The experiment was laid out on a Complete Randomized Block Design (CRBD) which was replicated three times, each replication consisted of seven plots, with two pots per plot and each pot consisted of two plants. Data was collected from the two plants per plot.

Preparation of the Treatment Concentrates

Gibberellic acid was prepared in the laboratory as described by John (1987), the stock solution of the GA_3 was prepared by dissolving 0.125g of GA_3 powder in a 60ml of distilled water. This stock solution was then used to prepare the different concentration of the GA_3 as follows; 100ppm was prepared by diluting 25ml of stock solution with 475ml of distilled water, 200ppm was prepared by diluting 50ml of stock solution with 450ml of distilled water and 300ppm was prepared by diluting 75ml of stock solution with 425ml of distilled water (John, 1987). While the coconut milk was prepared using Junita *et al*., (1988) method whereby 1kg of the fresh coconut flesh was crushed and blends using an electric blender in about 1000ml of water to obtain the aqueous extract of the coconut milk. 4% was obtained by diluting 4ml of the aqueous extract of coconut milk in 96ml of distilled water, 5% by diluting 5ml of the aqueous extract of coconut milk in 95ml of distilled water and 6% by diluting 6ml of the aqueous extract of coconut milk in 94ml of distilled water.

Application of the Treatments and Data Collection

Foliar application of the treatment was carried out using hand sprayer at vegetative, flowering and fruiting stages of the *Capsicum annuum* transplanted on the filled rubber pots at the age of four weeks after sowing. The data collected were subjected to analysis of variance (ANOVA) using Genstat and significant different means were separated using Duncan Multiple Range Test (DMRT).

RESULT AND DISCUSSION

Plant Height (cm)

Table 1 shows the Effect of Gibberellic acid and Coconut milk on plant height of Red bell pepper in the Nursery. The result shows significant difference ($P<0.05$) between the treatments at 4 weeks after transplanting. At 4 weeks after transplanting the highest plant height was recorded with treatment CM_6 Followed by treatment CM_4 and G_{300} statistically similar, followed by the rest of the treatments with exception of treatment G_{200} that

ISSN: 2814-0508

recorded the least plant height. However, the Result shows no any significant different among the treatments at the remaining sampling period of the trial.

Number of Flowers and Total Yield Plant^{-1}

Table 4 shows the Effect of Gibberellic acid and Coconut milk on Number of Flowers and total fruits yield plant^{-1} of Red bell pepper (*Capsicum annuum* L.) in the Nursery. The result shows significant difference (P<0.05) between the treatments at 8 weeks after transplanting, more number of flowers were recorded with Treatment CM_5 and CM_6 statistically the same, followed by the rest of the treatments G_{100}, G_{200} and control statistically at par, while the least number of flowers per plant were obtained with treatment G_{300} and CM_4. However, there were no significant differences between the treatments at 6WAT. While the effects of Gibberellic acid and Coconut milk on total yield of Red bell pepper plant^{-1} result obtained shows that there was no significant difference (P<0.05) between the treatments in regards to total Number of harvested fruits plant. However, the result shows significant difference (P<0.05) between the treatments based on weight of the total fruits harvested plant, treatment G_{200} and CM_5 statistically similar, recorded the highest fruit weight, followed by rest of the treatments statistically the same, however, the least fruit weight was recorded with treatment CM_4 and the control.

DISCUSSION

Effect of Gibberellic Acid (GA_3) on Growth and Yield of *Capsicum annuum* in the Nursery

Application of GA_3 at 300ppm have a significant effect on height of *Capsicum annuum* in the Nursery at 4WAT this finding is inconformity with the finding of Gut *et al.,* (2006) that conducted a research to study the impact of GA and Nitrogen on plant height and other growth parameters of *Araucaria heterophylla*, maximum height of 42.4cm and 36.1cm were obtained using 300ppm and 2.0g N respectively. It was also reported by Qureshi *et al.,* (2013) that GA alone or in combination with other materials such as $CaCl_2$ significantly increases plant height.

However, in this research finding 100ppm and 200ppm were found to be insignificant on plant height of *Capsicum annuum* in the Nursery this may be due to the inability of GA_3 to make the cell expand after cell division as reported by Haber and hippold (1960) that cell division alone cannot result in increased growth of tissues because the division of cell into two each one half the size of parent cell will not result in enlargement, cell expansion after cell division is necessary for normal growth.

Number of leaves and Branches of *Capsicum annuum* in the Nursery were not affected by the Application of GA_3 at all the level of concentrations in this research finding, The result is similar with what was obtained by Asadi *et al.,*(2013), who studied the influence of various GA_3 concentration on fruit yield and vegetative properties of strawberry plants, they concluded that GA_3 Application had no significant effect on number of leaves and branches crowns whereas runners and number of flowers increased significantly.

Application of GA_3 have no significant difference between the treatments on number of flowers per plant of *Capsicum annuum* in the nursery, this may be due to increase of vegetative growth which consequently decrease reproductive growth as reported by Baghel *et al.,* (2004), that in many woody plants and fruits, GA inhibits flower formation, in such case Growth retardants.

Yield of *Capsicum annuum* in the nursery was significantly affected by the application of GA_3 at all the concentrations, plant treated with GA_3 gives more fruits weight than the control this may be due to beneficial effect of GA_3 in delaying the formation of abscission layer as reported by Rani and Brahmachari (2004). The result of this finding is inconformity with the finding of Gut *et al.* (2012) that GA_3 application help in improvement in number of fruits per cluster, fruit set and marketable fruit number per plant and extended maturity time and harvest.

Effect of Coconut milk on Growth and Yield of *Capsicum annuum* in the Nursery

The research findings of this trial shows significant effect of coconut milk on plant height of *Capsicum annuum* in the Nursery, 6% and 4% coconut milk significantly increase plant height at 4WAT, this may be due to the presence of cytokinin in the coconut milk, this finding is in agreement with the finding of Carey *et al.,* (2007) who used cytokinin to increase plant height in petunia. Coconut milk at 6% was found to increased the number of leaves per plant of *Capsicum annuum* in the Nursery and 5% coconut milk significantly increase number of branches, this result is in conformity with the finding of Brintha and Kumuthini (2016) that found increase in number of leaves of Ixora at 38%, 50% and 70% respectively due to the treatment with Coconut milk. This is also in agreement with the finding of Amrut and Rajput (2013), who reported that application of coconut milk, increased the number of branches in fenugreek. Yield of *Capsicum annuum* was significantly affected by the application of coconut milk at 6 and 5% concentration in the nursery, more number of fruits were obtained with plants treated with coconut milk than the control, fruit weight was also significantly affected by the application of coconut milk, this may be due to presence of important components in coconut milk like the cytokinin, gibberellins, Auxin, inorganic ions e.g. phosphorus, sulphur etc as reported by Raghavan (1977).

CONCLUSION

From the results of this research, it can be concluded that GA_3 at all the levels of concentration have a significant effect on yield of *Capsicum annuum* in the nursery, the optimum concentration of GA_3 on yield was 200ppm followed by the rest of the concentrations. While coconut milk had a significant effect on both growth and yield of *Capscicum annuum* in the nursery, the optimum concentration of coconut milk on growth and yield of *Capsicum annuum* in the nursery was 6%, then 5%. Therefore, it is recommended that 6% Coconut milk should be used to increase Growth and yield of *Capsicum annuum* in the area of study.

ABSTRACT

Field experiments were conducted at the experimental field plot of Kabba College of Agriculture in 2019 and 2020 seasons to evaluate the effect of integrated use of organic and inorganic fertilizer on growth and yield of pepper in Southern Guinea Savanna agro-ecology of Nigeria. The treatments consisted of different sources of nutrients through organic sources compared to that of untreated control and chemical fertilizer. The different sources of organic manure used were Poultry manure and Cow dung manure and commercially available inorganic fertilizer (urea). The experiment was arranged in randomized complete block design and replicated three times. Data were taken on growth and yield characters of pepper. All plots with amendment whether organic residue alone or in combination with urea was better than the control plots. Plot with poultry manure alone or at reduced rate with urea were better than plots with cow dung manure in plant height and number of leaves. Mean highest number of fruits and heaviest fruits occurred in plots with poultry manure + cow dung manure + urea combined at reduced rate of 2.5t/ha:2.5 t/ha:30 kg/ha.

Key words: Pepper; Poultry manure; Cow dung manure; Urea fertilizer; Inorganic fertilizer

INTRODUCTION

Capsicum (*Capsicum annum*) Sweet pepper belongs to family Solanaceae and is native to Mexico with secondary center of origin at Guatemala and Bulgaria (Safford, 1926; Adhikari *et al*, 2016). The fruits are non-pungent and have been widely used in immature or green stage as vegetable for salads. Considered as high cash crop, it has occupied an important rank in world agriculture due to its high profit and nutritional values for human health. Sweet pepper fruits are a rich source of vitamin C, polyphenols, chlorophylls, carotenoids, sugars (Flores, 2009) magnesium, calcium, potassium, phosphorus and iron (Jadczak *et al.,* 2010).

Pepper production cuts across Nigeria's geo-political zones and generates income to the farmers, but the production system is on a low scale in southern Guinea Savannah, due to improper fertilizer usage which lead increases soil acidity (Cheezy and Yayock, 1989). To meet the increasing demand for pepper, the use of excessive inorganic fertilizers is becoming a common practice as a means of raising the productivity. This has created negative effects on human health and environment. Application of chemical fertilizers alone can supply only one or two nutrient elements to the crop. The use of chemical fertilizers has been many-a-times reported for degrading soil and water resources. The use of organic manure alone is also faced with problems of bulkiness and dirt. Supplying only organic inputs can improve soil physical and biological environment but suffers from drawback of low content of plant nutrients (Adhikari *et al*, 2016). Stockdale *et al*. (2001) organic farming is both a philosophy and a system of agriculture which avoids or largely excludes the use of synthetically produced fertilizers, pesticides and to the maximum extent possible relies upon crop rotations, crop residues, animal manures, legumes, green manures, off farm organic wastes, mineral bearing rocks and bio-fertilizers to maintain soil productivity and to supply plant nutrients and biological means to control insects, weeds and other pests. A balanced use of organic and inorganic fertilizers could enhance soil chemical, physical, and biological properties as well as rate of nutrient turn over within the soil-plant system (Paul and Mannan, 2006). Combined use of organic and Inorganic fertilizer reduced cost and amount of fertilizer required by crops (Krupnik *et al*., 2004). It also produced highest plant growth (Alam, 2006).

The high cost of pepper in the Nigerian market justifies that the production is far lower than the demand. If proper nutrient management is adapted by the pepper producer, the production will certainly goes up to meet the demand. This study was therefore designed to evaluate the effect of integrated use of organic and inorganic fertilizer on growth and yield of pepper in Southern Guinea Savanna agro-ecology of Nigeria.

MATERIALS AND METHODS

Field experiments were conducted at the experimental field plot of Kabba College of Agriculture in 2019 and 2020 seasons. Kabba is located in the Southern Guinea Savanna Ecological Zone of Nigeria of latitude 07° 53' N and longitude 6° 8' E. The rainy season spans from April to November with the maximum rainfall in August while dry season extends from December to March. The mean annual rainfall is 1570mm, while annual temperature ranges from 18 to 32 °C and mean relative humidity is 59%.

The experiment was carried out in Complete Randomized Block Design (RCBD) with six treatments replicated thrice. The treatments consisted of different sources of nutrients through organic sources compared to that of untreated control and chemical fertilizer. The different sources of organic manure used were Poultry manure and Cow dung manure and commercially available inorganic fertilizer (urea). Weeding, crop management and harvesting was done manually. Various growth and yield attributes were examined at various times of crop cycle.

All data collected were analyze using the analysis of variance (ANOVA) using general linear model procedure of the statistical analysis system (SAS Institute, 2003) and means were compared using least significant difference Test at p = 0.05 probability level (Steel and Torres, 1987).

RESULTS AND DISCUSSION

The physicochemical properties of the soil in the study area were given in the Table 1. The results showed that the texture of the soil was sand, clay loam and was slightly acidic in nature with PH of 6.1. The organic matter content was low (1.51 g/100g). Total N was low (0.13 g/100g). The available P and potassium were equally low with values of 2.26 mg/kg-1 and 0.41Cmol/kg-1 respectively. The cation-exchange-capacity was low. Generally, the soil fertility was low based on the above fertility indices. The chemical composition of agricultural waste materials used is also shown in Table 1. The chemical characteristics of poultry manure and cow dung differed significantly (p=0.05). The materials were relatively high in the essential nutrients required for the growth and development of crop.

Table 1. pre planting soil analysis and composition of poultry manure and cow dung manure used

Properties	Soil	Poultry manure	Cow dung manure
Particle size (g/kg)			
Sand	514	-	-
Clay	289	-	-
Silt	197	-	-
pH(water)	6.1		
Organic carbon (%)	1.51	35.6	46.4
Total nitrogen (%)	0.62	4.14	2.73
C/N ratio	-	11.34	17.00
Available phosphorus	2.26	34.16	36.8
Exchangeable cation (Cmol/kg)			
Potassium	0.41	58.46	13.32
Calcium	2.26	3.76	3.87
Magnesium	2.12	3.16	2.23

The effect of different organic materials and their combinations with urea fertilizer on plant height and number of leaves produced in a pepper are presented in Table 2. Significant differences were observed in pepper height and number of leaves produced in 2019 and 2020.

All plots with amendment whether organic residue alone or in combination with urea was better than the control plots. Plot with poultry manure alone or at reduced rate with urea were better than plots with cow dung manure in plant height and number of leaves in both years.

These could be attributed to the nutrient released to the plant by the amendment applied to soil and crops. The better performance of plots with either cow dung or poultry manure either simply or in combination with urea corroborated the result of Kang and Balasubramanian (1990), Ogundare (2011) and Asaidu and Unagwu (2021). This was attributed to the nutrient released by the materials applied to the soil.

Table 2: Effect of integrated use of organic and inorganic fertilizer on growth characters of pepper

Treatments	Plant height cm			Number of leaves		
	2019	2020	MEAN	2019	2020	MEAN
PM5 t/ha	15.61	14.27	14.94	38	30	34
CDM t/ha	14.22	13.40	13.81	27	31	29
PM 2.5t/ha+Urea 30kg/ha	17.41	15.59	16.50	28	42	35
CDM 2.5 kg/ha + Urea 30kg/ha	12.63	15.01	13.82	26	30	28
PM2.5 t/ha 2.5+CM2.5t/ha +Urea 30 kg/ha	14.44	16.14	15.29	31	37	34
CTRL	12.48	6.92	9.70	22	24	23
LSD	3.46	2.89	2.11	4.14	4.83	3.96

Plots with poultry manure produced taller plants and more number of leaves compared to plots with cow dung manure either alone or in combination with urea. Analysis of the material shows that cow dung was high in C\N ratio compared to poultry manure. This indicated that mineralization is easier with poultry manure compared to cow dung manure. This could be responsible for the better performance of poultry manure plots compare to cow dung plots.

Table 3 presents the effect of poultry manure, cow dung manure and their combinations with urea on number of fruits per plant and individual fruits weight. The mean highest number of fruits and heaviest fruits occurred in plots with poultry manure, cow dung manure and urea combined at reduce rate. Followed by plots with poultry manure combined with urea at reduce rate. While plots with poultry manure alone was better in number of fruits and fruit weight than plots with cow dung alone or in combination with urea. The least number of fruits and lightest fruits occurred in the control plots. The better performance of plots with poultry manure+ cow dung manure + urea could be as a result of prompt released of nutrient to the plant. Urea released it nutrient, then poultry manure white at later stage cow dung mineralized and releases it nutrients. Plots with poultry manure alone or in combination with urea gave more number of fruits and heavier fruits compare to plots with cow dung manure. This is expected because poultry manure releases it nutrient quicker than cow dung manure due to the differences in their C\N ratio.

The least number of fruits and fruits weight occurred in control plots. Control plots only dependent on the soil inherent nutrient and from the analysis of the soil use for the experiment, the soil was low in soil fertility and consequently low fruit yield of the control plots.

CONCLUSION

For optimum production of pepper in the study area, Pepper farmer should make use of poultry manure, cow dung and urea combined at ratio of 2.5t/ha:2.5 t/ha:30 kg/ha. This will improve the production of pepper in the area

ABSTRACT

Field experiment to study effect of crop residues combined with NPK fertilizer (NPKF) on soil chemical and physical properties, growth and yield of white seed melon was carried out at Kabba, Kogi State Nigeria. Soil amendments tested involved application of cocoa bean husk (CBH), cocoa pod husk (CPH), cocoa pod waste (CPW), weed much (WM) in combination with NPK 15:15:15 Fertilizer to produce eleven treatments 4 t/ha CBH + 200 kg/ha NPKF, 4 t/ha. CBH + 100 kg/ha NPKF, 4 t/ha CPH + 200 kg/ha NPKF, 4 t/ha CPH + 100 kg/ha NPKF, 4 t/ha CPW + 200 kg/ha NPKF, 4 t/ha CPW + 100 kg/ha NPKF, 4 t/ha KPH + 200 kg/ha NPKF, 4 t/ha KPH + 100 kg/ha NPKF, 2 t/ha WM + 200 kg/ha NPKF, 2 t/ha WM + 100 kg/ha NPKF and control (no treatment), all the amendments tested significantly improved soil physical and chemical properties and growth performance of white seed melon relative to control. Three cocoa plants residues in combination with NPKF at reduced rates 4 t/ha CBH + 200 kg/ha NPKF, 4 t/ha CPW + 200 kg/ha NPKF and 4 t/ha CPH + 200 kg/ha NPKF respectively significantly ($p < 0.05$) improved soil pH, organic matter (OM), available P, exchangeable k, Ca and Mg, Na, Fe, Al and ECEC among the amendments tested. 4 t/ha CBH + 200 kg/ha NPKF, 4 t/ha CPW + 200 kg/ha NPKF and 4 t/ha CPH + 200 kg/ha NPKF reduced soil bulk density and increased total porosity. All treatments increased number of leaf and branches, vine length, leaf length and width of white seed melon compared to the control. 4 t/ha CBH + 200 kg/ha NPKF, 4 t/ha CPW + 200 kg/ha NPKF, 4 t/ha CPH + 200 kg/ha NPKF, had highest value of branches.

Keywords: White seed melon, plant residues, soil physical properties, soil chemical properties, yield.

INTRODUCTION

Food production in Sub-Sahara Africa is constrained by inadequate soil fertility, Nigeria inclusive. Soil fertility is the status of the soil with respect to its ability to supply essential elements for plant growth without a toxic concentration (Boyd, 1996). When soil is not fertile, methods of replenishing lost nutrients such as bush fallowing, application of organic and inorganic fertilizer, crop rotation could be adopted to return the lost nutrients. Increase in population pressure has led to inadequacy of traditional bush fallowing in meeting requirement of fertile land due to drastic reduction in length of fallow period, which may be up to ten (10) years or at least three (3) years. Recent experience in Nigeria agriculture shows that the use of inorganic fertilizers to achieve high crop yield is unsustainable due to its scarcity and high cost (Ojeniyi, 2000). Inorganic fertilizers ensure quick availability of nutrients to crops but they have limited residual effect of the applied nutrients (Okigbo, 2000). In addition, inorganic fertilizer has not been helpful in intensive agriculture because it is often associated with reduction in crop yield, soil acidity, nutrient imbalance and degradation of soil physical attributes. Other limitations include nutrients leaching, erosion and volatilization (Ojeniyi, 2000). Chemical fertilizers are said to have the following characteristics (Jim Ellison, 2011); Water solubility of chemical fertilizers result in fast release. Many chemical fertilizers own high acid content like sulphuric and hydrochloric acids which going through soil acidity successfully results in the death of Nitrogen fixing bacterium, the organism that plays a central role in refurbishing plants nitrogen demands. Organic fertilizers are known to be slow released nutrient sources. This implies that crops can suffer initial starvation from nutrient immobilization prior to mineralization. They are also required in large quantities which may not be readily available to farmers (Agbede, and Kalu, 1995; Okigbo, 2000; Adekiya et al, 2012). Organic fertilizer can be used to improved soil characteristics and obtain high crop yields in addition with inorganic fertilizer (Cezar, 2004). Akanbi et al., (2013) and Ojeniyi (2016) recognized the need to intensify studies into locally sourced, cheap, adoptable organic sources of plant nutrients. Babadele and Ojeniyi (2013) found that plant variety such as those of siam weed and sawdust used alone or combined further with NPK fertilizer at reduced rate supplied nutrients and improved yield. Manures were found to suppress diseases by generating ammonia and other nitrous acid in the soil (Larzarovite, 2000). Organic amendments discharge their nourishing contents only when they break down through the intricate ecology of living creatures in the soil at that time they steadily discharge contents. All the components in the organic amendments are completely essential soil nutrients. The fact that the material is organic signifies that it is derived from a once living plant, animal or a mix of both, which assures us that all components there are crucial to life. Organic amendment is relatively cheaper and it has all the carbon and vitality to conform to the demands of soil microbs. The above characteristic of organic and inorganic fertilizers which complements each other makes its combination a necessary component for crop production. While the importance of the mixture has been demonstrated (Onunka, et. al, 2002). Mann's cucumeropsis (*Cucumeropsis mannii)* a member of the Cucurbitaceae family, a species of melon native to tropical Africa. It is an important quality and a very high nutrient – demanding crop. It requires adequate nutrition for maximum performance. The fruit is egg-shaped with about 19cm long and 8cm wide. This crop is primarily harvested for its large white seeds called egusi-itoo. The seeds are commonly processed into soups and oil products, and are also eaten individually as a snack (National Research Council, 2006). Benefits of *Cucumeropsis mannii* are many but soil fertility is one of the most important factors limiting its production. (National Research Council, 2006) reported that a complete fertilizer should be applied before the propagation of *Cucumeropsis mannii* with periodical application of nitrogenous fertilizer Growing of *Cucumeropsis mannii* in savannahs with low fertility and organic matter was reported to be more challenging (National Research Council, 2006). The objective of this experiment was to determine the effect of combined amendments on soil properties and growth performance of white seed melon

MATERIALS AND METHODS

The study was conducted during 2019 cropping season at the Teaching and Research Farm of ABU College of Agriculture, Kabba, Kogi State. Kabba is located in the Southern Guinea savanna Agro - Ecological Zone of Nigeria on latitude 7^0 50' N and longitude of 6^0 03'E and altitude of 427 m with average rainfall of 130 mm and mean annual temperature between 28.8 ^{0}C to 35 ^{0}C. The annual relative humidity is 81.2 percent.

Experimental design and treatments

The experiment was arranged in a randomized complete block with each treatment replicated four times. The area used was 24 m x 51 m (1224 m^2) in total. Each plot measured 4 m x 3 m with discard of 1 m within the plots and 2 m between the block. The trial involved six treatments of cocoa bean husk (CBH); cocoa pod husk (CPH); cocoa pod waste (CPW); Kola pod husk (KPH) at 6 t/ha each, 4 t/ha (*Tithonia diversifolia*) weed mulch (WM), 300 kg/ha. NPK 15:15:15 fertilizer (NPKF) and control (no amendment). Two seeds of white seeds melon were planted per hole and later thinned to one at a spacing of 1 m x 1 m with a total of twenty (20) plants per plot

Prior to commencement of experiment, soil samples randomly collected from 0 – 20 cm depth were thoroughly mixed to form a composite which was later analyzed for physical and chemical properties. At the harvest, another set of composite samples were collected per plot basis and similarly analyzed for routine chemical analysis as described by Carter (1993). The soil samples were air-dried and sieved using a 2 mm sieve before making the determinations. Soil organic matter was determined by the procedure of Walkley and Black using the dichromate wet oxidation method (Nelson and Sommers, 1996), total N was determined by micro-Kjeldahl digestion method (Bremner, 1996), available P was determined by Bray-1 extraction followed by molybdenum blue colorimetry (Frank et al., 1998). Exchangeable K, Ca and Mg were extracted using 1.0 N ammonium acetate. Thereafter, K was determined using a flame photometer and Ca and Mg were determined by EDTA titration method (Hendershot and Lalande, 1993). Soil pH was determined in soil water (1:2) medium using the digital electronic pH meter. Particle size analysis was done using Bouyoucos hydrometer method (Sheldrick and Hand Wang, 1993). Soil bulk density was determined using the core method (Campbell and Henshall, 1991).

Data collection and statistical analysis

Five plants of white seed melon were randomly selected from each plot across the three blocks for growth determination. The parameters assessed included number of leaves, number of branches, vine length, leaf length and width.

The data collected were subjected to analysis of variance (ANOVA) using the SPSS package (version 16) and treatment means were compared using the Duncan's multiple range test (DMRT).

RESULTS

Pre-Planting Soil properties

Table 1 shows soil properties of the experimental site prior to planting. The values of soil Bulk density were (1.45 and 1.38 g/cm^3), Porosity (43.2 and 42.4 %), Soil temperature 36.1 and Soil moisture 6.31 % The result revealed that the soil of the experimental site was sandy loam, acidic, low in N, available P, exchangeable K and OM in accordance with the rating of Akinrinde and Obigbesan (2000). Therefore, the results revealed that effective production of crop would therefore require additional soil conditioner.

Table 2 presents data on effects of combined application of amendments on growth performance of white seed melon. All the amendments tested significantly improved growth performance of white seed melon relative to the control. Highest number of leaf was obtained for plant treated with 4 t/ha CBH + 200 kg/ha NPKF although showed no significant difference with the value recorded for 4 t/ha CBH + 200 kg/ha NPKF but significantly ($p < 0.05$) higher than the values recorded for other amendments. Number of branches experienced significant improvement by combined amendments compared with the control. Highest and least number of branches (11.30 and 10.13) were recorded for 4 t/ha CBH + 200 kg/ha NPKF and 2 t/ha WM + 100 kg/ha NPKF respectively. The plant residues combined with NPKF also increased vine length significantly relative to control. Highest value of vine length was recorded for 4 t/ha CPW + 200 kg/ha NPKF and was not significantly different from other amendments. Highest and least values of leaf length and width (16.97, 13.70) and (22.57, 18.57) were recorded for 4 t/ha CPW + 200 kg/ha NPKF and Control respectively.

Table 2: Effects of combined amendments on growth components of white seed melon (*Cucumeropsis mannii*) at Kabba

Treatments	No of leaf	No of branches	Vine length (cm)	Leaf Length (cm)	Leaf width (cm)

NPKF = NPK 15:15:15 fertilizer, CBH = cocoa bean husk, CPH = cocoa pod husk, CPW = cocoa pod waste, KPH = kola pod husk and WM = weed mulch: means with the same letters are not significantly different ($P < 0.05$) from other.

The results of the effects of combined amendments on soil physical properties are presented in table 3. All the amendments tested significantly ($p < 0.05$) improved soil moisture content, porosity, bulk density and temperature relative to control. Among the amendments tested, highest values of soil moisture content and porosity (9.32 and 46.40) were obtained for soil treated with 4 t/ha CBH + 200 kg/ha NPKF and were significantly different from other amendments including control except value of porosity (46.10) recorded for 4 t/ha CPH + 200 kg/ha NPKF. Values of soil bulk density and temperature were significantly improved by the amendments relative to control. Least and highest bulk density and temperature (1.12, 1.30) and (25.7, 33.6) were recorded for 4 t/ha CBH + 200 kg/ha NPKF and Control respectively.

Table 3: Effects of combined amendments on soil physical properties at Kabba

Treatments	MC **(%)**	Porosity **(%)**	BD g/cm^3	Temperature **(^oC)**
Control	6.07i	32.40h	1.30a	33.6a

Soil pH, OM, N and P as affected by amendments are presented in table 4. All the amendments tested significantly ($p < 0.05$) increased soil pH, OM, N and P concentration relative to control after harvest. Concentration of soil pH, OM, N and P were significantly increased by 4 t/ha CBH + 200 kg/ha NPKF relative to other amendments while the least values of soil pH, OM, N and P (6.09, 3.45, 0.68 and 18.29) were respectively recorded for 2 t/ha WM + 100 kg/ha NPKF.

DISCUSSION

Optimum yield could not be obtained from sole application of organic manures due to slow release of nutrients.

Use of organic and inorganic fertilizers has been advocated for sustainable soil productivity under intensive continuous cultivation in southwest Nigeria (Adepetu, 1997), sustainable nutrient management on small holder farms can be achieved by a combination of mineral fertilizers and organic soil amendments (Vanauwe, 2004). From this study, contribution of amendments to soil fertility has clearly shown through increased availability of plant nutrients for its growth and development (Brandy and Weil, 2007; Adeoluwa et al., 2010). Combination of organic and inorganic sources of nutrients led to optimal pH of about 6.0 – 7.0 which is recommended for nutrient availability and suitable for most tropical field and arable crops. It could be seen that combination of 4 t/ha CBH + 200 kg/ha NPKF, 4 t/ha CBH + 100 kg/ha NPKF and 4 t/ha CBH + 200 kg/ha NPKF gave highest value of soil N, P and K which are the nutrients most often limiting to tropical crops and deficient tropical soils (especially N and P). The improved soil chemical and physical properties should have enhanced nutrients and moisture uptake by melon. The better attributes of combination of nutrient

ISSN: 2814-0508

sources is further confirmed by the relatively high soil organic matter contents at the experimental site and in the cases of 4 t/ha CBH plus any of 200 or 100 kg/ha NPKF. The integrated soil fertility Management (ISFM) approach supports that there are positive interrelations and complementarities of organic and mineral nutrient sources to support sustained soil fertility and crop productivity. The trend in the values of soil physical and chemical properties indicated that higher values of soil organic matter were more favourable to soil quality hence melon performance. The result of the experiment also showed that soil amendments improved soil fertility and increased growth components of white seed melon relative to control. This is consistent with the findings of Liu and Stutzel (2004) and Adeoluwa *et al.* (2010). The result is also in agreement with that of Prasad and Singh (2000) who reported that soils treated with soil amendments increased number of leaves and other growth components compared with untreated soil.

CONCLUSION

Combination of selected plant residues with synthetic fertilizer (NPK 15:15:15) showed improving effects on soil physical and chemical properties and growth components of white seed melon compared with control. Combination of 4 t/ha CBH + 200 kg/ha NPKF, 4 t/ha CPW + 200 kg/ha NPKF and 4 t/ha CPH + 200 kg/ha NPKF gave highest value of soil N, P, K, Ca, Mg, ECEC and BS respectively compared to others. The overall results revealed that combination of plant residues with NPKF particularly 4 t/ha CBH + 200 kg/ha NPKF can be used for improving soil with profitable production of white seed melon in the study area.

ABSTRACT

Experiment were conducted at the Vegetable field of National Horticultural Research Institute, Ibadan to investigate the dry matter partition and nutrient content of cucumber when grown with NPK (15:15:15) and compost on an alfisol. The study was a 2 x 3 x 4 factorial experiment, with two varieties of cucumber (Marketmore and Poinsett), three Nitrogen levels (0, 30, 60 kg ha-^{1}) and four levels of compost (0,5,10 and 20 tons ha-^{1}) fitted into split- split plots with variety as main plot, NPK (15:15:15) and compost as sub and sub-sub plots respectively and the treatments were replicated thrice. Results indicated that Poinsett variety had higher content of P and K, and also it is 37%, 0.24% and 0.44% higher in Mg, Fe and Zn content respectively than Marketmore variety when planted on an alfisol. Cucumber planted with 10 tons ha^{-1} of compost had higher content of P, K, Mg and Fe. Poinsett variety accumulated more dry matter into roots and shoot than Marketmore variety.

Key words: Alfisol, nutrient, Poinsett, Marketmore and dry matter.

INTRODUCTION

Cucumber (*Cucumis sativus* L.) is one of the oldest vegetables cultivated by man with historical records dating back 5000 years (Wehner, 2007). It is one of the most popular members of the *Cucurbitaceae* family. It is cultivated for fresh fruit which is locally consumed or exported for generation of national income. Cucumber is an important component in vegetable salad for human nutrition, and serves as remedy in the treatment of constipation, jaundice and indigestion. The fruit varies in shape, size and color. A matured cucumber fruit when analyzed for fruit nutrient composition is 3.8 g dry matter, 0.6 g protein, 2.0 mg calcium, 0.4 mg riboflavin, 0.2 mg niacin and 11 mg vitamin. Cucumber production requires soil that is rich in organic matter content such that can provide the essential nutrients required for its growth and development, because nutrient deficient soil results to bitter and misshapen produce that will not be accepted by consumers thereby causing economic loss to farmers (Eifedeyi, 2010).The scarce and costly mineral fertilizer with its other limitations cannot be the only solution to improve soil productivity in tropical Africa, there is a need to explore the potential of combining organic fertilizers with synthetic fertilizers to provide solution to cucumber production challenges. There is paucity of information on the use of composted organic materials combined with NPK (15:15:15) fertilizers for the production of cucumber crop. This study was conducted to investigate the dry matter yield and mineral content of cucumber fruit when grown with NPK (15:15:15) and compost fertilizers.

MATERIALS AND METHODS

Experiments were carried out in Vegetable field of National Horticultural Research Institute, Ibadan, Nigeria (7^{0} 25'' and 3^{0} 52E) to determine the effects of variety, NPK (15:15:15) and Compost on dry matter partitioning and fruit nutrient content of cucumber planted on an alfisol in Ibadan, Southwest, Nigeria. The experiment was a 2 x 3 x 4 factorial experiment, with two varieties of cucumber (Marketmore and Poinsett), three Nitrogen levels (0, 30, 60 kg ha-^{1}) and four levels of compost (0,5,10 and 20 tons ha-^{1}) fitted into split- split plots with variety as main plot, NPK (15:15:15) and compost as sub and sub-sub plots respectively and the treatments were replicated thrice. Compost was prepared by combining dried and sorted cassava peel with dried and sorted poultry manure obtained from battery cage system, and mixed together on 3:1 ratio dry basis. Cucumber seeds (4) were sown at a spacing of 50 cm x 50 cm and later thinned to one seedling per stand at two weeks after planting. Compost fertilizer was incorporated into the soil two weeks before planting to allow for mineralization into the soil while NPK (15:15:15) was split applied at 2, 4 WAP and anthesis. Weed control was achieved by hand weeding at specific period as required to maintain a weed free plot throughout the period of the crop growth. Four plants were randomly selected and tagged per plot for plant growth characteristics and from which fruit harvested were analyzed for fruit nutrient content. Four plants were also destructively sampled per plot at flowering for dry matter determination. They were carefully uprooted and separated into roots, vines and leaves after which they were bagged separately in brown envelopes and oven dried to a constant weight at 75^{0}C for 48hours. From these, the mean dry weights of each plant part were taken. Data collected were subjected to analysis of variance (ANOVA) using Genstat 2013 Version. The means of the main effects and their interactions were compared with Least Significant Different (LSD) at P = 0.05.

RESULTS AND DISCUSSION

Table 1 represents the chemical composition of initial materials and the matured compost after composting process, it indicated that the matured compost contained the major and trace elements that can support cucumber production on an alfisol.

Table 1. Chemical properties of compost materials and matured compost

Properties	Poultry manure	Cassava peel	Matured compost
pH [H2O] *	8.4	6.0	8.2
Org. C (%)	18.30	20.57	64.86
Total N (%)	0.46	0.46	0.50
P (%)	3.90	0.05	1.59
K (%)	0.88	0.97	0.76
Na (%)	0.25	0.03	0.17
Fe (%)	0.70	0.07	1.20
Zn (mg kg^{-1})	385	14	154
Cu (mg kg^{-1})	59	10	31
Mn (mg kg^{-1})	526	80	372

Effects of variety, NPK (15:15:15) and Compost on dry matter partitioning of cucumber on an alfisol.

The main effects of variety, NPK (15:15:15) and compost rates on dry matter partitioning of cucumber in alfisol for the two cropping seasons are shown in Tables 2. The varietal effect was significant (P = 0.05) only on dry matter accumulated to shoot in both years at the time of harvest. Poinsett variety generally had higher dry matter partitioned to root and shoot. Even though dry matter to root was not significantly influenced by variety, its partitioning to stem was significant, as Poinsett variety significantly accumulated 2.15 g in first planting and 2.39 g per plant in second trial dry matter than Marketmore variety. Dry matter partitioning in both years of study in alfisol was not significantly influenced by NPK (15:15:15) and compost application. The various two way and three-way interactions of variety, NPK (15:15:15) and compost had no significant effect on dry matter partitioning to root and shoot in both years of study

Effects of variety, NPK (15:15:15) and compost on nutrient content of cucumber on an alfisol

Table 3 illustrates the main effects of variety, NPK (15:15:15) and compost on mineral contents of cucumber fruits. Nitrogen (N) content of cucumber were not significantly influenced by varietal differences, NPK (15:15:15) levels or compost applied, but the three factors significantly influenced the Phosphorus (P) and Potassium (K) content. Poinsett fruits significantly had higher content of P and K minerals. This further proved the superiority of Poinsett performance in absorption and utilization of mineral elements in same environment. The same trend was also observed for Calcium (Ca), Magnesium (Mg) and content Iron (Fe) content of Poinsett. Poinsett variety was more superior in Fe and Zinc (Zn) content of fruit than Marketmore variety. It was 0.24% and 0.44% higher in Fe and Mg content than Marketmore when grown on an alfisol.

NPK (15:15:15) application had significant effects on P and K content of cucumber fruits, the higher the NPK applied, the higher the P and K contents of the fruits up to 60 kg N ha^{-1}NPK application (Table 3). NPK (15:15:15) and compost rates, had no significant effect on Fe content of cucumber fruits on an alfisol, but both had significant effects on Fe content. Cucumber treated with 60 kg N ha^{-1}NPK

(15:15:15) significantly had higher Fe content in the study, while cucumber grown with 10tons ha^{-1} also significantly had higher Fe content in their fruit than other treatments (Table 3).

NPK (15:15:15) and compost had no significant effect on Zn content of fruit of cucumber grown in the alfisol (Table 3). All the interaction produced significant effect on Fe content of cucumber fruit. For both varieties the higher the quantity of NPK applied up to 60 kg N ha^{-1}NPK (15:15:15) the higher is the quantity of Fe mineral in their fruits. Application of NPK (15:15:15) also influenced Mg content of cucumber fruit, the higher the NPK fertilizer applied, the higher the Mg content fruit up to 60 kg N ha^{-1}NPK, the higher the NPK fertilizer, the higher also is the Ca content of fruit, but this was not significant (Table 3).

Table 2: Effects of variety, NPK (15:15:15) and compost on dry matter partitioning of cucumber on an alfisol

Prob. of F:	ns	x	x	ns	x	x	ns
LSD (P = 0.05)	0.02	0.0007	0.0008	0.08	0.001	0.0007	0.80

x = Significant at 0.05 probability level; ns = not significantly different at p = 0.05

Compost application significantly influenced P and K content of fruits. 10 tons ha^{-1} compost application significantly had higher P and K contents in their fruits (Table 3). Calcium content of cucumber was not influenced by variety, NPK (15:15:15) and compost, but the three factors had effects on Mg content. Poinsett fruits under same environment contained 37% more Mg than Marketmore variety (Table 3). Compost application had significant effects on Mg in cucumber, the higher the quantity applied, the higher is the content of Mg in the fruit up to 10 tons ha^{-1} application, beyond this rate, the fruits Mg quantity declines (Table 3). Storey (1995) and Epstein (1997) confirmed that compost is of more importance than inorganic fertilizer because it consists of relatively stable decomposed materials resulting from accelerated biological degradation of organic matter under controlled aerobic conditions. The report of other studies (Rizk 2012; *AL*-Kahtani *et al* 2012), supported the role of compost in increasing the nutrient of fruits and that compost fertilizers contain more nutrients than mineral fertilizers.

The effects of Variety, NPK and compost interaction is represented in Table 4, it indicated that the interaction had no significant effects N, Ca, Mg and Zn content of the fruit, but the interaction was significant on K, P and Fe content of cucumber on the alfisol. Poinsett grown with 60 kg N ha^{-1} combined with 10 tons ha^{-1} of compost had higher P content, followed in ranking by same variety planted with 60 kg N kg ha^{-1} and same variety grown with 60 kg N ha^{-1} with 5 tons ha^{-1} of compost. Also, for K and Fe, Poinsett grown with 60 kg N ha^{-1} combined with 10 tons of compost had higher fruit content of K and Fe (Table 4).

Table 4: Effects of variety, NPK and compost interaction on fruit content of cucumber an alfisol

x = Significant at 0.05 probability level, ns: non-significant at P < 0.05

CONCLUSION AND RECOMMENDATION

The chemical analysis of compost and the material used (cassava peel and poultry manure) indicated high nutrient content, absence of heavy and toxic metals like cadmium, (Cd), chromium (Cr), lead (Pb) and Selenium (SE). This shows their suitability as potential organic fertilizer for cucumber production. Poinsett variety of cucumber gave higher dry matter yield and nutrient content of minerals in their fruit than Marketmore variety.

ISSN: 2814-0508

Highest mean values of dry weight and mineral content of fruit for the two cucumbers were obtained at 60 kg N ha^{-1}NPK when grown on an alfisol.

ABSTRACT

Thin basal stem and robust aerial stem diameters (BSD and ASD) along the stem of tomato plants majorly accounts for prostrate growth observed under field conditions. A pot experiment was conducted to study the effects of combined N:P:K and silicon fertilizer rates (0ml+0kgN, 0ml+50kgN, 0ml+100kgN, 500ml+50kgN, 500ml+100kgN, 1000ml+50kgN, 1000ml+100kgN) on growth and yield of improved tomato cultivars; Tropimech, UC-82, Roma-VF and a local cultivar- Kerewa. The aim was to identify the best combinations that could minimize the variation in BSD and ASD in favour of BSD for improved growth and yield of tomato under controlled condition. Data on growth parameters such as BSD and ASD, leaf thickness, total number of fruits, and total weight of fruits were collected at maturity. Combined N:P:K and silicon fertilizer generally reduced the stem diameter variation. Application of 50 kg ha^{-1} of N:P:K fertilizer in combination with 500 or 1000 ml ha^{-1} of orthosilicic acid (OSA) improved the yield components of tomato while application of 100 kg ha^{-1} of N:P:K with 500 or 1000 ml ha^{-1} of OSA improved the vegetative parameters of tomato cultivars. Kerewa had the highest yield (54.84 g) with the widest BSD (6.22 mm) and ASD (5.66 mm) while UC-82 maintained average vegetative growth and fruit yield. Across treatment combinations, the BSD was wider than the ASD revealing the possibility of growth conditions having different effect on BSD and ASD of tomato.

Key words: aerial stem; basal stem; combined fertilizers; N:P:K fertilizer; orthosilicic acid fertilizer; tomato

INTRODUCTION

Tomato cultivars are known for their high vegetative growth and fruit yield which make them susceptible to prostrate growth at maturity. Prostrate growth develops when plant stem cannot withstand the heavy weight of fruits. Variations in basal and aerial stem diameters caused by thin basal stem and robust aerial stem diameter along stem height combined with increase fruit yield have been observed to be the major causes of prostrate growth in tomato under field condition(Olagunju et al., 2019). This necessitated staking which can increase cost of production(Kemble et al., 1994). However, it remains unclear if the observed variation in field is the same under controlled condition and whether the combination of silicon with NPK fertilizer can effectively minimize this variation. In addition, cultivars that can combine reduced variation in basal and aerial stem diameters along the stem of tomato with higher yield can minimize the cost associated with staking in tomato production under combined silicon and NPK fertilizer rates. Nitrogen and silicon are nutrient elements that can increase the vegetative growth and fruit yield of plants. Though higher application rates of nitrogen fertilizer can increase yield, it can also increase the susceptibility of tomato cultivars to prostrate growth. Silicon, on the other hand, is an essential element because it is known to be beneficial to plant but its absence would not prevent plant from completing its life cycle. Furthermore, while nitrogen is an essential element that improves both the vegetative growth and yield of crops, silicon increases the mechanical strength of the stem through increase in structural stability of the stem in addition to alleviating both biotic and abiotic stresses in plant(He et al., 2015). Orthosilicic acid fertilizer is a silicon fertilizer formulated in the form that can easily be absorbed by plant. However, its role in improving the growth and yield of tomato has not been investigated. Tomato is one of the low silicon accumulating plants and has been observed to display passive absorption of silicon (Shi et al., 2014). Despite its limited response to silicon, tomato has been reported to benefit from both silicon and nitrogen fertilizers. Therefore, this study was conducted to establish the effectiveness of combined silicon and nitrogen fertilizer rates in improving growth and yield of tomato cultivars under controlled condition.

MATERIALS AND METHODS

The experiment was conducted in the screen house of College of Agricultural Sciences Olabisi Onabanjo University, Ayetoro Campus. Four tomato cultivars comprising three improved cultivars namely, Tropimech, UC-82, Roma-VF and a local cultivar- Kerewa, were planted in soils contained in 7-liter sized pot. Combination of nitrogen and orthosilicic acid fertilizer rates comprising; 0ml+0kgN, 0ml+50kgN, 0ml+100kgN, 500ml+50kgN, 500ml+100kgN, 100ml+50kgN, 1000ml+100kgN were applied on the tomato cultivars before flowering. The soils, scooped to a depth of 0-15 cm from Teaching and Research Farm of the College. The seeds of the tomato cultivars were nursed in separate pot for three weeks after which they were transplanted into the pots based on treatment arrangement fitted into Completely Randomized Design and replicated three times. Application of orthosilicic acid fertilizer commenced at one week after transplanting and was sprayed at two weeks' interval over six weeks according to recommended spray schedule of the manufacturer (Privi Life Science, India). Meanwhile N:P:K 20:10:10 fertilizer rates at 50 kg N ha^{-1} and 100 kg N ha^{-1} equivalent of0.78 g and 1.56 g per 7 kg soils, respectively were applied at two weeks after transplanting At maturity, when all fruits had reached physiological maturity and when fruits were firmed, growth parameters such as plant height, aerial and basal stem diameter, leaf thickness, leaf area were taken from the plants. Stem diameter variation (SDV) was computed using the method of (Olagunju et al., 2019) with little modification as

$$Stem\ diameter\ variation = \frac{\left[\left\{\frac{BSD - ASD}{BSD}\right\} \times 100\right]}{Plant\ height}$$

Yield parameters such as average number of fruits, average weight of fruits and total weight of fruits were also taken.

Data analyses

Data collected on growth and yield parameters were subjected to Analyses of Variance (ANOVA). Significant treatment means were separated using Fischer's Protected Least Significance Difference. Polygon view of Genotype x traits and fertilizer combinations x traits biplots were also plotted against the growth and yield parameters. The statistical package used was Genstat 12th Edition.

RESULTS AND DISCUSSION

The effects of combined N:P:K and silicon fertilizer rates was significant on the vegetative growth and fruit yield of the tomato cultivars (Table 1).Application of 50 kg ha^{-1} of N:P:K fertilizer in combination with 500 or 1000 ml ha^{-1} of OSA effectively improved the fruit yield and its component parameters (Sector BOC in Fig 1a) while application of 100 kg ha^{-1} of N:P:K in combination with 500 or 1000 ml ha^{-1} of OSA contributed to improved vegetative growth including basal and aerial stem diameters of the tomato cultivars (Sector AOD, Fig 1a). Application of 50 kg ha^{-1} had earlier been recommended for improving both the growth and yield of improved tomato cultivars towards reducing prostrate growth while maintaining appreciable yield increase(Olagunju et al., 2019). The result further suggested that doubling N:P:K fertilizer to 100 kg ha^{-1} may not be beneficial to tomato yield. The reduced growth and fruit yield of the tomato cultivars under no application of the fertilizers revealed the importance of the two fertilizers in improving the growth and yield of the tomato cultivars. However, the increased effectiveness of N:P:K fertilizer on growth and fruit yield of the tomato cultivars when applied in combination with orthosilicic acid fertilizer revealed the beneficial roles of silicon in increasing nutrient absorption in plants. Among the cultivars, Kerewawas exceptional in having the highest number of fruits which resulted in increased total weight of fruits (Table 1). The cultivar was also observed to have better growth in terms of wider basal and aerial stem diameter and reduced stem diameter variation. The adaptability of the cultivar to the local condition of growth could have contributed to the better performance observed. The cultivar, UC-82 was however exceptional in having the most average growth and yield among the cultivars (Fig 1b) but performed better than Roma-VF, a cultivar that has been reported to be less productive to UC-82 under field condition(Isah et al., 2014). The robust basal and stem diameters of Kerewa combined with its reduced stem diameter variation and the average performance of UC-82 for these traits suggest the two cultivars are suitable for erect growth and high yield. Combined N:P:K and orthosilicic acid fertilizer can effectively improve the growth and yield of improved tomato cultivars especially when applied at the rate of 50 kg ha^{-1} N + 1000 ml ha^{-1} OSA while no application of the two fertilizers can significantly reduce the growth and yield of tomato cultivars. The wider BSD than the ASD observed in this study which is at variance to the observed variation under field condition, where the reverse was observed, is an indication that the growth condition may influence the pattern of variation in BSD and ASD and can affect growth habit of tomato.

ABSTRACT

Field experiments were conducted to study the influence of different levels of organic fertilizer on the performance and mineral composition of tomato. The experiment was carried out at the Landmark University Teaching and Research farm located at kilometer 4, Ipetu Road, Omu-aran, Kwara State (7°45 N and 9°30 N and longitudes 230 E and 6°25 E). Treatment consisted four levels of composted cocoa pod (0, 3.25, 6.50, and 9.75 g bag^{-1}) and NPK fertilizer. Treatments were replicated three times in a completely randomized design. The following parameters were taken – plant height, number of leaves, yield and mineral (Ca, Mg, K, and Zn) composition of the fruit. Data collected were subjected to statistical analyses of variance (ANOVA) using statistical Analysis Software (SAS, 2002). The significant treatment means were compared using Duncan Multiple Range Test (DMRT) at 0.05 level of probability. The results of the study showed that, vegetative growth, yield and mineral composition of tomato were highest under the application of 6.5 g of CP+PM, and 9.75 g of CP+PM. Values obtained under the control treatments were significantly lower than other treatments. Therefore, economically, application of 6.5 g of CP+PM can be considered as a sustainable strategy for the production and superior quality of tomato.

Key words: Tomato, performance, nutrient composition, organic and inorganic fertilizer

INTRODUCTION

Tomato (*Solanum lycopersycum* L), is one of the most important vegetables nationwide. It is relatively a short duration crop which gives a high yield, and it is also economically attractive. Tomatoes are warm season crop and are sensitive to high humidity / rain. Thus, high yield of tomato is as a result of well-drained, sandy loam, and rich in humus soils. Tomatoes are rich in phosphorus, essential amino acids, vitamin B and C, iron, minerals, sugars, and dietary fibres and are considered as one of cheapest sources of important vitamins A and C, as well as, minerals such as iron and phosphorus. Extensive use of synthetic fertilizer to maximize the productivity often leads to depletion of essential soil nutrients, environmental degradation and adversely affects soil rhizosphere microbiota. Inorganic fertilizers have played a significant role in increasing crop production since the "green revolution (Liu *et al*., 2010); however, they are not a sustainable solution for maintenance of crop yields (Vanlauwe *et al*., 2010). Long-term overuse of mineral fertilizers may accelerate soil acidification, affecting both the soil biota and biogeochemical processes, thus posing an environmental risk and decreasing crop production (Aciego Pietri *et al*., 2008). Recently, organically cultivated vegetables have attracted considerable scientific interest and consumer demand as healthier products with safer characteristics. In a similar vein, organic agriculture, a sustainable means of vegetable cultivation has often been identified as an eco-friendly production system that can produce food with minimal risk to the environment (Dorais, 2007). Organic farming restricts the use of agrochemicals and offers a way to reduce the adverse effects of chemical fertilization (Aguilera *et al*., 2013; Aires *et al*., 2013). Organic amendments, such as compost and agricultural wastes, could therefore be a useful tool to sustainably maintain or increase soil organic matter, preserving and improving soil fertility and crop yield. This study therefore focuses on the use of organic amendment (composted cocoa pod with poultry manure) on the performance and mineral composition of tomato

MATERIALS AND METHODS

Description of the study Area

The research was conducted during the 2020/2021 cropping season at the Teaching and Research Farm of Landmark University, Omu-Aran, Nigeria. The site lies between latitude 8.9°N and longitude 50°61 E of the equator. It has annual rainfall pattern which extends between the month of April and

October with minimum 600 mm-1200 mm, the dry season is between October and March.

Soil sterilization, bagging and analysis

A well tilled soil characterized with good pore spaces was obtained from Teaching and Research Farms, Landmark University and was thoroughly mixed and sterilized to ensure the complete absence of disease-causing pathogen. Ten kilograms of the sterilized soil was filled into a perforated polythene bags of size 30 cm x 17 cm. Soil samples were randomly taken from the transplanting bags, bulked, air-dried and allowed to pass through a 2-mm sieve for routine physical and chemical laboratory analysis as described by Carter (1993).

Characteristics of the tomato and sources of planting materials

The variety of tomato used for the study was the Omu-Aran local which was obtained at the local market of Omu-Aran. The variety attain maturity between 60 and 70 days after transplanting, with a long harvesting period and high yield potential (indeterminate). It is also known to have intermediate resistance to fusarium wilt. The amendment used was a formulated organic fertilizer produced and obtained from microbiology department of Landmark University. NPK 15:15:15 and grow bags were obtained from an agro-allied shop located in Omu-Aran market.

Mineral analysis of composted cocoa pod

Laboratory analysis of the amendments used for the experiments was carried out to determine its nutrient compositions. The analysis was done for pH, N, P, K, Ca, Mg, Zn, and C:N (AOAC, 2003)

Raising and transplanting of Seedlings

The tomato seed was raised in the nursery at the screen house of Teaching and Research Farm Landmark University Omu-Aran using a sterilized soil. The seed was sowed on the 9th March, 2021 and two healthy seedlings were transplanted per bag three weeks after sowing which was later thinned to one seedling per bag after they have established.

Application of amendments and experimental design

Composted cocoa pod was applied based on the layout two weeks before transplanting to allow for their nutrient release, while NPK 15:15:15 was applied two weeks after transplanting to give room for the stability of the transplanted seedlings. Four levels of composted cocoa pod were applied at 0, 5, 10 and 15 t ha^{-1} and 200 kg NPK ha^{-1}. The equivalent of 0, 5, 10 and 15 t ha^{-1} of composted cocoa pod per bag was 0, 3.25, 6.5, and 9.75 g per 10 kg of soil while 200 kg NPK ha^{-1} is equivalent to 0.05 g per planting bag. The bags were arranged in the screen house in accordance with a completely randomized design (CRD), using 30 cm by 60 cm inter- and intra-row spacing. Treatments were replicated four times.

Harvesting

Mature and ripped fruits were harvested at intervals of five days for four weeks before the experiment was terminated. Harvested fruits were weighed with the aid of automated weighing balance of maximum capacity of 2100 g, readable at 0.01 g, and a model by OHAUS Corporation, USA.

Observation and Data Collection

The following vegetative and yield parameters were taken during the study – plant height, number of leaves, number of days to flowering, number of days to fruiting, number of fruits, and weight of fruits. A sample of each treatment was thereafter taken to the laboratory for quality determination.

Determination of nutrient compositions of tomato fruits

Mature and ripped fresh tomato fruits were collected based on treatments and taken to the laboratory of Landmark University, Nigeria for analysis. Mature, ripe and fresh tomato fruits were collected, oven-dried for 24 hours at 80°C, and ground in a Willey mill. Mineral elements were determined according to the methods as recommended by the Association of Official Analytical Chemists (AOAC, 2003).

Statistical Analysis

The data collected were subjected to one-way statistical analyses of variance (ANOVA) using statistical Analysis Software (SAS, 2002). The significant treatment means were compared using Duncan Multiple Range Test (DMRT) at 0.05 level of probability.

RESULTS AND DISCUSSION

Initial Soil Properties

The pre-planting soil analysis is as shown in Table 1. The pH of the soil was slightly acidic, the nitrogen content of the soil was very low, the available phosphorus was high, and the exchangeable K was also low while the exchangeable Na, Ca and Mg were all suitable. The organic matter was low. The

ISSN: 2814-0508

soil is high in sand with relatively low values in both silt and clay; hence the textural class is Sandy Loam.

Table 1: Physico-chemical properties of the initial soil

Parameter	2019	Parameter	2019
Sand (%)	69.2	Organic matter (%)	1.88
Silt (%)	14.5	K (cmol·kg)	0.14
Clay (%)	16.3	Ca (cmol·kg)	2.45
Textural class	Sandy loam	Mg (cmol·kg)	0.34
pH (H_2O) 1:1	5.62	Available P (mg·kg)	9.71
Total nitrogen (%)	0.15	Zn (mg·kg)	0.33

Mineral components of the amendments used in the experiment

The results of the laboratory analysis of composted cocoa pod is shown in Table 2. The results showed that the amendment contained varying nutrient elements in ranges suitable for plant growth and development.

Table 2: Chemical composition of composted cocoa pod

Nutrients %	pH	N	P	K	Ca	Mg	Zn	C:N
Composted cocoa pod + poultry dropping	7.30	9.18	0.62	1.22	14.00	4.80	3.46	13.40

Effect of composted cocoa pod and NPK fertilizer on plant height and number of leaves of tomato plant

Table 3 and 4 shows the effect of application of varying levels of amendment and NPK fertilizer on plant height and number of leaves of tomato. Application of the amendment significantly resulted in taller plants and more number of leaves though there was no significant difference between the two parameters when 6.5 g of CP+PM, 9.75 g of CP+PM, and 5 g of NPK were applied except for NPK on number of leaves. Control treatment gave the least values for the two parameters.

The significant increase in the vegetative parameters could also be due to better availability of soil nutrients in the rhizosphere, especially nitrogen and phosphorus which have enhancing effect on the vegetative growth of plants by increasing cell division, elongation and varietal variability to absorb nutrient from the soil (Yahaya *et al*., 2010). It could also be as a result of as a result of application of composted cocoa pod which increased soil organic matter and enhanced microbial activities leading to increased soil nutrients availability (Ziblim *et al*. 2013). Similar result was by Ojeniyi *et al*. (2007) where they reported that organic manures are the major sources of nitrogen, phosphorus, potassium, calcium and magnesium in many Tropical countries.

Effect of composted cocoa pod and NPK fertilizer on the flowering, fruiting and yield parameters of tomato plant

Application of composted cocoa pod and NPK fertilizer significantly influenced the yield parameters. The yield and yield-contributing variables differed significantly among the treatments and were enhanced by the application of composted cocoa pod and NPK fertilizer (Table 5). Application of 6.5 g of CP+PM, 9.75 g of CP+PM, and 5 g of NPK showed better performance in enhancing the number and weight of fruits when compared with the control, though the number of days to flowering were reduced.

ISSN: 2814-0508

Organic fertilizers that are made from animal excreta or other agricultural wastes are usually used to improve the structure and stability of the soil as well as to enhance the yield and quality of the crop (Marzouka and Kassem 2018). It is well known that the growth and yield of vegetable crops is affected by the quality and quantity of fertilizers used (Chang *et al*., 2010). In this study, application of organic amendments at higher rates performed favourably with inorganic fertilizer.

Means with the same letter(s) in a column are not significantly different at $p \leq 0.05$.
CP= cocoa pod, PM= poultry manure.

Increase in the fruit yield of tomato as a result of the application of high rate of composted cocoa pod could be attributed to some major mineral elements and micronutrients needed for plant growth and development that are present in the amendment (Atakora *et al*., 2014). Increase in tomato weight could be attributed to taller plants and more number of leaves produced making the plant to trap more sunlight for photosynthesis and transporting assimilates to the fruits.

Effect of composted cocoa pod and NPK fertilizer on the flowering, fruiting and yield parameters of tomato plant

Results of the analysis of the mineral composition of tomato fruits after harvest is as shown in Table 6. Ca, Mg, K, and Zn content of fruits were higher in bags applied with composted cocoa pod than the control treatment. Application of 6.5 g of CP+PM, and 9.75 g of CP+PM significantly ($p \leq 0.05$) resulted in higher values for all the mineral elements. The highest K content was recorded with the application of NPK which was statistically identical to 6.5 g of CP+PM, and 9.75 g of CP+PM. Analysis of composted cocoa pod revealed that it contained adequate quantity of both macro and micronutrients needed for the cultivation of tomato when compared with inorganic fertilizer. The finding revealed that application of organic amendment significantly increased the nutrient constituents of tomato fruits. This might have been due to the fact that the organic amendments provided micronutrients, such as zinc, iron, copper, manganese, at optimum levels (Yadav *et al.,* 2003).

Table 6: Effect of composted cocoa pod and NPK fertilizer on the mineral composition (mg/100g) of tomato fruits yield parameters of tomato plant

Treatment (g/bag)	Ca	Mg	K	Zn
0 g of CP+PM	0.67c	0.65c	0.01c	0.12d
3.25 g of CP+PM	1.45b	1.40b	0.04b	0.25b
6.5 g of CP+PM	1.60a	2.30a	0.07a	0.30a
9.75 g of CP+PM	1.62a	2.35a	0.08a	0.32a
5 g of NPK	0.70c	1.30b	0.08a	0.18c

Means with the same letter(s) in a column are not significantly different at $p \leq 0.05$.
CP= cocoa pod, PM= poultry manure.

CONCLUSION

The high nutrient content of the composted cocoa pod was identified as the main factor for increasing vegetative parameters, yield and mineral elements of tomato. The result of the vegetative, yield and mineral composition of tomato indicated that composted cocoa pod improved growth and development. This study therefore revealed that application of 6.5 g of CP+PM and 9.75 g of CP+PM improved all the parameters tested better than the application of inorganic fertilizer. It can therefore be concluded that application of 6.5 g of CP+PM will be more economical and could sustain soil fertility than inorganic fertilizer.

EFFECT OF SITE-SPECIFIC APPLICATION OF N AND K FERTILIZERS ON THE GROWTH AND YIELD OF CASHEW AT OCHAJA, KOGI STATE NIGERIA

Ibiremo, O.S. and Akanbi, O.S.O.

Soils and Plant Nutrition, Section, Cocoa Research Institute of Nigeria, Ibadan Oyo State, Nigeria

ABSTRACT

The soil is sandy loam with the average values of sand, silt and clay were 888, 20 and 92g/kg respectively. The soil was deficient in Nitrogen (N) and Potassium (K) with values of 0.41g/kg soil and 0.012cmol/kg soil respectively at 0-40cm depths. The values were used to compute fertilizer rates for cashew at 54kgN/ha and 84kgK$_2$O/ha. Application of N fertilizer had significant depressive effect on the pH of soil at both soil depths compared to the control and when N and K fertilizers were applied jointly. Similarly, application of potassium-based fertilizer with or without Nitrogen fertilizer gave marginal increase of 5.4% in the pH of the soil. Also, application of N and K fertilizers significantly (P<0.05) affected total soil nitrogen at 0-20cm soil depth. The total N ranged from 0.5g/kg to 0.7g/kg soil across the fertilizer treatments. N and K fertilizers did not significantly improve the available Phosphorus (P) in the soil across the fertilizer treatments. The exchangeable K in the soil followed a similar trend of available P across the various treatments. The nut yield of cashew was significantly (P<.05) improved as a result of Nitrogen fertilizer applied alone without K and the control. Application of N only deficient nutrients gives better result in terms of efficiency than blanket application of fertilizer without recourse to native fertility of the soil.

INTRODUCTION

Cashew is an important commodity crop with great potentials as foreign exchange earner and source of industrial raw materials with the prospect of becoming a major commercial tree crop in Nigeria. Cashew as a result of its wide adaptation is often grown in very poor soils and this has affected its survival and establishment (Topper, *et al.* 2001). Cashew cultivation is variously limited by both biotic and abiotic factors particularly in poor soils. The soils upon which cashew is grown are of poor to low fertility level, this is due to the misleading assertion that cashew can survive in any soil regardless its fertility status. In most cashew plantations, productivity is largely dependent on natural soil endowment as fertilizers are not part of its production input system (Ibiremo *et al.,* 2017, Agbongiarhuoyi *et al.,* 2014). Consequently, the soils upon which cashew are cultivated were maintained through litter fall and other natural endowment which hinders the crop from realizing its full potentials. In cashew production, fertilizer is rarely used as an input in the production system and when it is used blanket application is employed. Hence, application of fertilizer is inevitable for the replacement of soil nutrients that are being mined through apple and nut harvest annually. This can be achieved through fertilizer application based on soil test value. At Ochaja substation, the site being considered is deficient in nitrogen and potassium and for effective management of the soil, the addition of nitrogen and potassium based fertilizers will enhance its productivity. Conventionally, the use of solid fertilizers of major nutrients of nitrogen, phosphorus and potassium are common with few farmers that use fertilizers on the crop in Nigeria. The objectives of the study were to evaluate the effect of application of N and K fertilizers based on soil test value on the yield of cashew and to assess its effect on soil properties.

MATERIALS AND METHODS

Soil samples were collected randomly within the plantation at Ochaja and the samples were processed and analyzed for both physical and chemical characteristics using standard laboratory procedures using IITA laboratory manual (1982). The fertilizer computed was based on the analytical result of samples at 0-20cm soil depth. The result of the analysis indicated that the total nitrogen was 0.04g/kg soil which is in adequate to sustain cashew as it requires 1g/kg soil and the available P was adequate while the exchangeable potassium was also deficient having a value of 0.012cmol/kg which is far below the critical of 0.12cmol/kg soil. From these values, four treatment combinations were formed from two rates of nitrogen fertilizer and two rates of potassium fertilizer that were applied to young cashew trees in the field. The Nitrogen fertilizer was applied at 0 and 54 kgN/ha while the

Potassium was applied at 0 and 84kgK/ha and the treatments were arranged in a RCBD with 3 replications and crop morphological parameters, nut yield and soil nutrient characteristics would be measured. The fertilizers were applied in two splits application. The first dose was applied in June while the second dose was applied in September of 2019 and 2020. Initial plant growth parameters were taken to form the basis for assessing the effect of the fertilizer treatments. The data collected were subjected to ANOVA and means were separated using LSD at 5% level of probability.

RESULTS AND DISCUSSION

The pre-cropping soil characteristics indicated that the soil is sandy loam with the average values of sand, silt and clay were 888, 20 and 92g/kg soil respectively (Table 1). The pH is slightly acidic and very close to neutral with a mean value of 6.7 while the organic carbon (OC) was low with an average value of 0.82g/kg soil. The OC in block B was higher that the OC in Block A. The total Nitrogen in the soil was 0.41g/kg soil which is below the critical value of 1g/kg soil. The deficiency of 0.6g/kg soil will require 54kg N for optimum production while the mean value for available P was 5.28mg/kg soil. This value is above the level required by cashew for optimum productivity. The average value of potassium was 0.012cmol/kg soil. The deficiency of 0.108cmol/kg requires 84kg/ha. The exchangeable calcium ranged from 1.26 to 2.26cmol/kg across the soil depth of 0-40cm with a mean value of 1.68cmol/kg. The mean value of exchangeable Mg was 0.29cmol/kg across the two soil depths. The pH of the soil at the two soil depths of 0 - 20 and 20 - 40cm was significantly ($p<0.05$) affected by application of nitrogen and potassium fertilizers ($P<0.005$). Application of N fertilizer had significant depressive effect on the pH of soil at both soil depths compared to the control and when N and K fertilizers were applied jointly. This could be as a result of the property of urea fertilizer that lowers soil pH as observed by Agbede (2009) and Adejumo, (2010). Similarly, application of N and K fertilizers significantly ($P < 0.05$) affected total soil nitrogen at 0 - 20cm soil depth. However, the effect was not significant at 20 - 40cm soil depth. Specifically, the total soil N in places where urea was applied seemed to be lower than the control (without fertilizer). The high level of sand in the soil might be the reason for low retention of applied N which is contrary to the observation by Adejumo, (2010) that application of urea increases total soil N. The soil available P was significantly ($P < 0.05$) influenced ($P<0.05$) by the application of N and K fertilizers across the two soil depths. Application of potassium alone depressed significantly ($P<0.05$) the available P at both depths (Table 2). The available P at both depths in the control plot was higher than when either of the fertilizers was applied. The initial soil P content was high, that informed its non-inclusion in the fertilizer formulation. The exchangeable K at both soil depths was not significantly affected by the application of N and K (Table 2). The exchangeable K ranged from 0.09 to 0.16 cmol/ kg soil at the two soil depths. The nut yield of cashew was significantly ($P < .05$) improved as a result of nitrogen and potassium fertilizers (Figure 1). Specifically, application of N fertilizer enhanced the nut yield of cashew significantly compared to the control. Similarly, N application increased the nut yield of cashew significantly ($P<0.05$) than when K alone or N and K fertilizer were applied together. The application of N enhanced the growth of cashew which translated to increase in the nut yield of cashew. This observation is consistent with the result obtained by Adejumo, (2010) in the improvement of the yield of cashew by N application.

CONCLUSION

Application of fertilizer based on the result of soil test and the need of the site in question will give an optimum result in terms fertilizer use efficiency and improve crop yield relative to blanket application of fertilizer without recourse to native nutrients of the soil.

ABSTRACT

Demystifying appropriate application modality for organic fertilizers is a major limiting factor to their use. The pot trial composed of two organic fertilizers: Poultry manure (tagged Pm containing 19.5 and 19.4g/kg N and P respectively) and compost (tagged Comp containing 10.5 and 15.7g/kg N and P respectively). Each was applied using three modalities: Nitrogen (tagged NM), phosphorus (tagged PM) and tonnage (TM) modalities at three application rates: Lower (tagged L), Optimum (tagged O) and Higher (tagged H) rates. The results were compared with conventional chemical fertilizer (CF) at similar rates. Optimum application rate regardless the organic fertilizer or application modality supported highest soil and plant parameters compared to lower and higher rates with the organic fertilizers been superior to the conventional CF. Compost and Pm using TM and NM respectively produced highest okra fruit weights while TM and NM enhanced soil total N and available P in Pm and compost treated soils respectively. The PM consistently produced least soil and plant parameters.

Key words: Compost; Application modality; Organic fertilizers; Okra fruit weight

INTRODUCTION

Organic fertilizers are plant nutrient sources obtained from the raw, biologically and/or thermally modified plant and animal wastes. Its forms include manure (such as farm yard, green manure, sludge and slurries), compost (including plain and fortified compost types such as phospho-compost) and biochar. They are multi-nutrient fertilizers containing nitrogen, phosphorus, exchangeable bases and micronutrients essential for plant growth. These nutrients are sometimes in lower concentrations compared to those of chemical origin. They are however superior to chemical fertilizers in their generally high organic matter contents which are of importance in enhancing soil aggregate stability (Ewetola *et al.,* 2019), carbon sequestration (Oyeyiola *et al.,* 2017; Oyeyiola 2017; Oyeyiola and Omueti 2016), microbial activities and CO2 emission mitigation from soils (Goeschel, 2016; Adesodun *et al.,* 2015; Niggli *et al.,* 2009).They are also well documented to contribute significantly to enhanced vegetable crop yield and quality (Oyeyiola *et al.,* 2020; Aluko *et al.,*2020; Khandaker *et al.,* 2017)

Despite all these benefits associated with organic fertilizers, their use in Nigerian soil is limited. The right modality for their field application remains a major bottle neck. Use of tonnage modality (e.g. 2.5, 5.0 and 10 t/ha) is widely used by researchers (Aluko *et al.,* 2020; Kakar *et al.,* 2020; Oyeyiola, 2017; Atijegbe *et al.,* 2014). Recently the use of selected nutrient components in the organic material especially the nitrogen and phosphorus contents have been proposed. There is however no reported work where these application modalities have been compared to know which is optimal for okra production in Nigerian soils. Assessing which of tonnage and nutrient (N and P) component application modalities that will compare favorably with the recommended conventional chemical fertilizer (NPK 15:15:15 spiked with urea) for okra production was the focus of this experiment.

MATERIALS AND METHODS

Soil sampling, preparation and routine analysis

The experimental top soil (0-15cm depth) was sampled from the Teaching and Research Farm of Ladoke Akintola University of Technology, Ogbomoso, Nigeria during the 2019 cropping season. The soil was prepared and subjected to routine analysis following standard procedures described by IITA (1978). The soil has near neutral pH value (6.8), deficient in total N (0.15 g/kg), organic carbon (1.7 g/kg) and Mehlich extracted available P (9.02 mg/kg). The soil was, however, sufficient in exchangeable bases with sandy loam textural class.

Treatments, experimental design and set up

The pot trial composed of two organic fertilizers: Poultry manure (tagged Pm containing 19.5 and 19.4g/kg N and P respectively) and compost (tagged Comp containing 10.5 and 15.7g/kg N and P respectively). Each was applied using three modalities: Nitrogen (tagged NM), phosphorus (tagged PM) and tonnage (TM) modalities at three application rates: Lower (tagged L), Optimum (tagged O) and Higher (tagged H) rates. Chemical fertilizer NPK 15:15:15 augmented with urea applied at three similar application rates and unamended soil that received no fertilizer were included. The trial was a one-way experiment arranged in completely randomized design with three replications. The fertilizer treatments and quantities applied per 5 kg soil are summarized in Table 1. After appropriate treatment applications, okra seeds were sown to achieve a plant per pot and were nurtured to maturity. Data were taken on fresh fruit, dry root and shoot weights per pot while total N and available P were determined in the soil samples collected at harvesting. Data were subjected analysis of variance using Genstat statistical package and means separated by LSD at 5% probability level.

Table 1: Equivalent quantities of organic fertilizers applied using nitrogen, phosphorus and tonnage modalities and chemical fertilizer at three application rates

Application modality	N, P and K application rate description	Fertilizer quantities (g/pot) Compost	Poultry manure	Chemical fertilizer
Nitrogen modality				
Lower rate	30:15:15	7.10	3.85	-
Optimum rate	60:30:30	14.30	7.69	-
Higher rate	90:45:45	21.30	11.55	-
Phosphorus modality				
Lower rate	30:15:15	0.69	0.84	-
Optimum rate	60:30:30	1.39	1.69	-
Higher rate	90:45:45	2.07	2.52	-
Tonnage modality				
Low rate	2.5 t/ha	6.25	6.25	-
Optimum rate	5.0 t/ha	12.50	12.50	-
Higher rate	7.5 t/ha	18.75	18.75	-
NPK 15:15:15 spiked with urea				
Lower rate	30:15:15	-	-	0.25 NPK + 0.09 Urea
Optimum rate	60:30:30	-	-	0.50 NPK + 0.17 Urea
Higher rate	90:45:45	-	-	0.75 NPK + 0.26 Urea

RESULTS AND DISCUSSION

Comparison of selected soil and plant parameters from soils amended with organic fertilizers using different application modalities with chemical fertilizer at lower application rate

The performance of the organic fertilizer treatment was significantly reduced under low application rate regardless the application modality compared to the conventional chemical fertilizer applied at similar lower rate (Fig. 1). The situation was severe on fruit production of the plant in the compost applied using phosphorus modality (PM) such that the plant could not produce any fruit. This treatment received the least quantity (0.7 g) of the organic fertilizer which seem not sufficient to supply enough nitrogen to carry the plant through its vegetative stage let alone reproductive stage. This 0.7 g compost received using PM will only deliver 2.94 kg N/ha to the plant which is far below the 29.82 and 26.46 kg N/ha received by plants raised under nitrogen (NM) and tonnage (TM) modalities. Lower application produced least soil and plant parameters across all the treatments tested. At lower rate, poultry manure applied using TM however produced higher soil available P and fruit weight while NM favored higher soil total N and total dry biomass. In compost treated soil, TM consistently supported highest soil available P, fruit weight and total dry biomass with NM highest in soil total N.

Comparison of selected soil and plant parameters from soils amended with organic fertilizers using different application modalities with chemical fertilizer at optimum application rate

The two organic fertilizers applied using different modalities produced superior soil and okra yield parameters over conventional chemical fertilizer applied at similar optimum rate ad unamended soil (AC) except fruit weights from poultry manure and compost applied using PM and NM respectively and total N and available P from compost applied using PM as shown in Fig. 2. Poultry manure using NM and compost at NM produced fruit weights and total dry biomass 194.5 and 114.3% respectively over the conventional chemical fertilizer. Poultry manure at PM and compost at N modality enhanced soil total N and available P by 31.7 and 296.3% respectively over chemical fertilizer.

Generally, optimum application rate across all the treatment tested produced better soil and plant parameters compared to lower and higher rates. At optimum application rate however, poultry manure at NM and PM supported highest fruit weight and soil total N respectively while TM favored highest soil available P and total dry biomass. For compost, NM supported highest total dry biomass, soil total N and available P while TM gave highest okra fruit weight.

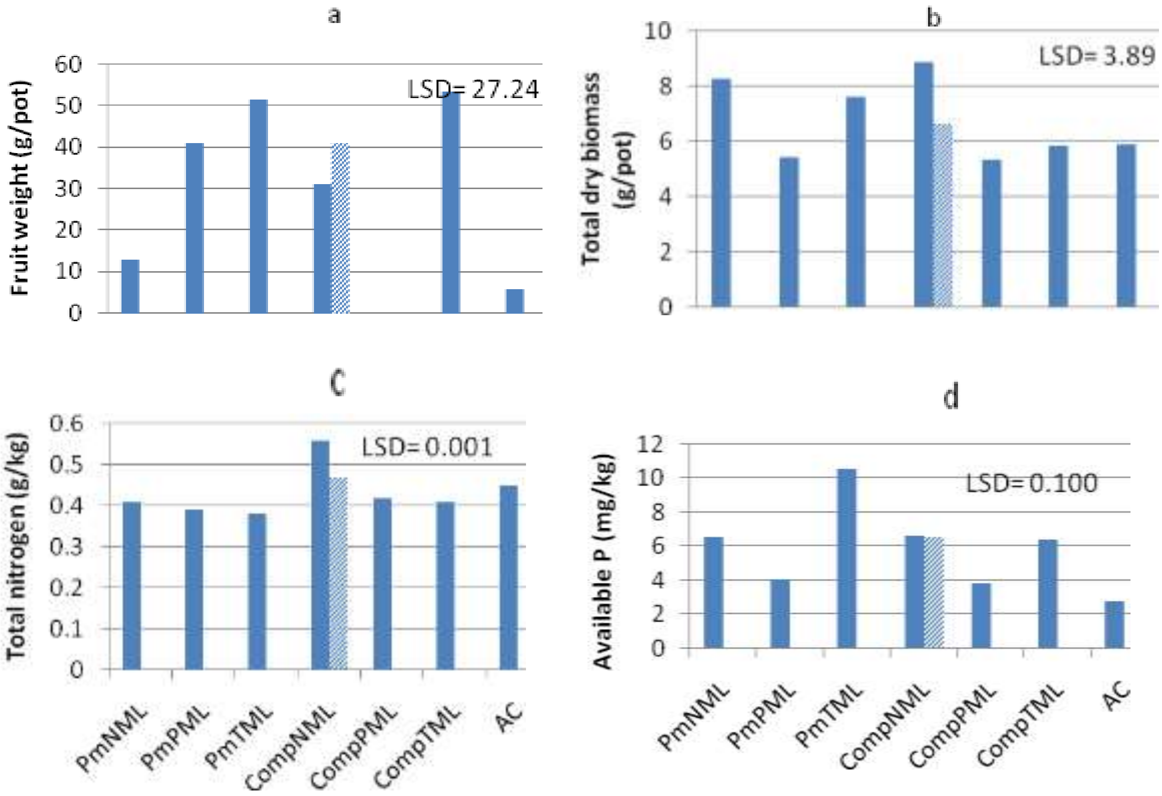

Fig. 1. Comparison of selected plant (a-b) and soil (c-d) parameters from soils amended with organic fertilizers using different application modalities with chemical fertilizer at lower application rate

NB: Crossed bar is chemical fertilizer treated soil

Comparison of selected soil and plant parameters from soils amended with organic fertilizers using different application modalities with chemical fertilizer at higher application rate

At high application rate, all the organic fertilizer combinations enhanced soil and okra yield parameters over the conventional chemical fertilizer and unamended soil except compost at PM (for fruit weight, total dry biomass and total N) and poultry manure at both NM and PM (total N) as shown in Fig. 3. Poultry manure at NM and compost at TM increased fruit weight and total dry biomass of okra by 120.5 and 52.4% respectively over chemical fertilizer at similar high rate. With reference to soil characteristics, poultry manure at TM enhanced total N by 14.3% while compost at NM was 322 % higher in improving available P over chemical fertilizer treated soil.

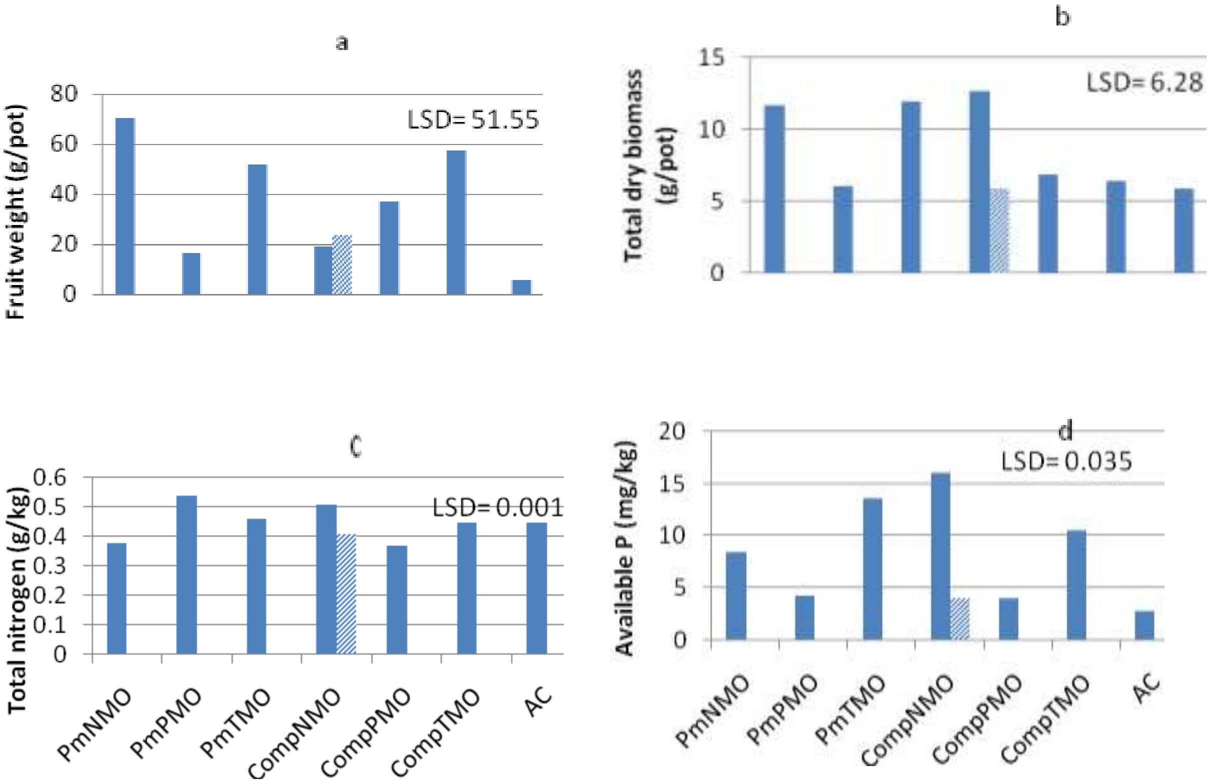

Figure 2. Comparison of selected plant (a-b) and soil (c-d) parameters from soils amended with organic fertilizers using different application modalities with chemical fertilizer at optimum application rate

NB: Crossed bar is chemical fertilizer treated soil

The selected soil and plant parameters were generally lower at higher application rate for the organic and chemical fertilizers although, both organic fertilizers outperformed the conventional chemical fertilizers. Poultry manure applied using the NM supported higher okra fruit weight and total dry biomass while TM had higher total N and available P over the others. The NM in compost treated soil produced higher okra fruit weight and soil available P while TM enhanced soil total N and total dry biomass of okra over other application modalities. The PM was the poorest for both organic fertilizers.

CONCLUSION

Okra plants raised under all the organic fertilizer combinations at the three application rate out-performed the chemical fertilizer with tonnage and nitrogen application modalities been superior to phosphorus modality. However, tonnage application modality favoured better performance in uncomposted organic fertilizers such as the poultry manure while nitrogen modality was optimal for composted organic fertilizer.

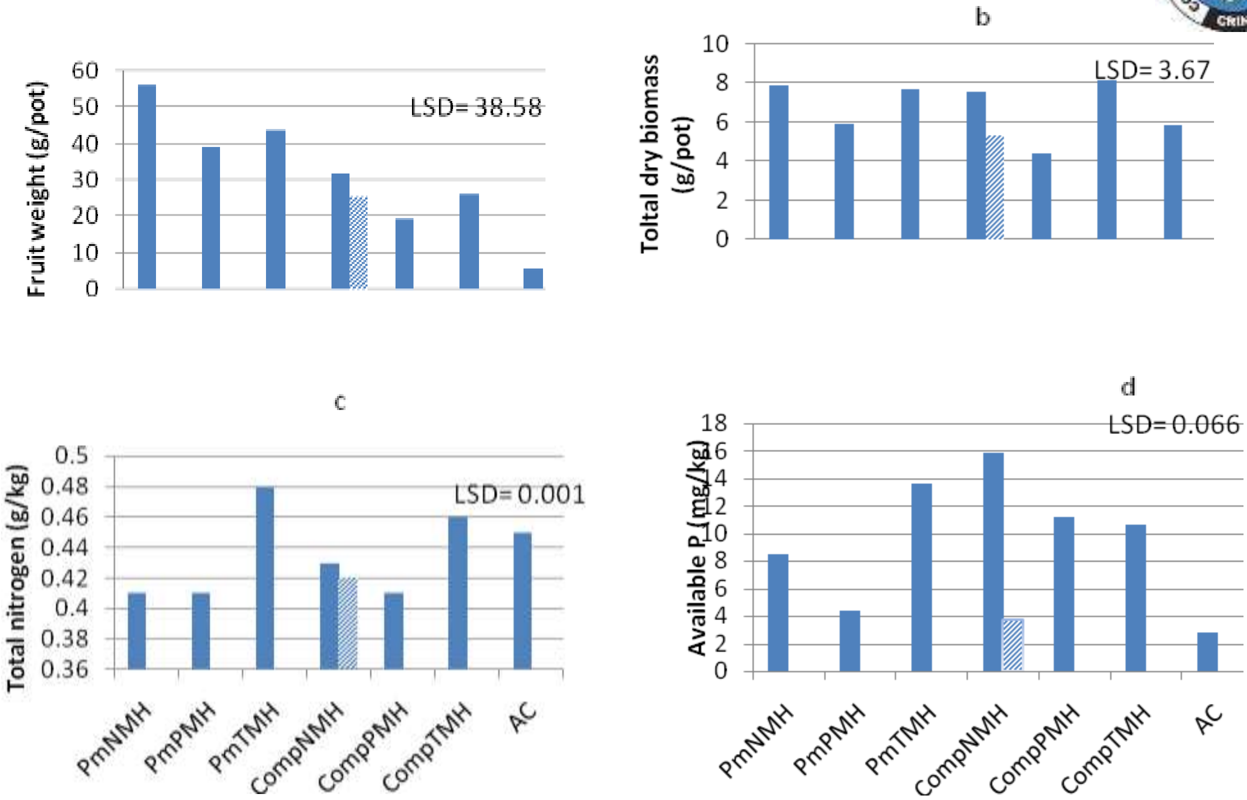

Figure 3. Comparison of selected plant (a-b) and soil (c-d) parameters from soils amended with organic fertilizers using different application modalities with chemical fertilizer at higher application rate

ABSTRACT

The effect of three organic fertilizers namely; Chromoleana odorata (Siam weed), Pennisetum purpureum (Napier grass) and cow dung were evaluated on the shoot and root nutrient content of Coffea Canephora seedlings at the rate of 0.5 and 10tha[1]. The result showed that, application of each of the organic fertilizers singly or combined significantly ($P \leq 0.05$) improved the nutrient content of Coffea Canephora seedlings. Application of Chromoleana odorata alone or in combination with either the two organic fertilizers improved nutrient content of the shoot mostly when applied at 5t ha[1]. The P content of the shoot increased between 0.23 – 0.24% and the K content between 0.25 – 0.27%. The exchangeable cations showed considerable increase Ca 0.26 – 0.27% and Mg 0.25 – 0.26%. The nutrient content of the root showed a similar trend of increase but most significant with plants that received Chromoleana odorata organic fertilizer based treatments. Organic fertilizers therefore can serve as good nutrient source supplement for coffee seedling production in the humid tropic.

Key word: *Chromoleana odorata* (Siam weed), *Pennisetum purpureum* (Napier grass)

INTRODUCTION

Coffee is one of the important agricultural produce traded worldwide (Mellissa, 2002) and stand as the second commodity in the market. This is why (Sara Lee, 2003) noted the essence of enhancing productivity of Coffee since it would be economically rewording to producing countries. More so, Coffee is mainly a cash crop produced by low income small scale farmers who are faced with the problems of inadequate funds, lack of modern cultural practices and nutritional requirement of Coffee for their desired growth, yield and quality. Coffee production worldwide has been found to require additional external input in form of fertilizers. Over the years, the high cost of inorganic fertilizers (Charles, 2001) has led to poor yield. This is primarily because coffee exerts a lot of demand on the soil in terms of nutrient uptake. The use of various materials as fertilizers has been reported to improve the soil fertility and increased yield (Obatolu and Agboola, 1990; Daniel, 2005). These organic materials are cheaply available within the reach of farmers. This study therefore evaluated the effect of three organic fertilizers on the shoot and root nutrient content of *Coffea Canephora* seedlings.

MATERIALS AND METHODS

A Greenhouse study was carried out at Cocoa Research Institute of Nigeria, Ibadan $7^0 10'$N, $3^0 52'$E) located at an altitude of 122m above mean sea level (abmsl) during the 2020 cropping season. The soil has been classified as Alfisol (Soil Survey Staff, 1990), belonging to Oba series (Smyth and Montgomery, 1962). Bulk soil samples were collected at a depth of 0 – 30cm, air – dried, crushed and sieve to pass through 2mm sieve and analysed before the experiment (Table 1). The plant materials used in compounding the organic fertilizers were *Chromoleana odorata* Siam weed (C), *Pennisetum purpureum* napier grass (P) and cow dung (D) respectively. The plant materials were freshly harvested, chopped to 5cm size, sun – dried and milled using Glen – Creston stainless hammer mills. The cow dung was collected at Bodija cattle market, Ibadan and packed in jut bags. The cow dung was later cured, sun – dried and milled. Ripe Coffee berries were collected from matured Coffee *Canephora* tree (Quillo variety). The berries were collected, depulped and sown (pre – nursed) in seed tray filled with river sand for six weeks. Five kilograms (Kg) of air – dried soil were weighed each into 5-litre size plastic pots perforated at the bottom. Three levels of the organic fertilizer viz; 0, 11 and 22g corresponding to 0, 5 and 10t ha[1] were each weighed out and applied as sole and in combinations in the ratios of 1:0:0; 1:1:0 and 1:1:1 for 5tha[1] and 2:0:0, 2:2:0 and 2:2:2 for 10tha[1] respectively and a control. The treatments were laid out in a complete replicated four times. The organic fertilizers were mixed with the soil in the 5-litre plastic pots and arranged before bare root coffee seedlings were transplanted into each pot and watered. Agronomic data (Plant height, leaf area, number of leave and stem diameter) for six months after which total sampling was done. The

ISSN: 2814-0508

seedling in each pot were uprooted, washed and separated into shoot and roots, enveloped and oven – dried at 68^{0}C for 48hrs. The oven – dried plant samples were later milled and analysed. The particle size analysis was carried out according to (Bouyoucous, 1965). The soil pH was carried out following (Schofield and Tylor,1955) procedure while the organic carbon was analyzed using chromic acid digestion method (Allison,1965). The total N was determined using the Macro – Kjeldhal apparatus as described by (Bremner, 1965) and the exchangeable cations (K, Ca and Mg) using NH_4OAC (Chapman, 1965) methods. Similarly, the plant analysis was carried by; Percent N by using Micro - Kjeldhal apparatus (Bremner, 1965), percent P by dry ashing (Jackson, 1970) and the percent K, Ca and Mg in the plant tissue were determined using the digest under percent P determination above respectively.

Table 1: Physical and chemical characteristics of the soil used

RESULTS AND DISCUSSIONS

Some physical and chemical properties of the soil used are presented in Table 1 and the nutrient content of the organic materials used in compounding the organic fertilizers in Table 2. Results from the study on the agronomic and dry matter yield is presented in Figure 1.

Application of sole organic fertilizers and the various combinations at 5tha[1] significantly ($P\leq0.05$) increased the N content of the shoot between 50 - 58% where *Chromoleana odorata* was applied as sole and in combination with *Pennisetum purpureum* and cow dung above the control (Table 3). This may be as a result of the high N content of the organic materials (Table 2). There was no significant difference in the P and Ca content across the treatments. This may be attributed to the magnitude of cations absorption by higher plants (Samuel and Werner, 1978).

Table 2: Nutrient Content of organic fertilizers materials used.

	N ←	P	K (%)	Ca	Mg →	Cu ← mg/kg	Zn →
Cow dung	1.29	0.60	0.88	1.57	0.43	36.60	284.00
Pennisetum purpureum	2.00	1.80	3.20	0.27	0.58	35.20	225.00
Chromoleana odorata (Siam weed)	2.47	0.21	3.08	1.21	0.76	48.10	391.00

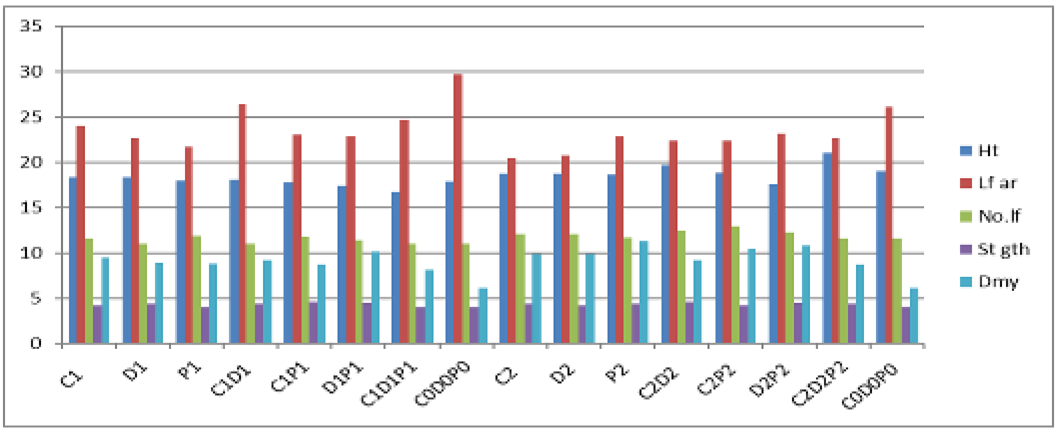

Figure 1: Effect of three organic fertilizers on the growth and dry matter yield of coffee seedlings

ISSN: 2814-0508

There was an increase in the range of 0.22 0.24% and 0.27 – 0.28 for K at 5t/ha compared to the application at 10tha^{1}. The K content increased significantly in the shoot where the combination of the three organic fertilizers ($C_1D_1P_1$) was applied 0.27% at 5tha^{1} and 0.28% at 10tha^{1} respectively. Similarly, the Mg content in the coffee seedling shoot showed a considerable increase. This finding is consistent with that earlier reported by (Brady and Weil, 1999; Jayarama, 2003). The rooting system of coffee trees is known to be concentrated within the 40cm depth of the soil. The addition of sole and the combination of the organic fertilizers enhanced the root growth significantly ($P \leq 0.05$) especially with the treatment *Chromoleana odorata* with *Pennisetum purpureum* (C_1P_1) and cow dung and *Pennisetum purpureum* (D_1P_1) at 5tha^{1}. There was a similar increase of 40% in the root N above other treatment and the control at 10tha^{1}. Similarly, where *Chromoleana odorata* (C_2) and the combination with cow dung (C_2D_2) showed an increased in the root N content (Table 3 & 4).

Means within the same column, followed with same letter are not significantly different from each other at 5% level of significance (New Duncan's Multiple Range Test). C = *Chromoleana odorata*; D = Cow dung; P = *Pennisetum purpureum*; O = Control; 1 = 5t/ha;2 = 10t/ha

There was no significant increase in the root P in all the treatments at both rate of application this may be as a result of the fate of P in the soil which is either slowly release or easily fixed. The exchangeable cations showed a significant increase especially where *Pennisetum purpureum* (P_1), the two *Chromoleana odorata* and the combination with cow dung (C_1D_1), *Pennisetum purpureum* and the combination with cow dung (P_2D_2) and the control were applied. There was no significant difference ($P \leq 0.05$) in the root Ca content across the treatments. The treatment that received *Chromoleana odorata* (C_1) application at 5tha^{1} significantly increased the root Mg content ($P \leq 0.05$) than all other treatments. Similarly, application of the organic fertilizers at 10tha^{1} on showed significant difference in all the treatment except where *Pennisetum purpureum* (P_2). Similar trend was observed for Ca and Mg content in the root content at 5tha^{1}. The Mg content was highest where alone cow dung (D_2) was added at 10tha^{1}. A significant correlation(r=0.05) was observed between the root N content and dry matter yield (Table 5) of coffee seedlings except P. All other nutrient element considered showed a negative correlation with the dry matter yield. Hence the study revealed that, of each of the three organic fertilizers either singly or in combinations enhanced coffee seedling growth resulting in high dry matter yield but most at 5tha^{1}. These organic fertilizers can serve as good nutrient supplement for coffee production with the imminent scarcity of inorganic fertilizers.

Table 4: Effect of each and different combination of three organic fertilizers on root nutrient content of coffee seedlings at 5t/ha and 10t/ha

ABSTRACT

Ginger is a medicinal spices crop rich in anti-inflamatory and antioxidant compounds such as gingerols, betacarotene, caffeic acid, vitamins and minerals. Plant growth and yield of crops like ginger are affected by level of soil fertility and cultural practices such as mulching. Although, management practices such as mulching and application of organic fertilizer (OF) improve soil quality and enhance crop yield. Limited information is available on the combined effects of Chromolena odorata mulch (CM) and organic fertilizer on the yield of gnger. Therefore, the combined effects of Chromolena odorata mulch and organic fertilizer on ginger growth, biomass and yield were investigated. Field experiment involving three of levels of Chromolena odorata mulch (0, 15 and 30 t/ha) and five rates of commercial organic fertilizer (0, 10, 15, 20 and 25 t/ha) was carried out at National Horticultural Research Institute, Ibadan. The N, P and K composition of organic fertilizer are 1.7, 1.2 and 2.4 % respectively. The experiment was a 3 x 5 factorial in a split plot design with three replicates. Organic fertilizer was applied two weeks before planting. The Chromolena odorata mulch was applied immediately after planting. Data were collected at four weeks' interval plant height, number of leaves, number of tillers, above and below biomass and rhizome ginger yield. The results showed that plant height ranged from 18.8 cm (0 t/ha CM) to 27.2 cm (30 t/ha CM) and 18.9 cm (0 t/ha OF) to 26.9 cm (25 t/ha OF). Number of leaves range from 11.1 (0 t/ha CM) to 13.7 (30 t/ha CM) and 11.1 (0 t/ha OF) to 13.9 (25 t/ha OF). Above ground biomass ranged from 34 kg/ha (0 t/ha CM) to 70.8 kg/ha (30 t/ha CM) and 34.9 kg/ha (0 t/ha OF) to 69.7 kg/ha (25 t/ha OF). Rhizome yield ranged from 3.6 t/ha (0 t/ha CM) to 7.2 t/ha (30 t/ha CM) and 4.7 t/ha (0 t/ha OF) to 6.9 t/ha (25 t/ha OF). Plant height, number of tiller, number of leaves and rhizome yield in 30 t/ha CM + 25 t/ha OF (30.9±0.5 cm, 6.8±0.2, 15.2±0.1 and 8.3±0.1 t/ha respectively) were significantly higher than other treatments.

Key words: biomass, *Chromolena odorata*, fertilizer, ginger, yield

INTRODUCTION

One of the major constraints to crop production in the tropics is the low fertility status of most of the soils which is a reflection of the low level of organic matter, nitrogen, phosphorus and exchangeable cations (Agbede and Adekiya, 2009). The challenge of food production in continuous cropping systems in the humid and sub-humid tropics of Nigeria is to manage the fragile soils to ensure sustained productivity without reverting to the bush fallow or shifting cultivation of traditional agriculture (Ndaeyo *et al.,* 1995).

Ginger (*Zingiber officinale* Roscoe) of the family Zingiberaceae is indigenous to warm tropical climates, particularly southeastern Asia. It is a monocotyledon with a slender perennial herb-like habit, but is usually grown as an annual. It is an erect plant propagated through its rhizomes which are underground. It contains stalkless leaves and attains a height of 2-3 feet (60-90cm), it is popularly known in countries like Jamaica and Europe, but it is assumed to have originated from tropical Asia. It benefits from manuring and does well when irrigated (Adegbola *et al*., 1972). Ginger is an important spice used as a condiment in vegetable preparations. Ginger tea is also used as a carminative and in the symptomatic treatment of colds. The oil and oleoresins obtained from ginger are also used in many food items, soft drinks and beverages (Singh *et al*., 2008). Ginger is basically considered to thrive best on rich medium loams with good supply of humus. High humidity throughout the crop period is necessary.

The decline of soil organic matter with cropping is a major factor affecting sustainability of many cropping systems in sub Saharan Africa (Buyanovzky *et al.,* 1984). Studies also indicate that soil physical, biological and chemical properties can sustainably be improved through the improvement of soil organic matter (Paul 1984). This can be done through practices like mulching and addition of manures (Unger 2001). Also studies carried out indicated positive effect of organic wastes on soil productivity. For instance, Mbah and Onweremadu (2009), reported that soil-incorporation of calliandra and leucaena green biomass with or without fertilizer increased total soil nitrogen by 1-8% over a period of four years.

Mulching is an effective method of manipulating crop growing environment to increase yield and improve product quality by controlling weed growth, ameliorating soil temperature, conserving soil moisture, reducing soil erosion, improving soil structure and enhancing organic matter content (Awodoyin and Ogunyemi, 2005). Awodoyin and Ogunyemi (2005) have reported that the weed control efficiency of different types of mulch in cayenne pepper production ranged from 27% to 97%. According to Ojeniyi (1995) and Agboola *et al*. (1992), soils in Nigeria suffer deficiencies common to tropical soils. These include low organic matter content, shallow depth and high acidity. About 63% of the agricultural soils in Nigeria are low in productivity and over 90% are Alfisols and Ultisols that are low in organic matter and have low activity clays. There is therefore the need to identify the best rate of organic fertilizer and the level of mulch suitable for ginger production with the ultimate aim of improving productivity.

MATERIALS AND METHODS

This study was conducted at National Horticultural Research Institute, Ibadan (7° 30'N, and 3° 54'E; in an altitude of 234m above sea level), Oyo State. Ibadan is located in the rain-forest agroecological zone (White, 1983). The average mean minimum and maximum temperatures were 22.8°C and 31.9°C respectively. The rainfall is bimodal, with total annual rainfall ranging between 1299.2mm and 1550.6mm. The experimental design was a slit plot design consisting of three levels of mulch as main plot and organic fertilizer treatments as the subplots replicated three times. The plot size was 2 m x 2 m. Ginger bits was planted at a spacing of 20 cm x 25 to a depth of 4 – 5 cm. Three levels of mulch were 0, 15 and 30 t/ha and five different rates of organic fertilizer were 0, 10, 15, 20 and 25 t/ha. The three levels of mulch and five rates of organic fertilizer resulted in 15 treatment combinations. Organic fertilizer was applied by spreading on the soil surface of each plot at different rates of 0, 10, 15, 20 and 25 t/ha two weeks before planting the ginger. Dried mulch was also applied by spreading the mulch material on the soil surface on each plot at different levels of 0, 15 and 30 t/ha immediately after planting on the same day. The mulching material was dried *Chromolaena odonrata* and the organic fertilizer was Alesinloye Asejere organic fertilizer. Weeding was done manually using hand or hoeing. Parameters considered included: plant height, number of leaves, number of branches, stems and leaves biomass and yield. Data were subjected to statistical analysis of variance (ANOVA) using general linear model procedure of the Statistical Analysis System (SAS Inst, 1998). Means were separated using the Duncan's Multiple Range Test (DMRT) at 0.05 level of probability.

RESULTS AND DISCUSSION

The results regarding the physical and chemical soil analyses at the time of cultivation indicated that the soil was loamy sand in nature, with pH of 5.7, a level suitable for many tropical crops. The organic carbon of 17.3 g/kg and total nitrogen of 1.3 g/kg were low. The available P of 8.5 cmol/kg was low. The exchangeable bases (K, Ca, Mg and Na) (0.1, 0.3, 0.3 and 0.1 cmol/kg respectively) were low. The extractable minerals such as Zn and Mn were high. Table 1a shows ginger plant height as influenced by mulch and different rates of organic fertilizer application. Significant differences were observed at the various weeks of observation after planting. Plant height was significantly affected by levels of mulch with 30 t/ha of mulch treatment having the highest value of 36.6 cm and 0 t/ha mulch having the least value of 28.3 cm. Also, significant differences were observed among the plant heights with different rates of organic fertilizer at 4 to 24 WAP. Interaction between mulch and organic fertilizer application did not significantly influence the plant height. Table 1b presents the combined effect of mulch and organic fertilizer on plant height. Mulch at 30 t/ha and organic fertilizer at 25 t/ha combination had the highest plant height 30.9 cm, followed by mulch at 15 t/ha and organic fertilizer at 25 t/ha with plant height 27.7 cm and least by mulch at 0 t/ha and organic fertilizer at 0 t/ha (control) with plant height of 14.7 cm. The same trends of observation were observed in number of leaves. The highest average number of leaves of ginger plant was also observed in 30 t/ha of mulch and 25 t/ha of organic fertilizer (Table 2).

LSD (P < 0.05) for comparing effects of mulch = 1.7
LSD (P < 0.05) for comparing effects of organic fertilizer = 2.2
LSD (P < 0.05) for comparing effects of mulch x fertilizer = NS

Table 2: Combined effects of mulch and organic fertilizer application on number of leaves of ginger after planting

	Organic fertilizer (t/ha)					Mulch
Mulch (t/ha)	0	10	15	20	25	Mean
0	9.5	10.7	10.9	12.0	12.5	11.1
15	11.5	12.5	13.1	13.9	14.1	13.0
30	12.2	13.3	13.8	14.1	15.2	13.7
Organic fertilizer mean	11.1	12.2	12.6	13.3	13.9	

LSD (P < 0.05) for comparing effects of mulch = 0.6
LSD (P < 0.05) for comparing effects of organic fertilizer = 0.7
LSD (P < 0.05) for comparing effects of mulch x fertilizer = NS

Between 8 and 24 WAP, significant differences (P < 0.05) were observed among the above ground biomass mean levels of mulch treatments and also observed among the above ground biomass treated with organic fertilizer (Table 3). The same trends of observation were observed in below ground biomass of ginger. Mulch and organic fertilizer interaction did not have significant influence on above ground biomass between 8 and 16 WAP. However, interaction between mulch and organic fertilizer had significant effect on above ground biomass at 24 WAP. Combination of 30 t/ha mulch and 25 t/ha organic fertilizer treated plots gave the highest quantity of the above ground biomass and the least value was obtained from control plot (Table 3).

Table 3: Combined effects of mulch and organic fertilizer application on above ground biomass (kg/ha) of ginger after planting

	Organic fertilizer (t/ha)					Mulch
Mulch (t/ha)	0	10	15	20	25	Mean
0	12.5	24.3	35	46.6	51.4	34.0
15	39.5	55.4	62.7	69.4	73.1	60.0
30	52.9	60.6	73.6	82.4	84.5	70.8
Organic fertilizer mean	34.9	46.8	57.1	66.2	69.7	

LSD (P < 0.05) for comparing effects of mulch = 4.0
LSD (P < 0.05) for comparing effects of organic fertilizer = 5.2
LSD (P < 0.05) for comparing effects of mulch x fertilizer = 20.9

Yields of ginger as affected by mulch and organic fertilizer application are presented in Table 4a and b. Significant difference (P < 0.05) were observed among the mean treatments. Mulch applied at 30 t/ha had the highest rhizome yield mean value of 7.2 t/ha and least value by the control. Organic fertilizer treatment had a significant effect on the rhizome yield with ginger plant fertilized with 25 t/ha organic fertilizer having highest rhizome yield value of 6.9 t/ha while 0 t/ha recorded the least value of 4.7 t/ha. Mulch and organic fertilizer interaction had significant effect on rhizome yield. The high value obtained in 25 tons/ha of organic fertilizer and 30 tons/ha of mulch in plant height, number of leaves, number of tillers, leaves biomass and yield is an indicator that ginger is a soil nutrient exhausting crop and requires heavy mulching and appreciable amount of organic fertilizer to obtain high yield. Cho *et al.,* (1987) opined that the ginger yield was positively correlated with the soil organic matter content. Awodoyin and Ogunyemi, (2005) reported that mulching is an effective method of manipulating crop growing environment to increase yield and improve product quality by controlling weed growth, ameliorating soil temperature, conserving soil moisture, reducing soil erosion, improving soil structure and enhancing organic matter content. Mulching increased the germination and growth of plants in terms of height and number of tillers. Applications of leaf mulch immediately after planting and 6 weeks after using a total of 20 t/ha of green leaves resulted in 200 percent increase in yield over the nonmulched crop, and this was found sufficient in the ginger growing areas of the higher elevations of Western Ghats, South India (Nybe and Mini Raj 2005).

Table 4a: Effect of mulch and organic fertilizer application on yield (t/ha) of ginger

Treatments (t/ha)	Yield (t/ha)
Mulch (M)	
0	3.6[c]
15	6.2[b]
30	7.2[a]
Organic Fertilizer (OF)	
0	4.7[e]
10	5.1[d]
15	5.5[c]
20	6.1[b]
25	6.9[a]

Means followed by the same letter in the same column under each factors are not significantly different by Duncan Multiple Range Test at P < 0.05 (DMRT). NS = Not significant, * = significant.

Table 4b: Combined effects of mulch and organic fertilizer application on yield (t/ha) of ginger after planting

Mulch (t/ha)	Organic fertilizer (t/ha) 0	10	15	20	25	Mulch Mean
0	2.6	3.2	3.3	3.9	5.3	3.6
15	5.5	5.8	5.9	6.7	7.2	6.2
30	6.1	6.3	7.4	7.8	8.3	7.2
Organic fertilizer mean	4.7	5.1	5.5	6.1	6.9	

LSD ($P < 0.05$) for comparing effects of mulch = 0.2
LSD ($P < 0.05$) for comparing effects of organic fertilizer = 0.3
LSD ($P < 0.05$) for comparing effects of mulch x fertilizer = 0.1

Studies on the effect of mulching on crop yields are numerous. For example, Lal (1995b) on maize (*Zea mays*), and Mbagwu (2000) on maize and cowpea (*Vigna unguiculata*). For example, Mbagwu (2000) recorded 40% increase in maize grain yield when 2 t/ha mulch were added and of 80 % when 4 t/ha mulch were placed on an Ultisol in Nigeria. He concluded that 2 to 4 t/ha straw mulch are the optimal rate for increasing yields, as no significant change occurred beyond a mulch rate of 2 t/ ha and no benefits were measured from applying higher quantities. Lal (2000) also recorded the increase of maize grain and stover yields with increasing mulch rates but mentioned the limitations of this soil conservation technology as well. As significant changes in soil properties require long periods of time. This agrees with the mulching done at planting which would have been decomposed and nutrients been released slowly for plant uptake because higher microbial activity in organically amended soils is essential for nutrient transformations and increased availability of these nutrients to the plants. Increased nutrient availability in organic manure treatment could also be due to increased dehydrogenase and phosphatase activity. In general, increase in microbial biomass carbon in organic manure amended soils was due to increased availability of substrate carbon that stimulates microbial growth, but a direct effect from microorganisms added through the compost is also possible (Ramesh *et al.,* 2008). In organically managed soils, both macronutrients (N, P and K) and micronutrients (Zn, Cu, Fe, Mn) were available in larger quantities compared to the conventional soils. It is well documented that there is a significant positive correlation between organic matter and micronutrient cation availability (Ramesh *et al.,* 2009).

CONCLUSION

Mulch and organic fertilizer improved soil organic matter and soil aggregation, lowered bulk density and increased soil porosity by elimination of crust formation and improved soil moisture properties which is required for proper growth and yield quality of ginger which is a soil nutrient exhausting crop (Adeleye *et al.,* 2010).

ABSTRACT

Field experiments were conducted in Aliero area of Kebbi state; during 2019/2020 dry season at Kebbi State University of Science and Technology Aliero (KSUSTA) Orchard (lat. 12°18.64'N; long. 4°29.85'E; 262 above sea level). The aim of the experiment was to study the effect of Cucumber (Cucumis sativus L.) crop to organic and inorganic fertilizer. The treatments consist of three levels of different fertilizer (NPK 15;15;15, poultry and cow dung) plus untreated control, each were designed to supply the recommended nitrogen dose of 120kg N ha^{-1}. The treatments were laid out in a Randomized Complete Block Design (RCBD) with three replications. The plot size is 4 x 3m (12m^2). Space measuring 1.5m is left between blocks and 1m between plots. Results revealed that growth and yield parameters such as Vine length, shoot dry weight, relative growth rate, mean fruit length, fresh fruit yield tha^{-1} and Unmarketable fruits were higher with the application of either poultry manure or NPK fertilizer. It could be concluded that, the application of either poultry manure or NPK fertilizer resulted in the high growth and yield attributes of Cucumber but poultry manure recorded superior performance among the fertilizers while the least fresh fruit yield was by untreated control.

Key words: Cucumber, Poultry manure, Cow dung, NPK, Growth, Yield and Aliero

INTRODUCTION

Cucumber (*Cucumis sativus* L.) is a member of the Cucurbitaceae family which is comprised of 118 genera and 825 species. Members of this family are spread mainly in tropical and subtropical regions of the world (Wang *et al*., 2007). According FAO (2006), the most important cucurbits in terms of world total production are water melon (*Citrullus lanatus* L.), cucumber (*Cucumis sativus* L.) and melon (*Cucumis melon* L.). The world's largest cucumber producer is China with 48,000 million kilograms which is 73% of total global production. Russia is second largest producer with 1,742 million kg (2.68%) followed by Turkey, with a production of 1,600 million kg (2.46%). Spain is in the seventh place with a production of 713 million kilograms of cucumber, which is 1.09% of this vegetables' global production. The Food and Agriculture Organization of the United Nations (FAO, 2016), reported that world cucumber production in 2012 surpassed 65,000 million kg for the first time, reaching 65,134.08 million kilograms. In tropical Africa, its place has not been ranked because of limited use. Fertile soils are used for the cultivation of cucumber; infertile soils result in bitter and misshapen fruits which are often rejected by consumers.

The demand of cucumber (*Cucumis sativus L)* is on the increase due to the continued awareness of the overwhelming importance of cucumber's health benefits along with skin care. But its supply is low because of a number of factors that militate against the production of the crop. The use of organic manure constitutes a constraint to farmer, because of its bulkiness, cost of transportation and handling. This type of problem is solved through the use of either organic or inorganic fertilizer. Generally, excessive amounts of inorganic fertilizers are applied to vegetables in order to achieve a higher yield and maximum value of growth (Dauda *et al*., 2008). However, the use of inorganic fertilizers alone may cause problems for human health and the environment (Aisha *et al*., 2007). So also, the use of inorganic fertilizer by resource-poor farmers is limited by its scarcity, cost and untimely availability. Cultivation with persistent application of inorganic fertilizers increases soil acidity and soil physical degradation which may reduce crop yield (Sa'idu *et al*., 2011). On the other hand, organic manure can serve as alternative practice to inorganic fertilizers for improving soil productivity (Sarkar *et al*., 2003). The use of organic manure also has their limitations including high risk of infection, high cost of transportation and labour on account of its bulkiness as well as a slow release of nutrients for plant uptake (Adekiya *et al*., 2012). Eneje and Uzoukwu (2012) has observed, the difficulty to meet the crop's nutrient demand with sole organic manure due to the slow nutrient release coupled with limited availability of organic material in many parts of the country.

Considering the cost, unavailability at the time needed and environmental pollution effects of inorganic fertilizers, as well as slow nutrient release coupled with limited availability of organic material in many parts of the country, there is need to look for alternative way of improving soil fertility and crop productivity which are affordable and environmentally-friendly. The aim of present study is, to assess the growth and yield of Cucumber crop as influenced by poultry manure, cow dung and NPK fertilizer in the study area.

MATERIALS AND METHODS

The research was conducted at Kebbi State University of Science and Technology Aliero (KSUSTA) Orchard (lat. 12°18.64'N; long. 4°29.85'E; 262 above sea level). The area has a long dry season that is characterized by cool dry air (Harmattan) that prevails from November to February; and hot dry air extending from March to May. The location is usually used for cultivation of vegetable and cereal crops. The treatments consist of three levels of different fertilizer (NPK 15; 15; 15, poultry and cow dung) plus untreated control, each were designed to supply the recommended nitrogen dose of 120kg N ha^{-1}. The treatments were laid out in a Randomized Complete Block Design (RCBD) with three replications.

The experimental site was ploughed and harrowed in other to obtain good tilt. The land was leveled and constructed into seed beds; water channels were constructed to facilitate free and efficient water movement and uniform distribution on the plots. The plot size is 4 x 3m ($12m^2$). Space measuring 1.5m is left between blocks and 1m between plots. Each plot contained 4 ridges 1.5m apart the two inner ridges constituted the net plot, the size of plot was 42 meter by 12m and spacing of 60x40cm that is 60cm inter row spacing and 40cm intra row spacing. Prior to sowing, the seeds were treated with Apron star at the rate of 10g of the chemical per 100g of seed, in other to protect the Cucumber seeds from soil borne diseases and pests. Four seeds were sown per hole at a depth of 2 to 4cm. After two weeks of germination, the seedlings were thinned to two plants per stand.

Weeds were controlled manually using hand hoe at 3 and 6 WAS and occasional hand pulling when necessary to ensure weed free plots. Compound fertilizer (NPK 15:15:15) was used. The rates 800kg ha^{-1} and 400kg ha^{-1} were applied according to the treatments in two equal split doses. The first dose was applied at 2 weeks after sowing (WAS) and the second dose at 5 WAS. Cucumber plants were also protected against insect pests and diseases by regular spraying of appropriate mixture of *Cypermerthrin* plus dimethoate at the rate of 4ml L^{-1} of water at 10days interval prior to flowering and 5days interval continuously after flowering till maturity. Cucumber fruits for fresh consumption were harvested before they are fully mature, depending on the variety, which was between 1–2 weeks after flowering. Harvesting was done between 3 to 4 days. Data were recorded on Vine Length, Shoot dry weight, Relative growth rate, Mean fruit length, Total fruit yield tha^{-1}, and Unmarketable fruits.

RESULTS AND DISCUSSION

Soil Physical and Chemical Properties of Experimental Site

Physical and chemical properties of soils of study locations prior to the experiments are presented in Table 1. The result indicated that particle size distribution at the location was dominated by sand, with values of 63.3 and 61.7% during 2019 and 2020, respectively. For silt particles, it was 24.9 and 28.2%, respectively. Least particle size distribution was observed with clay having recorded 11.8% for 2019 and 10.1% for 2020. The soils during 2019/2020 were found to be sandy loam. This suggests that the soil in both locations has high macro porosity and low ability to retain water. Soil pH during 2019 (7.46) and 2020 (6.11) indicated that the soil during 2019 was slightly alkaline while that of 2020 was slightly acidic. Organic carbon, total N, available P and Ca were observed to be low in both locations. Exchangeable Mg was moderate, while exchangeable K and Na were higher in both 2019 and 2020.

Chemical Composition of Cow Dung (CD) and Poultry Manure (PM)

Chemical compositions of manures prior to the experiments during 2019/2020 dry season are presented in Table 2. The result indicated that, cow dung and poultry manure contained organic manure carbon (g kg^{-1}) with values of 4.13 and 4.46 while 3.26 and 3.96. Cow dung pH (7.60 and 6.94) and poultry manure (6.20 and 6.45) indicated that cow dung was slightly alkaline while poultry manure was slightly acidic. However, the result indicated that poultry manure contained high amount of total N (1.83 and 1.73mg kg^{-1}) than cow dung (1.02 and 1.09mg kg^{-1}). So also, Cow dung contained high amount of potassium (3800 and 3600mg kg^{-1}) than poultry manure (2500 and 2350mg kg^{-1}) but amount of phosphorus is higher in poultry manure (8.04 and 7.84mg kg^{-1}) than cow dung (4.51 and 4.98mg kg^{-1}). The result shows an indication of the organic manure's capability of improving the soil nutrient status.

Effect of Organic and Inorganic Fertilization on Growth

Fertilization is among the various agronomic practices that influences growth and fruit yield of cucumber. Balanced nutrient management significantly increased cucumber fruit yield. Organic manures supply nutrients as well as improving the soil physical and chemical conditions (Belay *et al*., 2001). Fertilizers (organic and inorganic) play important role in enhancing vegetative growth, starch synthesis as well as translocation. Results revealed significant effect ($P\leq0.05$) of fertilization on Vine length at 8 and 10WAS in both 2019 and 2020 presented in Table 3. At 6WAS, at 2019, application of Poultry manure significantly ($P\leq0.05$) produced the tallest plants (12.35cm) followed by the Cow dung (11.98cm) which was followed by NPK (10.29cm). Shortest plants were recorded from the untreated control (7.48cm). But at 8WAS, application of Poultry manure (37.94cm) and Cow dung (34.36cm) recorded the statistically similar height of plants followed by the application of NPK (33.11cm) while the untreated control gave significantly shorter plants (19.56cm). At 2020, at 6

ISSN: 2814-0508

and 8WAS, plant height was similar irrespective of fertilizer levels, except the untreated control which gave significantly shorter plants. This may be attributed to the higher nitrogen content of Poultry manure (Table 2) and balanced nutrients in NPK fertilizer which enhanced vegetative growth (Ahmed *et al*., 2007).

Table 3: Vine length of cucumber crop as influenced by organic and inorganic fertilization during 2019/2020 dry season

Treatment	Vine Length (cm)

A significant effect ($P \leq 0.05$) of fertilization as regard to Shoot dry weight of Cucumber was observed (Table 4) during 2019/2020 dry seasons. At 6WAS, at 2019, application of Cow dung manure significantly ($P \leq 0.05$) produced recorded the higher values (1.53g) followed by the application of poultry manure (1.50g) which in turn was higher than the application of NPK (1.22g). Lowest value was recorded from the untreated control (1.00g). But at 8WAS, application of Cow dung (3.32g) and NPK fertilizer (3.30g) recorded the statistically similar values with respect to shoot dry weight followed by the application of poultry manure (2.71g) while the untreated control gave significantly lowest values with respect to shoot dry weight (1.20g). At 2020, at 6 WAS, application of NPK significantly ($P \leq 0.05$) produced the higher values (3.02g) followed by the application of poultry manure (2.99g) which in turn was higher than the application of cow dung (2.98g). The lower values of shoot dry weight were recorded by the untreated control (2.71g). But at 8WAS, application of NPK Fertilizer (3.86g) and Poultry manure (3.69g) recorded the statistically similar shoot dry weight followed by the application of Cow dung (3.68g) while the untreated control gave significantly minimum value of shoot dry weight (2.71g). Higher values of Shoot dry weight observed with the application of Cow dung indicate that, the Cow dung mineralization aids in soil nutrient buildup which in turn leads to improved nutrient availability to crops and it also shows that the Cow dung manure was readily available in the best form for easy absorption by the plant roots which boost the growth of the cucumber plant. This observation concurs with the works of Makinde and Ayoola (2012) which reported that, the higher values of shoot dry weight obtained from plants could likely due to higher rates of manure which improved the soil conditions for crop establishment as well as released adequate nutrient elements for growth and yield components of plant.

Table 4: Shoot Dry Weight of Cucumber crop as influenced by organic and inorganic fertilization during 2019/2020 dry season.

Means followed by the same later (s) in a treatment group are not significantly different at 5% level using DMRT. *= Significant at 5%, NS= not significant. WAS= Weeks after sowing

Results revealed significant effect (P≤0.05) of fertilization with respect to Relative Growth Rate during 2019/2020 dry seasons showed in Table 5. At both 2019 and 2020, Relative growth rate was similar irrespective of fertilizer levels and the untreated control throughout the sampling period. This could be attributed to the significant role played by NPK, Poultry manure and Cow dung in the improvement of soil fertility, nutrient uptake and enhancing production of assimilates during growth. This means that the higher the nutrients applied to the soil, the higher the growth characters. This observation is consistent with works of Aduloju *et al*. (2010) who reported and attributed increased growth of crop plants to the release of more nutrient elements through the moisture that has been made available by the manure.

Table 5: Relative Growth Rate of Cucumber crop as influenced by organic and inorganic fertilization during 2019/2020 dry season.

Treatment	Relative Growth Rate ($gg^{-1}day^{-1}$)

Effect of Organic and Inorganic Fertilization on the Yield

Results revealed significant effect (P≤0.05) of fertilization with respect to Mean fruit length during 2019/2020 dry seasons showed in Table 6. At 2019, higher mean fruit length was obtained from the application of Cow dung (17.66cm) followed by the application of poultry manure (16.68cm) which in turn higher than the application of NPK (15.97cm) while the lowest mean fruit length was recorded by the untreated control (11.78cm). But at 2020 Mean fruit length was similar irrespective of fertilizer levels while the untreated control recorded the lowest value (18.59cm). This may be attributed to the higher nitrogen content of Poultry manure (Table 2) and balanced nutrients in NPK fertilizer which enhanced yield characters (Ahmed *et al*., 2007).

Table 6 Mean fruit length of Cucumber crop as influenced by Varieties during 2019/2020 dry season

A significant effect (P≤0.05) of fertilization as regard to Total Fruit yield tha^{-1} of Cucumber was observed (Table 7) during 2019/2020 dry seasons. At 2019, application of poultry manure gave a significantly (P≤0.05) higher fruits yield (4.59t ha^{-1}) followed by the application of both NPK (4.35t ha^{-1}) and Cow dung (4.28t ha^{-1}), while the untreated control recorded the lowest yield (1.58t ha^{-1}). At 2020 trial, application of NPK gave a significant (P≤0.05) higher fruits yield (16.74t ha^{-1}) followed by the application of Poultry manure (15.84t ha^{-1}) which in turn higher than the application of Cow dung (14.36t ha^{-1}), the untreated control recorded the significant lower yield (5.90t ha^{-1}). This could be attributed to the significant role played by NPK fertilizer in the improvement of soil fertility, nutrient uptake and enhancement of crop yields and the role played by Poultry manure in terms of improving the soil physical properties by reducing soil temperature and bulk density, this shows that poultry manure was readily available in the best form of easy absorption by the plant roots. This observation agreed with the work of Muhammad *et al.* (2018) who stated that, the application 120kg of N from poultry manure improves moisture availability which results in improved nutrient release to plants for increased yield. The significant positive yield response of Cucumber to NPK could likely attributed to the role of applied NPK in enhancing production of assimilates during growth and consequent partitioning of these assimilates to Cucumber fruits. Shehata *et al.* (2012) reported that higher NPK fertilizer doses resulted to increase in the uptake of N, P and K nutrients which enhanced the Cucumber yield.

Table 7: Total Fruit yield tha^{-1} of Cucumber crop as influenced by Varieties during 2019/2020 dry season

Treatment	Total Fruit yield tha^{-1}	
	2019	**2020**
Fertilizer		
Control	1.58c	5.90c
Poultry manure	4.59a	15.84a
Cow Dung	4.28b	14.36ab
NPK(15;15;15)	4.35b	16.74a
SE±	**0.66**	**0.66**

Means followed by the same later (s) in a treatment group are not significantly different at 5% level using DMRT. *= Significant at 5%, NS= not significant. WAS= Weeks after sowing

CONCLUSION

Based on the results of this study, it could be concluded that, the application of either poultry manure or NPK fertilizer resulted in the high growth and yield attributes of Cucumber but poultry manure recorded superior performance among the fertilizers while the least fresh fruit yield was by untreated control

RECOMMENDATION

From the findings of this study, it could be recommended that the application of either poultry manure or NPK fertilizer could be adopted for higher Cucumber fruit yield in the study area.

ABSTRACT

Continuous use of mineral fertilizers on tropical soils results in soil acidity and pollution of underground environment. Organic fertilizers, such as compost, are good sources of plant nutrients for sustainable crop production and healthy underground environment. Thus, the focus of this study was to evaluate the influence of different organic fertilizers on growth, yield and nutrient uptake of amaranth (Amaranthus caudatus). The experiment was conducted at the experimental field of the Wesley University, Ondo, Nigeria. The study had five fertilizer treatments viz: rice bran based compost (RBC), conventional compost (CC), moringa leaf (ML), NPK 20-10-10 and the control (no soil additive). The treatments were laid out in a Randomized Completely Block Design with three replicates. The treatments were applied at the rate of 100 kg N ha^{-1} and the effects on nutrient uptake, biomass yields, plant height, number of leaves, as well as stem girth were observed. Analysis of variance (ANOVA) was carried out and significantly different means were separated using Duncan's Multiple Range Test (DMRT) at the 5 % probability level. The results of the analyses revealed that compost treatments (RBC and CC) produced similar plant height (37.2 cm and 29.5 cm), number of leaves (26.4 and 29.5 per plant) and stem girth (11.1 cm and 10.1 cm) at 8 weeks after sowing of amaranth. However, the above values were higher than those for ML and NPK (23.6 cm and 23.6 cm), (18.5 and 22.5 per plant) and (9.3 cm and 6.1 cm) with respect to plant height, number of leaves and stem girth of the crop. Also, RBC treated soils had the highest mean fresh biomass yield of amaranth plants, leaves (0.3 kg ha^{-1}), stem (0.2 kg ha^{-1}) and root (0.2 kg ha^{-1}) while ML had the lowest fresh biomass yield; leaves (0.07 kg ha^{-1}), stem (0.04 kg ha^{-1}) and root (0.04 kg ha^{-1}). In terms of nutrient uptake, N, P and K uptake of amaranth were significantly enhanced with fertilizer treatments compared to the control. Rice bran based-compost improved nutrient uptake as much as conventional compost. RBC application resulted in highest growth and yield of green amaranth. It is therefore reasonable to recommend the use of rice bran based-compost as an alternative to the recommended NPK dose for production of amaranth.

Key words: Fertilizer materials, sandy loam, *Amaranthus caudatus*, biomass yields, nutrient uptake.

INTRODUCTION

Sustainable agriculture is, nowadays, an urgent requirement to minimize the environmental pollution that has increased as a result of unhealthy agricultural practices such as extensive use of mineral fertilizers. Mineral fertilizers are important for plant nutrition; however, they are also a potential sources of environmental pollution, particularly mineral-nitrogen (N) fertilizers. In addition, farmers are suffering from declining soil fertility and increasing soil salinization. Consequently, management of poor soil fertility in arid and semi-arid regions needs many effective solutions. The challenge of sustainable agriculture is more serious in developing countries, including Nigeria. This is due to the extensive use of mineral fertilizers, low rainfall, high evaporation rate, poor irrigation water and poor water management in these regions (Rady *et al.,* 2013). Attention is, therefore, focused on using various forms of composts as partial substitutions to mineral fertilizers. These practices have been recommended (Ojo *et al.,* 2014; Smith *et al.,* 2015) under normal or saline conditions in arid and semi-arid regions as sources of nutrients, because these soils inherently have low organic matter and low mineralization (Okusami *et al.,* 1997), due to high alkalinity and low rains. The beneficial effects of this practice in terms of improved crop productivity, soil fertility and sustainability, and balanced plant nutrition have been reported (Moyin-Jesu, 2015 and Semida *et al.,* 2015).

Agricultural dry residues such as rice bran residue and sunflower plant parts (i.e leaves and stems) are produced in large amounts as a by-product of crop productions in arid and semi-arid regions (Semida *et al.,* 2015). Majority of these agricultural residues are disposed by burning, mulched in crop fields, or discarded. In addition, some are used in animal feed, mulched in crop fields or are discarded. However, an attractive usage of all these residues/wastes is composting after they are mixed with some organic and mineral components, such as farm yard manure to produce organic composts (Akanbi *et al.,* 2007). Semalulu *et al.* (2011) had defined the composting as a biological process of aerobic decomposition, which degrades labile organic matter to carbon dioxide, water vapour, ammonia, inorganic nutrients and a stable organic material containing humic like substances. Compost has several advantages over mineral fertilizers, such as nutrient availability, uptake efficiency and quality of yields produced by crop. (Akanbi *et al.,* 2007).

Amaranth is one of the most popular vegetable crops grown in the Middle Eastern countries for human diet due to its rich source of proteins, carbohydrates, and nutrients. Its cultivation requires considerable amounts of nitrogen so that the crop can grow well, and leaves acquire the dark green color sought by consumers. Production usually involves the use of inorganic nitrogen fertilizers in quantities ≥150 kg N ha^{-1}, being one of the most critical elements in plant growth and quality (Rouphael *et al*., 2018). Nitrogen plays a significant role in biosynthesis of secondary plant metabolites such as phenols, ascorbate, and glutathione as well as antioxidant enzymes such as glutathione reductase (Ibrahim *et al.,* 2012; Argyropoulou *et al.,* 2015). Thus, cultivation of amaranth and other different crop plants under soil application with composts, as a partial alternative to mineral-NPK fertilizers, has the potential to increase crop production and soil sustainability (Abdelhamid *et al.,* 2004 and Smith *et al.,* 2015). This practice promotes higher plant growth and productivity while reducing mineral fertilizer use, crop production cost and indirectly increasing income. Therefore, the objective of this study was to assess the effects of various organic fertilizer applications on the growth, yield and nutrient uptake of amaranth plants grown on sandy loam soil.

MATERIALS AND METHODS

The trial was carried out at the Department of Agriculture, Wesley University, Ondo, Nigeria (Lat. 6°51'N and Long. 3°42'E). Ondo is located in the tropical rain forest ecological zone of Nigeria, characterized with bimodal rainfall distribution with distinct dry and rainy seasons. The zone has an average annual rainfall of 1532±227 mm over a period of 10 years (2011 to 2021), average temperature ranges of 2.2 ℃ (max. temp.; 27.8 ℃, min temp.; 25.6 ℃) and average relative humidity of 86.1% over the same period (NASA-Power, 2016). The vegetation is classified into two; low and top layers. The low layer vegetation is characterized with abundance of herbs, shrubs and grasses while the top layer is characterized with valuable economic trees such as *Chlorophora excelsa*, *Eucalyptus marginata*, *Khaya ivorensis* among others (Sowunmi and Akintola, 2010).

Rice bran compost (RBC) was prepared using windrow aeration composting method based on the standardized procedure adopted for use at the organomineral preparation plant as described (Omueti *et al*. (2000). Briefly, rice bran was measured by volume and mixed with cattle dung (CD) in ratio 1:3 inside the windrow. The rice bran was piled up in layers with CD, turned manually and sprinkled with water once in a week with moisture content maintained at 60% Field capacity (Fadare *et al*., 2000). The monitoring of the composting commenced immediately after heap building. The temperature builds up in each composting bin was measured daily at 11:00 hour with the aid of a thermometer dipped to a depth of about 0.35m in three different parts of the compost pile and the average temperature value was thereafter obtained. The pH of the pile was determined fortnightly using a pH meter in aqueous extract of 5g decomposing samples with distilled water at solid: water ratio of 1:4 (w.v) according to Guerra-Rodriguez *et al*. (2000) and Banout *et al*. (2008). At eight weeks when the temperature of the pile dropped to that of ambient temperature and remained relatively constant over a period of two weeks, compost samples were randomly taken from the pile, homogenized and labeled.

The conventional compost used as a check was also a company's product, obtained from Alesinloye Compost Company, Alesinloye market, Ibadan, Oyo State, Nigeria. Moringa leaves were harvested at the Department of Agronomy, University of Ibadan, Nigeria and then air dried for five days to reduce the moisture content. Chemical analyses of the composts and moringa leaves (Table 1) were carried out using standard procedures (Okalebo *et al.,* 1993; Bremner, 1996; Thomas, 1996).

Table 1. Chemical analysis of the composts and moringa leaf

The physical and chemical analyses of the pre-treated soil was also carried out using standard procedures (Hendershot and Lalande, 1993; Bremner, 1996; Nelson and Sommers, 1996; Thomas, 1996; Gee and Or, 2002) and are shown in Table 2. The Wesley University Ondo soil was low in N, P and organic carbon, but marginal in K (FFD, 2012). The textural class was sandy loam based on USDA textural triangle (Soil Survey Division Staff, 1993).

The treatments applied were rice bran-based compost (RBC), conventional compost (CC), moringa leaves (ML) and NPK 20-15-15 mineral fertilizer at 100 kg N ha^{-1} each. All the fertilizer materials were milled into powder before application. The amaranth variety planted was obtained from National Institute of Horticultural Research (NIHORT), Ibadan, Nigeria and the design was randomized complete block replicated three times to give 15 experimental plots. Each plot size was $2m^2$. Seeds of green amaranth were drilled in 20 cm rows and thinned to one plant per stand two weeks after sowing, giving a plant population of 55 stands per plot. The inter-row spacing was also 20 cm equivalent to 250, 000 plants/ha. The compost treatments were applied a week before sowing while the inorganic fertilizer was applied at one weeks after sowing (WAS) and weeding was carried out as necessary. Data were collected on growth parameters; plant height (cm), number of leaves/ plant, stem girth (cm) at 4, 6 and 8 WAS and biomass (fresh and dry yields). At 8 WAS, the roots were carefully removed and washed. Thereafter, root, leaves and stem were oven-dried at 70°C until constant weight. After oven drying, the materials were milled and analyzed for N, P and K concentrations.

Nutrient uptake in leaves was calculated using the formula: Nutrient uptake = % nutrient concentration x dry matter yield ($kgha^{-1}$).

Data were statistically analyzed and significantly different means were separated by Duncan's Multiple Range Test (DMRT) at 5 % probability level.

RESULTS

Effects of various organic fertilizers on amaranth plant height, number of leaves and stem girth.

The result showed significant differences among the treatment means for all the parameters (Table 3). The result of the fertilizer treatment on height, number of leaves and stem girth of amaranth are presented in Table 3. With respect to the plant height, the result showed that there were significantly differences ($p<0.05$) among the treatment means in 4, 6 and 8 weeks after sowing (WAS). At 4 WAS, the RBC gave the highest mean plant height (21.9 cm) which was significantly taller than CC (17.5 cm), ML (14.9 cm) and NPK (13.8 cm). The control gave the shortest plant (10.2 cm). However, at 6 WAT, RBC gave the highest mean plant height (32.6 cm) which differ significantly from other treatments apart from CC (25.3 cm) while the control gave the significantly lowest plant height (12.4 cm). A similar result was obtained at 8 WAT.

In terms of number of leaves, at 4 WAT, RBC gave the highest mean number of leaves (15.3) which differ significantly from other treatments. The control treatment resulted into significantly lowest mean value of number of leaves (8.4). However, at 6 WAT, RBC gave the highest number of leaves (23.1) which differ significantly from other treatments apart from CC (20.2) while the control gave the significantly lowest number of leaves (9.4). A similar result was obtained at 8 WAS.

The result obtained in stem girth showed that at 4 WAS, RBC gave the highest mean value of (7.5 cm) stem diameter which did not differ significantly from CC (6.5 cm) but significantly higher than ML (5.2 cm), NPK (4.0 cm) and control (2.5 cm). At 6 WAT, RBC still gave the highest mean stem diameter of amaranth (10.5 cm) which was not significantly different from ML (9.2 cm) but higher than others. The control treatment resulted into significantly lowest mean value of stem diameter (3.5 cm). At 8 WAT, there were significant differences ($p<0.05$) among the treatment means. The RBC still gave the highest mean stem diameter (11.1 cm) which was not significantly different from CC (10.1 cm) but significantly higher than other treatments.

Table 3: Effects of fertilizer treatment on growth performance of Amaranth at different weeks after planting

Treatment	Plant height (cm)			Number of leaves			Stem girth (cm)		
	WAS								
	4	6	8	4	6	8	4	6	8
Control	10.2d	12.4c	15.2c	8.4d	9.4c	12.3c	2.5b	3.5c	3.9c
Rice-bran based compost	21.9a	32.6a	37.2a	15.3a	23.1a	26.4a	7.5a	10.5a	11.1a
Conventional compost	17.5b	25.3a	29.5a	13.5b	20.2a	23.6a	6.5a	8.7b	10.1ab
Moringa leaf	14.9bc	19.7b	23.6b	11.8c	14.9b	18.5b	5.2b	9.2ab	9.3b
NPK (20:10:10)	13.8c	19.5b	23.6b	10.8c	14.1b	22.5b	4.0b	5.5c	6.1c

Means with the same letter (s) in the column are not significantly ($p<0.05$) using Duncan's Multiple Range Test.
WAS= weeks after sowing

Effects of various organic fertilizers on amaranth fresh and dry biomass yield.

The result showed that there were significantly differences ($p<0.05$) among the treatment means across all the parameters (Fig. 1). With respect to fresh biomass yield, RBC produced the highest mean of fresh weight of leaves (0.3 $kgha^{-1}$) which was significantly different from others, while the control gave the lowest significant fresh weight of leaves (0.03 $kgha^{-1}$). It was also noted that in both fresh root and stem, RBC performed significantly than other treatments. With dry biomass yield (Fig. 2), RBC gave the highest mean value (0.04 $kgha^{-1}$) of dry weight of leaves which was significantly different from other treatments. The control gave the lowest (0.005 $kgha^{-1}$) significant value. A similar result was obtained in dry root and stem.

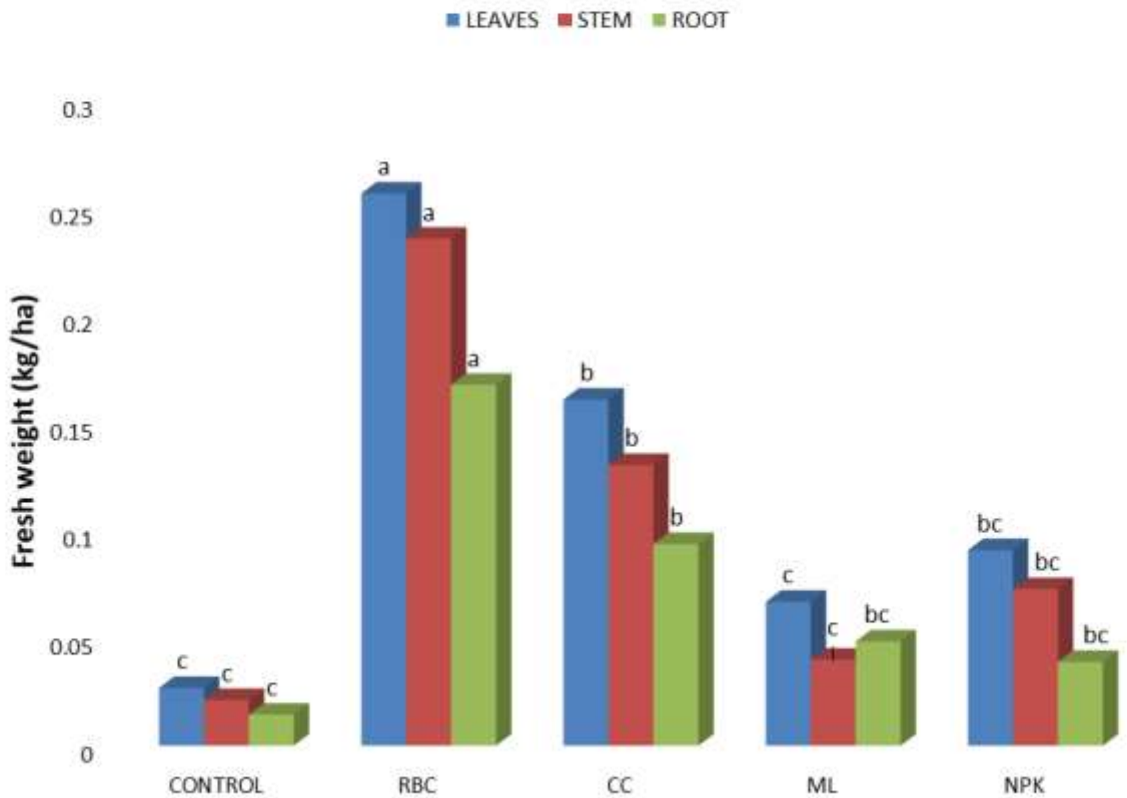

Figure 1: Effects of the treatments on fresh biomass yield
Legend: RBC= Rice bran based compost, CC= Conventional compost, ML= Moringa leaves, NPK= NPK 20 - 10 - 10. Means with the same alphabet are not significantly different at p<0.05

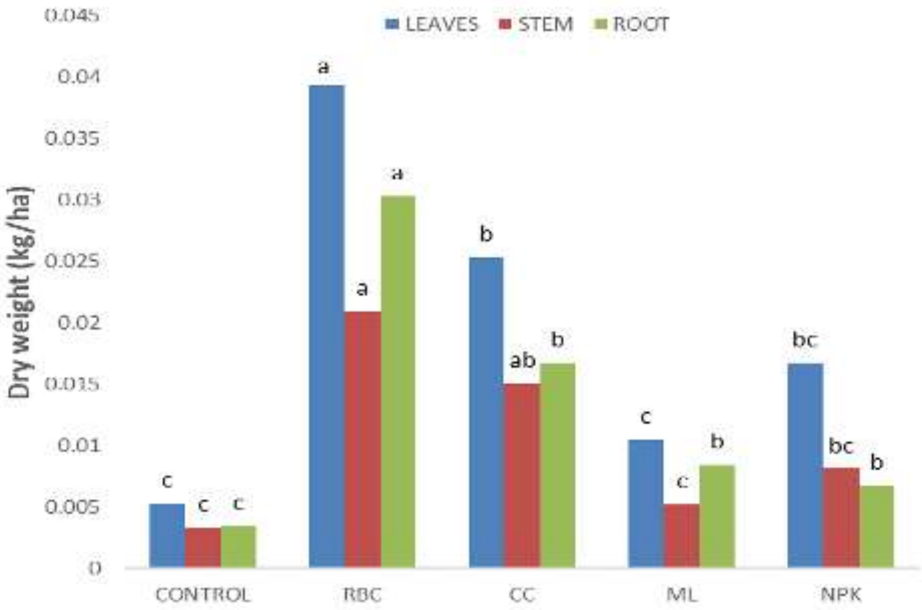

Figure 2: Effects of the treatments on dry biomass yield
Legend: RBC= Rice bran based compost, CC= Conventional compost, ML= Moringa leaves, NPK= NPK 20 - 10 - 10. Means with the same alphabet are not significantly different at $p<0.05$

Nitrogen, Phosphorus and Potassium concentration (gkg^{-1}) and uptake ($kgha^{-1}$) in the amaranth leaves at 8 weeks after transplanting as influenced by various organic fertilizers.

The result of the N, P and K concentrations and uptake in the tissue of the amaranth plants due to the different fertilizer treatments is shown in Table 4. With the nitrogen content, RBC gave the highest nitrogen content (39.3 gkg^{-1}) which was not significantly different from CC (32.1 gkg^{-1}). However, ML (28.2 gkg^{-1}) was not significantly different from NPK (24.9 gkg^{-1}) which was significantly higher than the control (3.1 gkg^{-1}). However, application of organic fertilizers showed no significant differences in the nutrient contents of phosphorus and potassium.

With the nitrogen uptake, RBC treatment gave the highest nitrogen uptake (1.5 $kgha^{-1}$) which was not significantly different from CC (0.8 $kgha^{-1}$). However, ML (0.3 $kgha^{-1}$) and NPK (0.4 $kgha^{-1}$) were not significantly different from one another and that of control gave the lowest nitrogen uptake (0.01 $kgha^{-1}$). In phosphorus and potassium uptake, RBC gave the highest value (0.4 and 1.3 $kgha^{-1}$). Also, the result showed no significant difference among the CC, ML and NPK in phosphorous and potassium uptake.

Table 4: Nutrient content (gkg^{-1}) and uptake ($kgha^{-1}$) of amaranth as influenced by organic fertilizers.

Treatment	Nutrient content (gkg^{-1})			Nutrient uptake ($kgha^{-1}$)		
	N	P	K	N	P	K
Control	3.1c	10.5	32.2	0.1c	0.1c	0.2c
Rice-bran based-compost (RBC)	39.3a	10.9	32.9	1.5a	0.4a	1.3a
Conventional compost (CC)	32.1ab	9.33	35.2	0.8a	0.2b	0.9b
Moringa leaf (ML)	28.3b	10.7	34.0	0.3bc	0.2b	0.4c
NPK (20:10:10)	24.9b	11.8 ns	34.2 ns	0.4b	0.2b	0.5bc

ns: not significant. Means with the same letter(s) in a column are not significantly different at 5 % level of probability by Duncan Multiple Range Test (DMRT).

DISCUSSION

Adding compost to the soil increased the crop yields compared to the mineral fertilizer and control. This increase was a function of the dose of compost applied and shows the importance of the use of organic matter, in particular RBC recognized to be rich in nutrients. The obtained yields with the soil show that with the use of compost, it is possible to sustainably increase the yields of amaranth. The results indicate that the applied compost has the potential to be used as a fertilizer. The results indicate that the most effective compost was obtained from RBC. A number of reports illustrated that composts obtained from solid organic waste are capable to increase nutrient supply and meet subsequent plant demand in soil (Iglesias-Jimenez and Alvarez, 1993; Mylavarapu and Zinati, 2009). Moreover, sufficient amount of cowdung which serve as nitrogen source was present in the compost and it increased the morphological growth and development of vegetables. In this study, RBC exhibited a significant influence on growth characteristics of vegetables at different growth period. The improved growth characteristics of amaranth plants produced as a result of RBC could be attributed to the enhanced decomposition of the RBC and mineralization of nutrients (Abdelhamid *et al.*, 2004; Ojo *et al.,* 2014). In unfertilized soil, amaranth plants did not grow well. The leaves of the plants were very small and chlorotic presenting a yellowish color, probably due to nitrogen deficiency. The addition of organic compost to soil significantly increased the plant growth. Weinfurtner (2001) also reported a positive effect of organic compost on yield.

However, plants grown only with NPK and ML had lesser biomass yields (fresh and dry weights) than those grown with composts. The high increase in biomass yields due to the addition of RBC could be related to the increase of availability of nitrogen source (cowdung) throughout the growing season. The high biomass (fresh and dry yields) in treatments with RBC and CC applications, shown that amaranth yield is very dependent on the nitrogen source that is embedded in the composts. Therefore, this can be a strategy to reduce greenhouse emissions due to the use of the compost, as pointed out by Gruda (2019). It also indicates that the application of composts allowed obtaining a high amaranth biomass yields. Also Xu *et al.* (2005) in a study on yield and quality of leafy vegetables grown with organic fertilizers reported that vegetables grown with organic fertilizers grew better and resulted in a higher total yield than those grown with chemical fertilizers. Similar result was also found in a study by Magkos *et al.* (2003) who evaluated the dry matter yields of several vegetables and found that organically cultivated crops had higher yields than those grown conventionally.

Application of fertilizer increase the supply of nutrients which ultimately result in greater nutrient uptake. Plant growth and development depend on nutrient supply and in general enhances good yield. The findings with regard to nutrient uptake by amaranth revealed that the uptake of N, P and K were higher with the application of composts and NPK but least with control plants indicating short supply of these nutrient elements to amaranth in the control plots. This is in agreement with the findings of Kayode *et al.,* (2018) that the application of compost improved N, P and K uptake of amaranth. The application of nitrogen led to an increase in leaf nutrient concentration of N. Leaf N concentration in plants of the RBC was 73% higher than in the plants fertilized with nitrogen fertilizer. The increase in leaf nitrogen concentration may be related to an increase in the availability of nitrate in root medium, since is know that when the nitrate is taken by plants roots, nitrogen uptake is enhanced (Jones, 2016). In the case of leaf P, concentrations were above the sufficiency range. This was probably due to the high availability of P in soil and the addition of organic compost to the soil. The addition of organic compost to soil can increase water-extractable soil P by direct addition, dissolution, displacing sorbed, or reducing sorption capacity for P (Adler and Sikora, 2003). Organic matter is a source of phosphorus and it may reduce P sorption (Gorgin *et al.,* 2011). It may increase P uptake by plants since it forms complexes with organic phosphate and increases the volume of soil that plant roots explore (Ouni *et al.,* 2014). In spinach, Maftoun *et al.*, (2005) also reported that the addition of municipal waste compost to soil led to an increase in P uptake. While the highest K uptake was observed in plots that received recommended rates of RBC but not significantly different from the applied CC.

CONCLUSION

The result revealed that the performance of RBC followed the same pattern across the plant growth and with no significant difference in CC. Amaranth growth increased with inorganic fertilizer application but was not affected by nitrogen source of ML. RBC led to an increased in fresh and dry biomass yields and nutrient uptake of amaranth plants. NPK and ML had no influence in the biomass yields and nutrient uptake. RBC is a veritable source of plant nutrition. It is easily available, affordable and harmless to soil ecosystem. It would be best to use RBC for crop production to minimize the harmful effects of NO_3^- to humans from the use of NPK. The RBC showed promise, as an alternative to recommended dose of NPK fertilizers, for amaranth production and also for the benefits of human nutrition and health. It is therefore reasonable to recommend the use of rice bran based-compost (RBC) as an alternative to the recommended NPK dose for production of amaranth.

ABSTRACT

This study was carried out to determine the effects of different rate of liquid organic fertilizer (SuperGro) on the growth and yield of chili pepper (Capsicum annum). The experiment was laid out on Randomized Complete Block Design with four experimental treatments replicated three times. The treatments were applied at 2days, 2 weeks, 4 weeks, and 6 weeks after transplanting. Data collected were plant height (cm), number of leaves, number of branches, stem girth (mm), days to 50% flowering, weight of fruit (kg), number of fruits, length of fruit (cm) and width of fruits (cm). The results of the data collected and analyzed shows that supergro at rate of 2ml/3litres of water per plot had the highest yield, growth performance and cost effective than other treatments therefore it is recommended for the production of chili pepper in Ikorodu, agroecological zone, Lagos State.

Key words: liquid organic fertilizer, SuperGro, chili pepper, growth and yield.

INTRODUCTION

One of the main problems faced by the pepper farmers is the high cost of production due to the use of inorganic fertilizers (Smith, 2015). Plant growth and development are dependent on supply of nutrient, availability of nitrogen and phosphorous are among the major limitations for crop production (Murphy *et al.,* 2017), which is aggravated under environmental stresses, mainly water stress. Application of chemical fertilizers alone can supply only one or two nutrient elements to the crop. On the other hand, supplying only organic inputs can improve soil physical and biological environment but suffers from drawback of low content of plant nutrients (Weider *et al.,* 2015). However, in the modern days, when agriculture is motivated not only for production, but also accounts for the sustainability of all the resources including soil for the generations to come. Consequently, the yield of the crops is declined. Super Gro is a natural liquid fertilizer which was developed to ensure the enhancement of crops and agricultural productivity both in quality and quantity. It is a natural fertilizer that increase agricultural yield more compare to synthetic or chemical fertilizer. Super Gro is a 100% organic liquid fertilizer, which is made from poultry droppings and sea bird guano. Being made from organic matter with absolutely no chemicals added to it, it is 100% safe to use on any vegetables or crop. Super Gro can be applied to any plant, tree, vegetable and even grass that require fertilization (Super Gro User manual). The use of chemical fertilizers has been many times reported for degrading soil and water resources. Moreover, organic farming is both a philosophy and a system of agriculture, which avoids or largely excludes the use of synthetically produced fertilizers, pesticides and to the maximum extent possible relies upon crop rotations, crop residues, animal manures, legumes, green manures, off farm organic wastes, mineral bearing rocks and bio-fertilizers to maintain soil productivity and to supply plant nutrients (Mitchell *et al.,*2016). In this context, this study is aim to investigate the response of growth and yield performance of chili pepper as affected by different rates of liquid organic fertilizer under Ikorodu agro-ecological zone.

MATERIALS AND METHODS

Experimental location, land preparation, experimental design and treatments

The experiment was carried out at the Teaching and Research Farms of Lagos State Polytechnic, Ikorodu, Lagos State Nigeria. The experiment was laid out in a Randomized Complete Block Design (RCBD) on a total area of land measuring 159.5m^2 which was divided into 3 blocks of 14.5m x 3m (43.5m^2), each plot size was 3m x 3m (9m^2) to give a total number of 12plots. Liquid organic fertilizer (Super Gro) was obtained from NEOLIFE NIG. LTD located at Makoko, Lagos and applied to the plant using foliar application at 2DAT (Days After Transplanting) and 2WAT (Weeks After Transplanting). That is, fertilizer was applied directly to the foliage (leaves) in a liquid form using garden hand sprayer of about 5Litres tank capacity at 2weeks interval.

Crop establishment and maintenance

Chili pepper seeds were obtained from an open market, Sabo, Ikorodu, Lagos. Seeds were sown in the nursery using broadcasting method of sowing and were later transplanted into the main field of cultivation using dibbling method of sowing with spacing of 0.6m x 0.5m to give total number of 30 plant stands (Smith, 2015). Manual weeding was carried out at three (3) weeks interval. Pest and disease were controlled using Cypermethrin (insecticide) and Z-Force (Fungicide) at two (2) weeks interval to ensure effective chemical control on devastating pest and fungi disease. In addition, good sanitation was implemented throughout the study so as to avoid entrance of pathogen in the study area (Smith, 2015).

Data collection and Statistical Analysis

Eight (8) plant stands was randomly sampled and tagged per plot for data collection. Data were collected at 2, 4, 6 and 8WAT (Weeks After Transplanting). Data that were collected include:

Growth Parameters; number of leaves. plant height (cm), stem girth (mm), and number of branches. Yield Parameters; days to 50% flowering, length of the fruits (cm), fruits diameter (mm), weight of fruits per plot (kg).

Data collected were subjected to Analysis of Variance (ANOVA), and means of treatments were compared using Duncan Multiple Range Test (DMRT) at 5% level of probability using SAS (version 9.4).

RESULTS

Effects of supergro application rate of *Capsicun annum* on number of leaves, stem girth and plant height at 2, 4, and weeks after transplanting

Statistical analysis showed that there was no significant effect of the treatments on number of leaves of Chili pepper. Table 4.1 showed that Chili pepper plants grown with 2ml/3Lwater of super grow produced the highest mean number of leaves (8.44) at 2 WAT, followed by 8.39 mean number of leaves obtained from Chili pepper plants grown with 2ml/2L of water of supergro. The least mean number of leaves (8.00) was obtained from Chili pepper plants grown with 2ml/1.5Lwater of supergro.

The different application rates of supergro did not significantly influence the stem girth of Chili pepper. Table 1 revealed at 2 WAT, that Chili pepper treated with 2ml/3Lwater of supergroproduced the thickest mean stem girth of 1.62 mm, while the least mean stem girths of 0.37 mm, was produced by Chili pepper plants treated with no supergro.

There was also no significant effect of supergro application rate on plant height of Chili pepper. It was shown in table 1 that Chili pepper plants grown with 2ml/3Lwater of super grow produced the tallest plants with mean value of 8.51 cm at 2 WAT, followed by 8.07 cm mean plant height obtained from Chili pepper plants grown with 2ml/1.5Lwater of supergro. The least mean plant height (6.84) was obtained from Chili pepper plants grown with no supergro application.

Table 1: Effects of supergro application rate of *Capsicum annum* at 2 weeks after Transplanting

Manure Types	No. of leaves	Stem girth (cm)	Plant height (cm)
2ml/3Lwater	8.44	1.62	8.51
2ml/2Lwater	8.39	1.09	7.30
2ml/1.5Lwater	8.00	0.48	8.07
No application	8.06	0.37	6.84
Significance	NS	NS	NS

Statistical analysis showed that there was no significant effect of the treatments on number of leaves of Chili pepper. Table 2 showed that Chili pepper plants grown with 2ml/3Lwater of super grow produced the highest mean number of leaves (15.97) at 4 WAT, followed by 15.17 mean number of leaves obtained from Chili pepper plants grown with 2ml/1.5Lwater of supergro. While the least mean number of leaves (13.43) was obtained from Chili pepper plants grown with no supergro application.

The different application rates of supergro did not significantly influence the stem girth of Chili pepper at 4 WAT. Table 2 revealed at 4 WAT, that Chili pepper treated with 2ml/2Lwater of supergroproduced the thickest mean stem girth of 2.05 mm, while the least mean stem girths of 1.38 mm, was produced by Chili pepper plants treated with no supergro application.

There was a significant difference in the effects of Supergro application rates on number of branches of Chili pepper plants at 4 WAT. However, Chili pepper grown with 2ml/2Lwater of supergrosignificantly produced the highest mean number of branches (3.40) than 3.37 and 3.11 mean number of branches produced by Chili pepper plants treated with 2ml/1.5Lwater of supergro and with no supergro application respectively. The least mean number of branches was produced by chili pepper treated with 2ml/3Lwater of supergro.

There was also no significant effect of supergro application rate on plant height of Chili pepper. It was shown in table 2 that Chili pepper plants grown with 2ml/3Lwater of super grow produced the tallest plants with mean value of 13.44 cm at 4 WAT, followed by 12.96 cm mean plant height obtained from Chili pepper plants grown with 2ml/1.5Lwater of supergro. The least mean plant height (11.02) was obtained from Chili pepper plants grown with no supergro application.

Table 2: Effects of supergro application rate on the growth of *Capsicum annum* at 4 weeks after Transplanting

Manure Types	No. of leaves	Stem girth (cm)	No. of branches	Plant height (cm)
2ml/3Lwater	15.97	1.60	2.51b	13.44
2ml/2Lwater	13.87	2.05	3.40a	11.63
2ml/1.5Lwater	15.17	1.88	3.37ab	12.96
No application	13.43	1.38	3.11ab	11.02

Values represent treatment means. Means were separated using Duncan multiple range test and means within a column followed by different letters are significantly different at P≤0.05.

Statistical analysis showed that there was no significant effect of the treatments on number of leaves of Chili pepper. Table 3 showed that Chili pepper plants grown with 2ml/3Lwater of super grow produced the highest mean number of leaves (40.17) at 6 WAT, followed by 36.73 mean number of leaves obtained from Chili pepper plants grown with 2ml/1.5Lwater of supergro. While the least mean number of leaves (28.94) was obtained from Chili pepper plants grown with no supergro application.

The different application rates of supergro did not significantly influence the stem girth of Chili pepper at 6 WAT. Table 3 revealed at 6 WAT, that Chili pepper treated with 2ml/2Lwater of supergroproduced the thickest mean stem girth of 2.86 mm, while the least mean stem girths of 2.05 mm, was produced by Chili pepper plants treated with no supergro application.

There was no significant difference in the effects of Supergro application rates on number of branches of Chili pepper plants at 6 WAT. However, Chili pepper grown with 2ml/2Lwater of supergroproduced the highest mean number of branches (7.41) than 6.39 mean number of branches produced by Chili pepper plants treated with 2ml/3Lwater and2ml/1.5Lwater of supergro. The least mean number of branches (5.48) was produced by chili pepper treated with no supergro application.

There was also no significant effect of supergro application rate on plant height of Chili pepper. It was shown in table 3 that Chili pepper plants grown with 2ml/1.5Lwater of super grow produced the tallest plants with mean value of 20.87 cm at 6 WAT, followed by 16.60 cm mean plant height obtained from Chili pepper plants grown with 2ml/3Lwater of supergro. The least mean plant height (16.20) was obtained from Chili pepper plants grown with no supergro application.

Table 3: Effects of supergro application rate on the growth of *Capsicum annum* at 6 weeks after Transplanting

Manure Types	No. of leaves	Stem girth (cm)	No. of branches	Plant height (cm)
2ml/3Lwater	40.17	2.56	6.39	16.60
2ml/2Lwater	33.09	2.86	7.41	16.57
2ml/1.5Lwater	36.73	2.65	6.39	20.87
No application	28.94	2.05	5.48	16.20
	NS	NS	NS	NS

Values represent treatment means. Means were separated using Duncan multiple range test and means within a column followed by different letters are significantly different at P≤0.05.

Effects of supergro application rate of *Capsicum annum* on number of days to 50% flowering

Table 4 showed that there was no significant difference in the effects of supergro application rate on number of days to 50% flowering. However, *Capsicum annum* grown with no supergro application had the shortest days to flowering of mean value 46 days, followed by Chili pepper plants grown with 2ml/3Lwater of supergro which had 46.33days as mean number of days to 50% flowering. While the mean longest days to 50% flowering (47.33 days) was observed from Chili pepper plants grown with 2ml/2Lwater and 2ml/1.5Lwater of supergro.

Effects of supergro application rate on number of fruits of *Capsicum annum*

Chili pepper grown with 2ml/3Lwater of supergro significantly produced the highest number of fruits with mean value of 15.67 than 5.67 mean number of fruits obtained from Chili pepper grown with 2ml/1.5Lwater of supergro which was also significantly different from 3.33 and 1.33 mean number of fruits obtained from Chili peppergrown with no supergro application and 2ml/2Lwater (Table 4).

Effects of supergro application rate on fruit length(cm) of *Capsicum annum*

There was no significant difference among the treatment means of fruit length. Chili pepper grown with 2ml/3Lwater of supergro produced the longest fruits with mean value of 7.05 cm, followed by 2.88 cm mean fruit length obtained from 2ml/1.5Lwater of supergro -grown Chili pepper. The shortest fruits with mean value of 1.91 cm was obtained from Chili pepper grown without supergro application (Table 4).

Effects of supergro application rate on fruit width (cm) of *Capsicum annum*

Chili pepper grown with 2ml/3Lwater of supergro produced the fattest fruit with mean value of 3.86 mm, followed by 2.82 mm mean fruit width obtained from Chili pepper grown with 2ml/1.5Lwater of supergro which was not significantly different from 2.39 mm and 1.85 mm mean fruit width obtained from Chili pepper grown with 2ml/2Lwater and no supergro application (Table 4).

Effects of supergro application rate on fruit yield (kg) of *Capsicum annum*

Chili pepper grown with 2ml/3Lwater of supergro produced the highest fruits weight with mean value of 0.14 kg/plot, but not significantly different from 0.02 kg/plot mean fruits weight obtained from 2ml/1.5Lwater of supergro -grown Chili pepper and the least fruits weight with mean value of 0.01 kg/plot was obtained from Chili pepper grown with 2ml/2Lwater and without supergro application.

Table 4: Effects of supergro application rate on yield component of *Capsicum annum*.

Application rate	Days to 50% Flowering	NF	FL (cm)	FD (mm)	FWg (kg)
2ml/3Lwater	46.33	15.67	7.05	3.86	0.14
2ml/2Lwater	47.33	1.33	2.35	2.39	0.01
2ml/1.5Lwater	47.33	5.67	2.88	2.82	0.02
No application	46.00	3.33	1.91	1.85	0.01
	NS	NS	NS	NS	NS

DISCUSSION

This study revealed that the agronomic growth and yield of Chili pepper were not significantly affected by the different rates of supergro application used in this study except number of branches at 4 weeks after Transplanting and number of fruits. However, the differences observed among the growth and yields could therefore be implicated by the effects of other possible factors such as spatial variation in soil fertility and other soil properties, but not the application rates effects of supergro (Gulser 2015).

The non-significance is however in contrast with the findings of Toonsiri *et al*. (2016) who observed significant difference in the growth and yield of plants as affected by liquid fertilizers application.

CONCLUSION

It can be concluded statistically, based on the outcome of this study that no application rate of super gro among the rates experimented is better than the other.

RECOMMENDATION

It can be recommended base on the performance of the *Capsicum annum* plants to the 2ml/3Lwater of supergro in terms of yield and other growth be adopted for use. Although, there were no significant differences in the effects of the three supergro application rates tested in this study.

ABSTRACT

This study was carried out at the Department of Crop Science Teaching and Research Farm, Faculty of Agriculture, University of Nigeria, Nsukka to evaluate early growth pattern of four accessions of Saba sourced from Kabba, Okoro, Unosi and Oforachi in Kogi State in response to seven fertilizer rates in the nursery. The experiment was a 4x7 split plot in CRD with five replications. Data collected were: vine length, number of leaves and number of branches at 2, 3, 4, 5, 6 and 7 months after transplanting (MAT). Analysis of variance results indicated Oforachi accession had the longest vine (19.9 and 27.4 cm) at 2 and 3 MAT, respectively. More leaves (6.9) was obtained from Kabba accession at 2 MAT which was statistically similar with 6.8 recorded from Unosi. At 3 MAT, Unosi took the lead with 12.6. Unosi had more number of branches (1.4, 4.8 and 5.6) at 3, 6 and 7 MAT, respectively. Application of 50 t ha^{-1} of PM produced the longest vine (19.9 and 45.9 cm) at 2 and 5 MAT. Application of 40 t ha^{-1} of PM had more branches (5.0) at 6 MAT but similar with 4.8 obtained from 50 t ha^{-1}. However, application of 40 and 50 t ha^{-1} of PM produced more branches (6.1) at 7 MAT. Conclusively, Unosi accession had more number of leaves and highest number of branches and could be recommended for famers. Application of 50 t ha^{-1} of PM that enhanced better growth could be appropriate for Saba seedling.

Key words: Accession, *Saba senegalensis*, fertilizer rates, growth

INTRODUCTION

Saba senegalensis is an African indigenous large, woody plant that belongs to the family Apocynaceae (Arbonnier, 2000). It is found in the wild of Africa and distributed across Nigeria, Burkina Faso, Côte d'Ivoire, Gambia, Guinea, Guinea-Bissau, Ghana, Mali, Niger, Senegal, and Tanzania (Fatim *et al.,* 2019). It is a climber that usually seeks support from other plant species to rest upon and grow, but the seeds germinate in places where there is no support and therefore the plant manages to grow at the place where it sprouted (Baiyeri *et al.,* 2019). In Nigeria, it is found largely in North central and Southern parts of the country (Baiyeri *et al.,* 2019). It is known as 'Utu' by the Igbo of southeastern Nigeria, 'Ibo' by Okun-Yoruba of north central Nigeria (Baiyeri *et al.,* 2019).

It is an acidulous fruit that is very popular with the population; it is tasty, sweet sour with yellow pulp when ripe and can be consumed as such or can be processed into puree, nectar, jams and preservers (Arbonnier, 2000 and Tanor, 2001). The fruit is rich in vitamin A, vitamin C, dietary fiber and contains minerals such as potassium, magnesium and calcium (Omale *et al.,* 2010; Fatim *et al.,* 2019). The presence of active compounds in *Saba* fruit could play an important role in the prevention and treatment of certain vitamin deficiencies and metabolic diseases (Kini *et al.,* 2008). In some West African nations, it can be mashed and used for porridge (Bandoma, 2009). The latex is used to treat pulmonary diseases and tuberculosis; the leaves can cure chronic headache, wounds, food poisoning and vomiting (Kerharo, 1964 and Baiyeri *et al.,* 2019). It also has the potential of contributing to soil and water conservation (Baiyeri *et al.,* 2019).

Despite the importance of *Saba senegalensis*, the crop has not been brought under cultivation like the other indigenous species in Nigeria due to lack of adequate knowledge on their propagation, fertilizer requirement, climatic requirement, agronomic practices and pests. Yield of any crop is determined by its nutritional requirements and sustaining the yield and quality of a new crop requires appropriate crop management practices, especially soil fertility management (Ani and Baiyeri, 2008; Ndukwe and Baiyeri, 2020). Soil nutrients could be supplied in organic or inorganic form (chemical fertilizers and lime) and in combinations (Aba *et al.,* 2020). It has been established that soil amendments using both organic and inorganic sources (otherwise known as integrated plant nutrition system) supports the best crop performance (Shiyam *et al.,* 2010; Osundare *et al.,* 2015). The combined application of manure with mineral fertilizers supports the prompt release of applied nutrients to satisfy crop nutrient demand (Mohammed, 2002). However, to the best of our knowledge, this is the first report on growing of Saba seedlings under different fertilizer rates in Nigeria. Therefore, investigations into Saba fertilizer requirement in the nursery can provide valuable information that can encourage the domestication of this wild species for commercial cultivation and prevent it from going into extinction. Therefore, the objective of this study was to determine the effect of organic and inorganic fertilizers on early growth pattern of *Saba senegalensis* in the nursery.

MATERIALS AND METHODS

Experimental site: The experiment was conducted in the Department of Crop Science teaching and research farm of University of Nigeria, Nsukka (07° 29'N, 06° 51'E, and 400 m above mean sea level). A study (Uguru *et al.,* 2011) characterized Nsukka to have lowland humid tropical conditions with bimodal annual rainfall distribution, which ranges from 1155 to 1955 mm with a shift in the second peak of rainfall from September to October. A mean annual temperature of 29°C to 31°C and relative humidity that ranges from 69 to 79% also prevail in Nsukka.

Collection of plant material: Fully matured Saba fruits (see Fig. 1) for the study were harvested from the wild in four Local Government Areas (LGAs), they are Kabba in Kabba Bunu LGA, Okoro in Ijumu LGA, Unosi in Ajaokuta LGA and Oforachi in Igala Mela/Odollu LGA of Kogi State. The fruits from each location were collected from different liana in the same forest. After the seeds were extracted, the seeds were planted in pre-nursery and after emergence, thirty-five uniformly sized seedlings per accession was transplanted into the nursery in October 2020 where polyethylene bag of size 48 x 38.5 cm was used for each seedling. The polyethylene bags were filled with 12.0 kg soil and doubled for reinforcement. The experiment was a 4x7 split plot in CRD with five replications. The main plot were the seven fertilizer application rates (0 t ha^{-1}, 20 t ha^{-1} of PM + 200 kg ha^{-1} of NPK (20:10:10), 30 t ha^{-1} of PM, 30 t ha^{-1} of PM + 100 kg ha^{-1} of NPK, 30 t ha^{-1} of PM + 150 kg ha^{-1} of NPK, 40 t ha^{-1} of PM and 50 t ha^{-1} of PM) and the sub plot were the four accessions of Saba (Kabba, Okoro, Unosi and Oforachi). Equivalent weights of poultry manure rates were proportioned by referring the weight of the potting medium to the weight of sliced furrow of one hectare (2 242 000 kg) and multiplying by the chosen rate per hectare. Fertilizers were applied at the required quantity one month after transplanting to the nursery.

Data collected were: vine length, number of leaves and number of branches at 2, 3, 4, and 5 months after transplanting. All the data collected were subjected to the analysis of variance (ANOVA) following the procedures outlined for split plot in CRD using GENSTAT Discovery edition 3 Release 7.22 DE (GENSTAT, 2008). Significant treatment means were compared using least significant difference (LSD) at 5 % level of probability.

Figure 1: *Saba senegalensis* whole fruit and yellowish fruit pulp with seeds

RESULTS

Effect of accession and fertilizer rates on vine length (cm) of *Saba senegalensis* seedlings at 2, 3, 4, 5, 6 and 7 months after transplanting is presented in Table 1. Accession had significant ($p<0.05$) effect on vine length of Saba only at 2 and

3 MAT. Oforachi accession had the longest fine (19.9 and 27.4 cm) at 2 and 3 MAT, respectively while Kabba accession produced the shortest height of 16.4 and 23.0 cm.

Table 1: Effect of accession and fertilizer rates on vine length (cm) of *Saba senegalensis* at 2, 3, 4 and 5 months after transplanting

	Vine length in months after transplanting					
Accession	2	3	4	5	6	7
Kabba	16.4	23.0	29.6	38.2	45.9	52.5
Oforachi	19.9	27.4	34.2	44.2	50.2	54.5
Okoro	16.7	24.0	29.7	39.5	47.3	52.1
Unosi	18.3	24.8	31.6	39.6	47.1	52.3
LSD (0.05)	1.86	3.14	NS	NS	NS	NS
Fertilizer rates						
0 t ha^{-1}	16.7	23.3	28.5	37.1	49.1	50.8
20 t ha^{-1}	17.7	24.2	29.0	38.1	45.3	50.7
30 t ha^{-1}	17.2	24.1	32.0	38.0	46.0	48.5
30 t ha^{-1} + 100 kg ha^{-1}	18.6	25.3	32.8	43.0	50.8	56.4
30 t ha^{-1} +150 kg ha^{-1}	17.0	23.7	30.1	41.0	49.8	55.2
40 t ha^{-1}	17.8	24.6	32.5	39.7	47.4	56.3
50 t ha^{-1}	19.9	28.3	34.2	45.9	50.0	52.1
LSD (0.05)	2.03	NS	NS	6.075	NS	NS

NS-non-significant

Fertilizer rates significantly ($p<0.05$) affected vine length of Saba at 2 and 5 MAT but all other months did not vary statistically. Sole application of poultry manure at 50 t ha^{-1} produced the longest vine of 19.9 and 45.9 cm at 2 and 5 MAT. The shortest vine (16.7 and 37.1 cm) was obtained from plants grown in plots without any amendment. Interaction of accession x fertilizer rates on all the growth parameters measured were not significantly influenced across the months (Tables not shown for want of space). Effect of accession and fertilizer rates on number of leaves of *Saba senegalensis* seedlings at 2, 3, 4, 5, 6 and 7 months after transplanting is presented in Table 2. Number of leaves differed significantly with the accession at 2 and 3 MAT but statistically similar at 4, 5, 6 and 7 MAT. More leaves (6.9) was obtained from Kabba accessions at 2 MAT which was statistically similar with (6.8) recorded in Unosi accession, Okoro accession had the least (5.1). However, at 3 MAT, Unosi accession took the lead (12.6) with respect to number of leaves produced by Saba plants. The least number of leaves at 3 MAT was attributed to Oforachi accession with 9.2. Poultry manure application rate had no significant ($p>0.05$) effect on number of leaves of Saba seedlings at 2, 3, 4, 5, 6 and 7 MAT.

Table 2: Effect of accession and fertilizer rates on number of leaves of *Saba senegalensis* at 2, 3, 4 and 5 months after transplanting

	Number of leaves in months after transplanting					
Accession	2	3	4	5	6	7

NS-non-significant

Table 3 presents the effect of accession and fertilizer rates on number of branches of *Saba senegalensis* seedlings at 2, 3, 4, 5, 6 and 7 MAT. Number of branches was not affected by the accessions at 2, 4 and 5 MAT but significantly different at 3, 6 and 7 MAT. More number of branches were attributed to accession collected from Unosi with 1.4, 4.8 and 5.6 at 3, 6 and 7 MAT, respectively while Oforachi had the least of 0.3 and 3.1 at 3 and 6 MAT, respectively. However, accession from Kabba had the least (4.3) at 7 MAT.

Number of branches was not influenced by the fertilizer rates at 2, 3, 4 and 5 MAT but differed at 6 and 7 MAT. Sole application of poultry manure at 40 t ha^{-1} had the highest number of branches (5.0) at 6 MAT while combination of 30 t ha^{-1} PM + 100 kg ha^{-1} NPK had the least of (2.8). However, application of 40 and 50 t ha^{-1} of PM produced greater number of branches (6.1) at 7 MAT, the least (3.8) was obtained where no fertilizer was applied (0 t ha^{-1}).

DISCUSSION

The study revealed that variability probably existed among the accessions in some growth traits assessed at different months. Unosi accession significantly produced more leaves and greater number of branches than others. The variability observed in some growth parameters in this study could be attributed to genetic difference in the accessions of Saba. This conforms with the result of Maforikan *et al.* (2018) who reported that genetic variation among the individual and within the different population are likely to influence seedling growth in Baobab from Benin. Results of Baiyeri *et al.* (2015) showed accessional differences in seedling emergence, early growth and leaf proximate composition of *M. oleifera* in Nsukka which could probably be due to variations in the genetic potentials of the accessions. Another study Nwofia and Okwu (2015) reported genotypic variation in early seedling growth of five *Carica papaya* morphotypes from Umudike. Observation from Suthar *et al.* (2019) revealed significant genotypic differences in seedlings growth and biomass production in 15 guar accessions in Texas. Genetic variation in any given crop population is essential to successfully select and manage yield improvement programs (Idahosa *et al.,* 2010; Ndukauba *et al.,* 2015).

The results obtained in this study revealed that organic and inorganic fertilizers significantly influenced some growth attributes measured. Sole application of poultry manure at 50 t ha^{-1} increased vine length of *Saba senegalensis* at 2 and 5 MAT. Also, sole application of 40 or 50 t ha^{-1} of PM produced more branches at 7 MAT. Increase in early growth of Saba with the sole application of poultry manure at 50 t ha^{-1} than other treatment combinations indicated that these rate provided adequate nutrients to the seedlings in the nursery since the plants depend solely on the nutrient given which the roots of the plants were able to absorb and used for growth and development. The results obtained in this work corroborates with the findings of Baiyeri *et al.* (2015) who found that application of the highest rate of organic manure at 20 t ha^{-1} increased growth parameters in *Moringa oleifera* grown as pot plant in Nsukka. The result also agreed with the report of Husseini *et al.* (2016) who observed that organic manure provided enough nutrients that perhaps contributed to the high leaf yield of Baobab seedling in the nursery from Ghana. Adebayo *et al.* (2011) found that organic amendment increased both the vegetative and dry matter yield of *M. oleifera* in the nursery. Stevens *et al.* (2018) reported that application of organic manure significantly influence growth and leaf yield of *Moringa oleifera* in Nsukka.

CONCLUSION

Some distinct differences in growth traits of four accessions of Saba were obtained, these variations were probably linked to the genetic makeup of the accession which warrant selection. Unosi accession that had more number of leaves and highest number of branches could be recommended for famers that may intend growing Saba for commercial purpose. It resulted that 50 t ha^{-1} of PM enhanced better growth which indicates that Saba seedlings require high dosage of nutrients in the nursey for early growth and development since the plants are solely dependent on the nutrient supplied. Therefore, this rate could be appropriate for early seedling growth of *Saba senegalensis*.

ABSTRACT

An experiment was conducted during the rainy season at the Research farm of the Institute for Agricultural Research (IAR), Samaru, Zaria to determine the effect of nitrogen fertilizer and intra-row spacing on the growth attributes of Roselle (Hisbiscus sabdariffa L.). The treatments consisted of four rates of nitrogen (0, 60, 120 and 180 kg N ha$^{-1)}$ and three intra-row spacing (45, 60 and 75 cm). The treatments were arranged in a randomized complete block design and replicated three times. The results showed that the application of 180 kg N ha^{-1} had significant effect on plant height and number of branches. Intra-row spacing of 45 cm significantly influenced on plant height, number of leaves and number of branches. Based on the results obtained 120 kg N ha^{-1} at 60 cm can be used for the production of Roselle in Samaru.

Key words: Intra-Row, Growth, Roselle, Nitrogen

INTRODUCTION

Roselle (*Hibiscus sabdariffa L*) is one of the most important traditional leafy vegetable in the tropics and sub-tropics. It belongs to the Malvaceae family and it is believed to have originated from Africa (Grubben and Denton, 2004). Roselle plays a great role in the socio economic life of many Africans when it comes to the diet, especially people from Nigeria, Ghana, and Sudan (McClintock, 2004). In spite of the fact that Roselle is a multi-product crop with diverse nutritious, medicinal and economic benefits, its productions in Nigeria is still under subsistence practices. Nitrogen fertilizer plays critical roles in plant nutrition. The most profound influence of nitrogen on crop grown is attributed to its direct positive effect on cell division, elongation and expansion, synthesis of Amino acid, enzymes and chlorophyll molecules (John *et al.,* 2006). A report by Dempsey (1964) for instance indicated that Kenaf a related crop to Roselle is a heavy feeder and soil depleting crop. Therefore, the response potentials of the Roselle to nitrogen fertilization in the savannah are very high.

MATERIALS AND METHODS

An experiment was conducted during the rainy season at the Research farm of the Institute for Agricultural Research (IAR), Samaru, Zaria to determine the effect of nitrogen fertilizer and intra-row spacing on the growth attributes of Roselle (*Hisbiscus sabdariffa L.*). The treatments consisted of four Nitrogen fertilizer rates (0, 60, 120, and 180 kg N ha^{-1}) and three Intra-row spacing (45, 60 and 75 cm) laid out in a randomized complete block design (RCBD) and replicated three times.

Agronomic Practices

The field for the experiment was harrowed and ridges were made at the inter row spacing of 75cm. The seeds were sown manually at spacing of 25, 60 and 75 cm x 75cm apart as per treatments. Weeding was done manually using hoe at 3 WAS and ridge molding at 8 WAS. Basal application of phosphorous fertilizer using SSP 18 % P_2O_5 at the rate of 60 kg ha^1 and Potassium using Muriate of potash K_20 at the rate of 32 kg ha^{-1} both were applied before sowing as per stands. While Nitrogen using Urea 46 % N was applied at 3 and 6 WAS as per treatment.

Data Collection

Data were collected on Plant Height (cm), Number of branches per plant, Number of leaves per plant, Leaf area Index (LAI) P^{-1}, Crop growth rate (CGR g^{-1} wk^{-1}), Relative growth Rate (RGR g^{-1} wk^{-1}). The data collected were subjected to statistical analysis of variance (ANOVA) and treatment means were compared using Duncan's Multiple Range Test (DMRT) at 5% level of probability.

RESULTS

The effect of nitrogen fertilizer and intra-row spacing on the plant of Roselle is shown in Table 1. The result shows that application of nitrogen fertilizer had no significant effect throughout the sampling periods except at 9 WAS where application of 180 kg N ha^{-1} produced the tallest plants. While effect of intra-row spacing on plant height showed that 45 cm produced the tallest plant at 6 and 9 WAS which was at par with 60 cm.

Table 2 shows the effect of nitrogen fertilizer and intra-row spacing on number of leaves per plant, the result shows that application of nitrogen fertilizer had no significant effect on number of leaves throughout the sampling periods. Intra-row spacing of 45 cm produced the most number of leaves only at 3 and 9WAS. The interaction was not significant.

Table 1: Effect of nitrogen fertilizer rates and intra-row spacing on plant height of Roselle

Table 3 shows the effect of nitrogen fertilizer and intra-row spacing on Leaf Area Index, the result shows that application of nitrogen fertilizer had no significant effect on number of leaves throughout the sampling periods. The effect of Intra-Row spacing had significant effect on Leaf Area Index, but there was no significant effect in interaction. Application of nitrogen fertilizer had no significant effect on number of leaves throughout the sampling periods except at 9 WAS where application of 180 kg N ha^{-1} produced the number of branches (Table 4). The Influence of intra-row spacing on number of branches was not significant throughout the sampling periods except at 6 and 9 WAS where 45cm intra-row spacing produced the highest number of branches. interaction was not significant.

The effect of nitrogen fertilizer and intra-row spacing on net assimilation rate of Roselle is shown in Table 5. The result shows that application of nitrogen fertilizer had no significant effect on net assimilation rate throughout the sampling periods. The response net assimilation rate to varying intra-row spacing was significant at 3-6 and 6-9 WAS where intra-row spacing of 45cm produced the highest net assimilation rate. While interaction was not significant.

DISCUSSION

Application of 180 kg N ha^{-1} produced the tallest plants, more number of branches and leaves. Crop growth rate, relative growth rate, net assimilation rate and leaf area index significantly increased with increased Nitrogen rate. The positive influence of Nitrogen on these parameters may associated with its role in promoting rapid vegetative growth and its direct effect on chlorophyll (John *et al.,* 2006). Ndayako (1997) reported significant increase in number of branches, number of leaves, leaf area and leaf area index were enhanced by nitrogen application. According to McClintock (2004), Nitrogen fertilizer application result in greater leaf area index whenever it is applied to actively growing plant in a vegetative condition. The effect of Nitrogen fertilizer could also be attributed to increase in leaf number and size. Since Nitrogen is involved in the synthesis of chlorophyll molecules, its application increases the crops ability to intercept more solar energy and increase CO_2 assimilation. The effect of Nitrogen fertilizer on net assimilation rate during initial stages of growth was in agreement with Mc Caleb (2005), who reported that, for a wide range of crop varieties net assimilation rate is relatively constant. The decrease in net assimilation in the later growth stages could be attributed to increased leaf senescence and increased photosynthesis. Intra-Row spacing of 45cm produced the tallest plants, more number of branches and leaves as well as higher growth rate, relative growth rate, net assimilation rate and leaf area index. This could be due to the fact that closer spacing gave room for better light interception for vegetative growth. This agreed with the findings of Giginyu *et al.* (1999) who reported that, plant height, canopy spread and number of branches per plant of Roselle were observed to be significantly influenced by varying intra-row spacing.

CONCLUSION

Based on the results obtained 120 kg N ha^{-1} at 60 cm can be used for the production of Roselle in Samaru.

ABSTRACT

Turmeric is an important spice crop throughout the world and Nigeria is among the leading producers of the crop. However, there is paucity of information on its fertilizer requirement as well as mycorrhiza inoculation on its development. The study was therefore to examine the influence of mycorrhiza inoculation with nitrogen (N) fertilizer application on the growth and yield of turmeric. The experiment was conducted inside pots with 5 levels of nitrogen (0, 45, 90, 135 and 180 kg N/ha), and 2 levels of mycorrhiza inoculation (with and without). The experiment was arranged in a 5 × 2 factorial fitted into a completely randomized design with three replications. Data were obtained on the plant height, number of tillers, dry above-ground biomass yield and rhizome yield. All data were subjected to analysis of variance using SAS PROC. GLM and significant treatment means separated using LSD values. Mycorrhiza inoculation with nitrogen applications significantly enhanced the dry above-ground biomass yield and rhizome yield. Mycorrhiza inoculation beyond 135 kg N/ha application no longer have any significant effect on the growth and yield of turmeric. The yield obtained with the application of 180 kg N/ha with and without mycorrhiza inoculation is not significantly different from the application of 135 kg N/ha with mycorrhiza inoculation. Hence, application of 135 kg N/ha with mycorrhiza inoculation will be beneficial to turmeric production under the same condition.

Key words: Nitrogen, above-ground biomass, turmeric, yield

INTRODUCTION

Turmeric (*Curcuma long* L.) a spice crop, it originates from the Indian subcontinent (Bose *et al*., 2008). It can grow under various conditions up to 1600 m above sea level with a temperature range of 20 to 40 ^{0}C and rainfall above 1500 mm (Olojede *et al*., 2005). Turmeric has multiple uses which include culinary, cosmetic, medicinal purposes as dye among others. It is the major constituent for the popular curry meant for adding flavour to our meals. It can also be used as dye and/or colouring agent. The main active compound of turmeric is the curcumin. Research has shown that turmeric can be used in treatment of so many medical problems and conditions ranging from constipation to skin diseases. It can be used in the treatment of wounds, infection, dysentry, arthrithis, jaundice, liver problems, cancer, Alzheimer's diseases etc. (Hermann and Martine, 1991; Osawa *et al*., 1995). Nitrogen (N) is about the most important nutrient element required by plants. It is a major part of all amino acids, which are the building blocks of all proteins, including the enzymes, which control virtually all biological processes. It is also essential for carbohydrate use within plants. The beneficial effect of mycorrhiza inoculation on growth and development of plants has been documented (Osonubi *et al*., 1995; Fagbola *et al*., 1998; Arihara, 2000). The beneficial effects of mycorrhiza inoculation include: synergistic interaction with other beneficial soil microorganisms, enhanced nutrient absorption and increased resistance to plant diseases. There is however, little information on the contributions of mycorrrhiza inoculation on the growth and yield of turmeric. This study was therefore aimed at determining the interactive effect of nitrogen and mycorrhiza inoculation on the growth and yield turmeric.

MATERIALS AND METHODS

A pot experiment was conducted at the National Horticultural Research Institute (NIHORT), Ibadan using approximately 5 kg soil. Pre-cropping soil analysis was done using standard procedures. The experiment was a 5 × 2 factorial arranged in a completely randomized design. The experiment was replicated three times. The factors include 5 levels of N (0, 45, 90, 135 and 180 kg N/ha), and 2 levels of mycorrhiza inoculation (with and without). The mycorrhiza inoculation was done at planting with the turmeric rhizome while the N was applied at 2 equal split dose a month and 3 months after planting. The source of the N was urea. Data were collected on plant height, number of leaves, rhizome yield and the above-ground dry biomass yield.

All data were subjected to analysis of variance using SAS software 9.2 version and significant treatment means separated using LSD.

RESULTS AND DISCUSSION

The effect of mycorrhiza inoculation with N application on the plant height of turmeric was not well pronounced. There was a slight increase in the plant height with mycorrhiza inoculation beyond 90 kg N/ha at 2 and 3 months after planting, while at 4 months upwards the increase occurs from 45 kg N/ha. Increase in plant height with N application and mycorrhiza inoculation ceases at 5 months after panting. However, there was a significant increase in the plant height with the application of 135 kg N/ha with mycorrhiza inoculation in all the months examined. Application of 180 kg N/ha with mycorrhiza inoculation gave the highest plant height at 5 months after planting, it was however not significantly different from the application of 135 kg N/ha with mycorrhiza inoculation. It was discovered that inoculation of mycorrhiza beyond N application at 135 kg N/ha was no longer effective (Figures 1-4). This implies that N application beyond 135 kg N/ha is the required quantity required by the crop but in other to minimize fertilizer input and still get the adequate result application of 135 kg N/ha with mycorrhiza inoculation may be suitable.

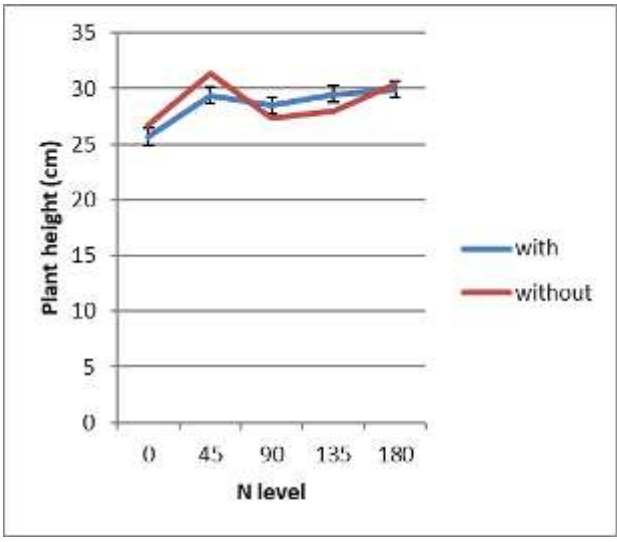

Fig. 1: Plant height of turmeric at 2 MAP

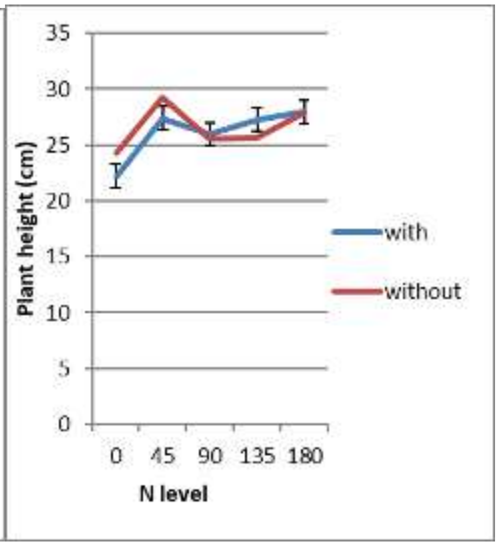

Fig. 2: Plant height of turmeric at 3 MAP

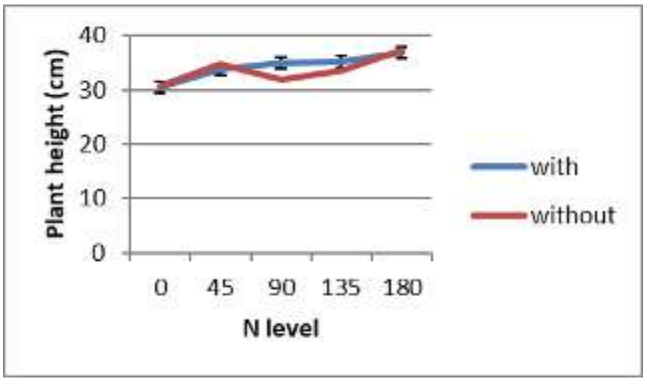

Fig. 3: Plant height of turmeric at 4 MAP

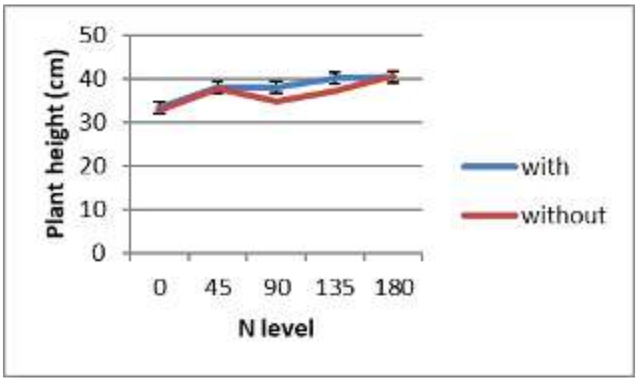

Fig. 4: Plant height of turmeric at 5 MAP

There was a contrasting effect in the number of tillers with mycorrhiza inoculation and N application. However, it was observed that the significant increase discovered in the number of tillers beyond

ISSN: 2814-0508

the application of 135 kg N/ha with mycorrhiza inoculation was rapid within the first 4 months after planting. The rate of increase however decreases at the fifth month. At two months after planting there was an increase in the number of tillers with mycorrhiza inoculation. However, between the application of 90 and 135 kg N/ha with mycorrhiza inoculation, there was no effect in the number of tillers. While at three and four months after planting there was a decrease in the number of tillers with mycorrhiza inoculation between N application at 45 – 135kg N/ha before further increase (Figures 5-8).

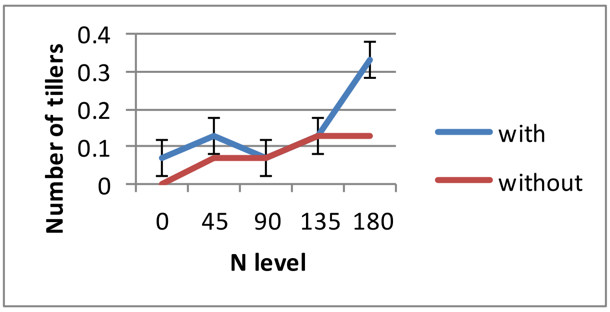

Fig. 5: Number of tillers of turmeric at 2 MAP

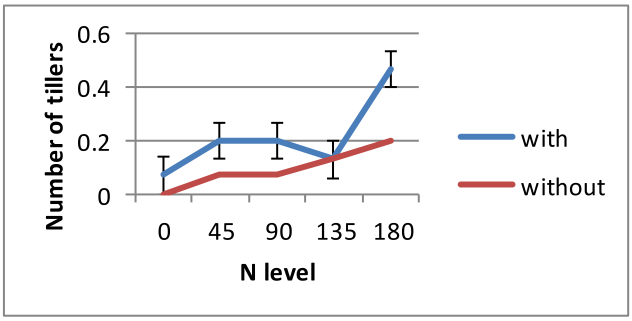

Fig. 6: Number of tillers of turmeric at 3 MAP

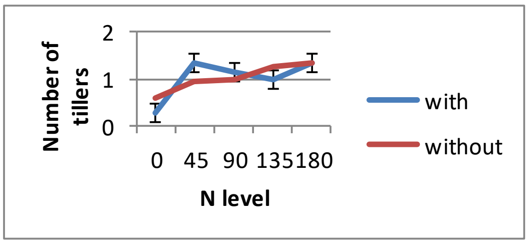

Fig. 7: Number of tillers of turmeric at 4 MAP

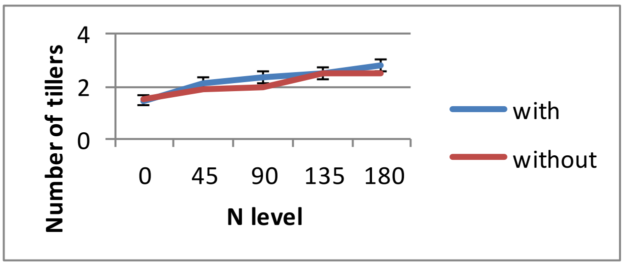

Fig. 8: Number of tillers of turmeric at 5 MAP

There was a consistent increase in the dry biomass yield with N application and mycorrhiza inoculation. Application of 135 kg N/ha with mycorrhiza inoculation gave a significantly higher dry biomass yield. Mycorrhiza inoculation with increased N application beyond 135 kg N/ha was no longer effective. The increase in the dry biomass yield with mycorrhiza inoculation was as a result of the increase in number of tillers with N application. Mycorrhiza inoculation with N application significantly enhanced the rhizome yield. The highest rhizome yield was with the application of 180 kg N/ha with mycorrhiza inoculation, this was however, not significantly different from the application of 135 kg N/ha with mycorrhiza inoculation (Figures 9, 10). This corroborates the findings of Ortas, 2012 that mycorrhizal inoculation can be used in reducing chemical fertilizer inputs on crops.

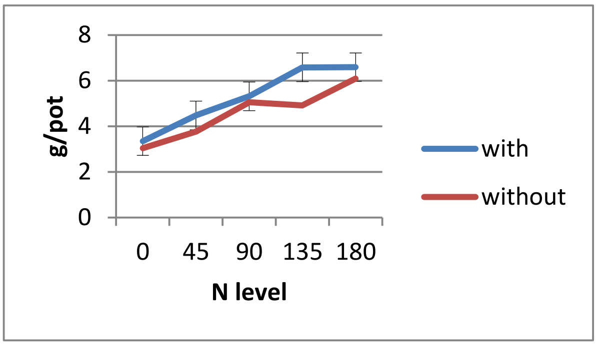

Fig. 9: Curcumin content of turmeric at maturity

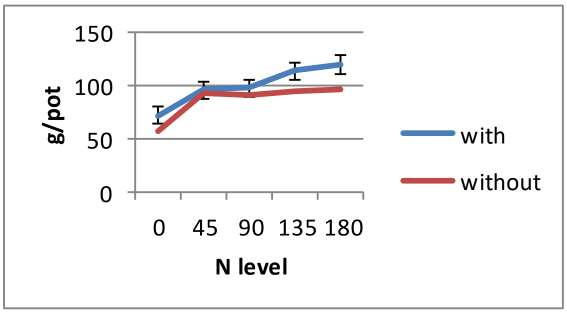

Fig. 10: Rhizome yield of turmeric

ISSN: 2814-0508

CONCLUSION

The effect of mycorrhiza inoculation with N application on the plant height and number of tillers was not clearly shown in the study, this might be as a result of the presence of native mycorrhiza in the soil used for the study. However, mycorrhiza inoculation with N application at 135kg N/ha gave the best index and yield of turmeric.

INFLUENCE OF NITROGEN ON THE PRODUCTION OF PINEAPPLE (*ANANAS COMOSUS* VAR. SUGARLOAF) SLIPS ON AN ALFISOL IN IBADAN, NIGERIA

Amosu, S.A. and Akinyemi, S.O.S.

Fruits Research Programme
National Horticultural Research Institute (NIHORT), Ibadan, Nigeria
Corresponding author's e-mail: amosu.semeton@nihort.gov.ng

ABSTRACT

Pineapples are majorly propagated asexually from different parts of the plant like the crown, suckers, stumps and slips. This trial was carried put to evaluate the influence of nitrogen on the production of slips in pineapple C.V. sugarloaf. The trial was conducted at NIHORT, Ibadan as a single factor experiment with six (6) nitrogen levels of 0kgN/ha, 120kgN/ha, 240kgN/ha, 360kgN/ha, 480kgN/ha and 600kgN/ha laid out in a randomized complete block design with 3 replications. Basal application of phosphorus at 30kg P_2O_5/ha with Single Super Phosphate (SSP) and potassium at 70kg K_2O/ha with Muriate of Potash (MOP) as their sources were applied after transplanting. The nitrogen treatments were applied in 3 splits during the life span of the trial. Pre-cropping soil sampling were done on the soil (an alfisol) and the samples were analysed for physical and chemical properties. Yield data were collected and analysed. Data on number and weight of slips were obtained 60 days after harvesting the fruits. The results showed that there was no significant difference in the mean number of slips, mean weight of slips and number of slips produced per hectare though the 600kgN/ha treatment gave the highest mean number of slips (13.22) and number of slips produced per ha (528,933) while 240kgN/ha recorded the best slip weight (579.25g). No significant effect of the N treatments was observed in yield although 480kgN/ha recorded the best yield at 52t/ha. With basal application of phosphorus (30kg P_2O_5/ha) and potassium (70kg K_2O/ha), urea applied at 600kgN/ha is recommended for optimal production of sugarloaf pineapple slips while 480kgN/ha is suggested for fruit yield.

Key words: pineapple slips, sugarloaf, nitrogen, alfisol

INTRODUCTION

Pineapple (*Ananas comosus* [L.] Merrill) is a fruit predominantly produced in sub-tropical countries. The fruit contributes to more than 20% of the tropical fruit production worldwide with 25.5 million tons (FAO, 2016). There are eight countries in West Africa producing pineapples, with Benin being the third largest fresh pineapple producer (next to Ghana and Nigeria) in 2018 with 372,507 tons (FAO, 2018). It is the most economically important plant in the family *Bromeliaceae* (Bartholomew *et al*., 2003). Pineapples are herbaceous perennials and are cultivated throughout the year mainly asexually by the use of vegetative propagules like crowns, slips, hapas or suckers (Bartholomew *et al*., 2003). Reinhardt *et al.* (2017) submitted that slips are a good sources of planting material as long as the overly large vestigial fruits at their base are removed before planting, as they may rot after planting under wet soil conditions. Table 1 shows the different vegetative parts of the pineapple plant, their location on the plant and maturity periods. The sugarloaf pineapple (Figure 1) cultivar is characterized by dark green, erect and spiny leaves with a long peduncle (±35cm). It produces many slips (8-12) around the base of the fruits during its reproductive phase. The pulp of the fruit is soft, white and juicy with a high sugar content of 12-16^{o} brix. (Junghans, 2010). Sugarloaf is also tolerant to drought, nematodes and mealybug wilt.

Table 1: Pineapple vegetative parts, maturity period and their location on the plant

S/N	VEGETATIVE PARTS	LOCATION ON THE PINEAPPLE PLANT	MATURITY PERIOD
1	Slips	Below the fruit on the peduncle or basal eye of the fruit	12-13 months
2	Collars		14-16 months
3	Ground Suckers (ratoon)	Shoots produced from the stem just above the ground	12-14 months
4	Suckers or Side Shoots	Produced from the above ground portion of the stem	18-20 months
5	Crown	Short stem and leaves growing from the apex of the fruit	24 months

Figure 1: A sugarloaf pineapple plant showing its reproductive parts

Typical plant densities for pineapples range from 29,000 to 86,000 plants per hectare (Bartholomew *et al.* 2003). Densities are usually based on the intensity of agricultural practices and planned use of the fruit. In Brazil, plant densities for perola (sugarloaf) range from 31,700 to 41,600 for single row spacing and 26,300 to 51,200 for double row spacing (Cunha and Reinhardt, 2004) while in Nigeria, the recommended spacing is 100cm X 50cm X 50cm giving a plant density of 40,000 plants per hectare. The lack of availability of these planting materials for large areas of land informed this study to ensure availability of both the fruits and slips of sugarloaf pineapples.

MATERIALS AND METHODS

The experiment was conducted between 2009 and 2011 at the National Horticultural Research Institute (NIHORT), Ibadan, Nigeria, with latitude 7° 22'N and longitude 3° 58'E. Ibadan is located in the derived Savanna Zone (Transition forest ecosystem of Nigeria). The soil of the study location is grouped under the Alfisol soil order. The experiment was a single factor experiment laid out in a randomized complete block design (RCBD) and replicated three times. The factor was the different levels of nitrogen (N) with urea (46% N) as the nitrogen source. The six N treatments were 0kgN/ha (control), 120kgN/ha (16g/plant), 240kgN/ha (32g/plant), 360kgN/ha (48g/plant), 480kgN/ha (64g/plant) and 600kgN/ha (80g/plant). The N treatments were applied in 3 splits. Basal application of phosphorus at 30kg P_2O_5/ha with Single Super Phosphate (SSP) and potassium at 70kg K_2O/ha with Muriate of Potash (MOP) as their sources. The field was ploughed, harrowed and bedded. Pre-cropping soil sampling was done and the samples were subjected to routine laboratory analysis. The soil parameters analysed for were particle size distribution, soil texture, bulk density, available phosphorus, total nitrogen, organic carbon, base saturation, exchangeable bases, exchangeable acidity, cation exchange capacity and micronutrients. The pineapple cultivar used was sugarloaf and planted on beds at spacing of 50 cm X 50 cm. Yield data were collected at specific intervals based on maturity index for pineapples and the yield components obtained were fruit weight and crown weight. At 60 days after harvesting the fruits, data on the number of slips and weight of slips were collected. Data were analysed using ANOVA at $\alpha_{0.05}$ with means separated with Fishers LSD.

RESULTS AND DISCUSSION

Pineapple Soil Requirements and Pre-Cropping Test Results

The soil was moderately acidic (5.8) with low levels of total nitrogen, available phosphorus (P) and exchangeable potassium (K) (Table 2). The organic carbon content was moderate at 1.36%. The soil was sandy loam with 12% clay and 72.6% sand, while the bulk density was 1.47g/cm^3 which was slightly above the ideal bulk density for sandy loam soils (1.40g/cm^3). The porosity was within the ideal range at 44.53%. The micronutrients were also low in the soil with the exception of manganese (Mn). Pineapples are sensitive to excess water in the soil (Souza and Reinhardt, 2007) hence the porosity of 44.53% favours good root growth and development. The crop also tolerates high aluminium and Mn in the soil (Malézieux and Bartholomew, 2003), hence the Mn level of 92.4mg/kg is tolerable for the plant. Nitrogen is important in the vegetative growth and development of the plant including the slips and suckers after fruiting in *perola* or sugarloaf variety (Souza and Reinhardt, 2007) while potassium has a significant effect on fruit quality. Phosphorus deficiency on the other hand caused reduction in growth in all the parts of the plant. The soil was thus applied basal doses of P and K in this study while N was varied.

Table 2: Pre-cropping soil test results

Parameters	Test Values
pH (H2O)	5.8
Organic Carbon (%)	1.36
Total Nitrogen (%)	0.31
Available Phosphorus (mg/kg)	0.58
Calcium (cmol/kg)	6.56
Magnesium (cmol/kg)	0.86
Sodium (cmol/kg)	0.32
Potassium (cmol/kg)	0.24
Exchangeable Acidity (cmol/kg)	0.8
Cation Exchange Capacity (cmol/kg)	8.78
Base Saturation (%)	90.89
Manganese (mg/kg)	92.4
Iron (mg/kg)	4.3
Copper (mg/kg)	2.0
Zinc (mg/kg)	6.1
Sand (%)	72.6
Silt (%)	15.4
Clay (%)	12.0
Bulk Density (g/cm^3)	1.47
Porosity (%)	44.53
Texture	Sandy loam

Effect of Nitrogen of Yield of Sugarloaf Pineapple

The 480kgN/ha treatment recorded the best mean fruit weight of 1.3kg though there was no significant effect of the N treatments on the mean fruit weight. The best yield per ha was also obtained with the 480kgN/ha treatment at 52t/ha fresh fruit yield (Table 3). The control recorded the largest crown weight though the fruit weight was the least. This could be attributed to the basal application of P and K which boosted the growth and development of the plant.

Table 3: Effect of nitrogen levels on some yield parameters of sugarloaf pineapple

Treatments	Mean Fruit Weight (kg)	Mean Crown Weight (g)	Yield (t/ha)
Control (No Fertilizer)	0.99a	**127.22a**	39.87a
120kgN/ha (Urea)	1.03a	105.74ab	41.33a
240kgN/ha (Urea)	1.20a	124.76ab	48.00a
360kgN/ha (Urea)	1.12a	104.60ab	44.93a
480kgN/ha (Urea)	**1.30a**	107.92ab	**52.00a**
600kgN/ha (Urea)	1.07a	102.59b	42.93a

Effect of Nitrogen on Number and Weight of Sugarloaf Pineapple Slips

There was no significant effect of the N treatments on the mean number of slips per plant, mean number of slips per hectare and the mean slip weight per plant (Table 4). The 600kgN/ha treatment gave the highest mean number of slips per plant (13.22) and highest number of slips per hectare at 528,933. The highest mean slip weight at 579.25g was recorded with 240kgN/ha treatment while the least weight of 460.76g was obtained under 360kgN/ha. Other factors could have contributed to these results including the prevailing weather conditions, nutrient drift etc. The non-significant effect of the N treatments also shows the characteristic nature of the pineapple C.V. sugarloaf's slip. The production capacity with minimal application of nutrients as seen in the result of the control treatment.

Table 4: Effect of nitrogen levels on number and weight of slips of sugarloaf pineapple

Treatments	Mean Number of Slips/plant	Mean Number of Slips/ha	Mean Slip Weight (g)
Control (No Fertilizer)	12.34a	493,733a	483.98a
120kgN/ha (Urea)	11.48a	459,200a	469.85a
240kgN/ha (Urea)	12.14a	485,733a	**579.25a**
360kgN/ha (Urea)	11.80a	475,200a	460.76a
480kgN/ha (Urea)	11.58a	463,333a	499.56a
600kgN/ha (Urea)	**13.22a**	**528,933a**	530.01a

CONCLUSION

Pineapples are primarily grown for their fresh fruits which is a good source of vitamins and minerals. The additional benefits of the planting materials from the slips after harvesting the medium sized fruits is good basis for choosing the variety. One hectare of land with a population density of 40,000 plants can give over 500,000 slips which can plant up to 12.5 ha.

ABSTRACT

Field trial was conducted at the Teaching and Research Farm of Federal College of Horticulture Dadinkowa during 2020 wet season to evaluate the effect of Nitrogen Fertilizer Rates and Spacing Intervals on the Growth and Yield on Onion. The experiment consisted of three Nitrogen fertilizer rates (80kg, 100kg and 120kg/ha) and three Spacing Intervals (15x30cm, 20x30cm and 25x30cm) laid in Randomized Complete Block Design (RCBD) in three replications of nine plots each making up a total number of 27 plots. 1m space was left between replications and 0.5m between plots of 1mx2m (2m^2). The results revealed that significant difference was recorded for Nitrogen on Plant Height, Number of Leaves, Bulb Diameter, Yield per Plot and Yield per Hectare. However, there was no significant difference on Collar Girth and Bulb weight. For spacing interval, significant difference was recorded on Plant Height and Collar Girth while the rest of the parameters measured were not significant. Interaction between the two factors was significant on Plant Height, Number of Leaves, Collar Girth and Bulb weight but no significant difference was recorded on Bulb diameter, Yield per plot and Yield per Hectare. Further research was recommended.

Key words: Nitrogen, Spacing, Growth, Yield, Collar Girth, Bulb Diameter.

INTRODUCTION

The onion (*Allium cepa* L.) is a vegetable crop grown for its pungent bulbs and flavorful leaves. It belongs to the genus *Allium* of the family*Alliaceae*or *Amaryllidaceae* (Welbaum, 2015; Boukary *et al.,* 2012). Onion is one of the most important vegetable crops commercially grown in the world. It probably originated from Central Asia between Turkmenistan and Afghanistan where some of its relatives still grow in the wild. Onion from Central Asia, the supposed onion ancestor had probably migrated to the Near East (Bagali *et al.,* 2012). In the country, the crop is believed to be more intensively consumed than any other vegetable crops (Joosten, *et al., 2011)*. Moreover, the onion contributes to the commercialization of the rural economy and creates jobs opportunities for young people in the country (Nikus and Mulugeta, 2010). According to Hussaini *et al*., (2000) the crop ranks second in importance after tomatoes among the vegetables in Nigeria.

The requirement of plants for nitrogen is mostly satisfied either from soil and or application of nitrogen fertilizer. In this regard, Minister of Agriculture (2015) Spacing is an important aspect regarding onion production and quality. Researchers indicated that wider spacing helped the individual plant to utilize more water, nutrients, air and light for their growth and development than those closer spaced plants (Devulkar, 2013). Optimization of plant population is therefore important to avoid competition between plants for growth factors as well as to utilize available cropland efficiently without wastage (Awas, *et al.,* 2010).

According to Tegen, *et al*. (2016) the proportion of medium-sized bulbs which are preferred by consumers was low at this intra-row spacing. A Recommended the spacing of 40 cm x 20 cm x 10 cm between furrows, row and plants, respectively, for the production of onion in Ethiopia without considering the status of soil fertility and environmental conditions of the growing areas. However, onion bulbs produced using this intra-row spacing are mostly bigger in size (>160g) which are not preferred by consumers for home consumption (Tegen, *et al,*.2016). There is no definite spacing adopted by onion farmers in the study area and this affects the number of stands per given area which is directly related to yield of Onion. Similarly, fertilizer application rate particularly nitrogen varies between one farm land and another farm in the same area. These affects cost of production, leads to unnecessary expenses and affect profit return. Therefore, this research will help a lot in coming up with the most suitable spacing for onion cultivation and the appropriate nitrogen rate for application by farmers in the study area for maximum production at affordable cost and high profit. The study was conducted to find out the most suitable spacing for onion production, to find out the appropriate nitrogen fertilizer rate for onion production and to evaluate the interaction between spacing and fertilizer rates.

MATERIALS AND METHODS

Experimental Site

The experiment was conducted at the Research and Training Farm of Federal College of Horticulture Dadinkowa in Yamlatu Deba local Government area of Gombe State located at latitude 11^{o} to 30 "E at and longitude 10^{o} to 20 "N with altitude of 240 meters above the sea level and annual rainfall of 760 to 1100mm. Optimum temperature range between 24^{o}c to 48^{o}c and the soil type of the area is predominantly loamy.

Treatment and Experimental Design:

The experiment consisted of three level of nitrogen (80, 100, and 120 kg/ha^{1}) fertilizer and three spacing (15 cm x 30 cm, 20 cm x 30 cm and 25 cm x 30 cm) laid in Randomized Complete Block Design (RCBD) in 3 replications. The plots size was 1m x 2m (2m^{2}) with 1m space between the replications and 0.5 m between plots. Total number of plots was 27.Data were collected from the five randomly sampled and tagged plants within each plot at 2 weeks' intervals on plant height, number of leaves, collar girth, bulb weight, bulb diameter, yield per plot which was extrapolated to yield per hectare

$$\frac{\text{Yield per plot}}{\text{plot size (m2)}} \times \frac{10{,}000}{1000}$$

Data Analysis

Data obtained were subjected to analysis of variance using Genestat. Means were separated using least significant difference (LSD) at 5% level of probability.

RESULTS AND DISCUSSION

The results in Table 1 were on the effect of Nitrogen Fertilizer Rates and Spacing interval on the Growth and Yield of Onion. The results showed that highly significant difference was recorded on plant height at harvest for both the factors. Significant difference was also recorded on number of Leaves, Bulb Diameter, Yield per Plot and yield per hectare. However, there was no significant difference on Collar Girth and Bulb weight for Fertilizer rates while for spacing significant difference was recorded on plant height and collar girth only while the rest of the parameters remained not significant.

Table 1: Effect of Nitrogen Fertilizer Rates and Spacing Intervals on the Plant Height, Number of Leaves, Collar Girth, Bulb Weight, Bulb Diameter, Yield Per Plot and Yield Per Hectare at Harvest of Onion in Dadinkowa During 2020 Wet Season.

Treatments	PH	NL	CG	BW	BD	YYP	YPH
Nitrogen Rate							
80kg	35.57	6.18	3.72	31.3	21.12	30.98	309.78
100kg	30.61	6.63	3.75	37.3	21.57	31.22	312.22
120kg	34.92	6.43	3.68	38.6	21.58	31.22	312.22
P<f	**	**	NS	NS	*	**	**
LSD	0.982	0.2651	0.1834	9.72	0.4051	0.0976	0.976
Spacing							
15x30cm	34.82	6.34	3.76	37.0	21.28	31.10	311.00
20x30cm	33.68	6.44	3.54	35.1	21.58	31.10	311.67
25x30cm	32.61	6.45	3.85	35.2	21.40	31.16	311.56
P<f	**	NS	**	NS	NS	NS	NS
LSD	0.982	0.2651	0.1834	9.72	0.4051	0.0976	0.976
Interaction							
NT x SP	**	**	**	*	NS	NS	NS

Key: **=highly significant, *=significant, NS=not significant, NT= Nitrogen, Sp=spacing
PH= Plant Height, NL= Number of Leaves, CG= Collar Girth, BW= Bulb Diameter,
BD= Bulb Diameter, YPP= Yield per Plot, YPH= Yield per hectare

The results were in agreement with the findings of Jilani *et al*., (2010); Morsy *et al*. (2012) especially on plant height, number of leaves, bulb diameter, yield per plot and yield per hectare who reported that 120 kg N ha^{1} appeared higher values of plant height, number of leaves per plant, bulb diameter and days to maturity as compared to adding of 90 kg ha^{1}. However, the result contradicts that of Jilani *et al.*, 2010) on collar girth and bulb weight who reported that Application of higher

ISSN: 2814-0508

nitrogen of 120 kg ha[1] recorded the maximum bulb size while the minimum bulb size was recorded in control and that of Aliyu *et al,* (2008) who reported an increase of onion bulb weight with increased nitrogen rate. The results also revealed that there was significant difference for spacing on plant height and collar girth, but no significant difference was recorded on number of leaves, bulb weight, bulb diameter, yield per plot and yield per hectare. This result is contrary to the findings of Dereje *et al*. (2012) who indicated that total yield per hectare increased as plant density increased although yield of the individual plants and their components were significantly reduced. The results also indicated that there was significant difference on interaction between Nitrogen and spacing for plant height, number of leaves, collar girth and bulb weight. However, interaction between the two factors showed no significant difference on bulb diameter, yield per plot and yield per hectare.

ABSTRACT

Mushroom cultivation is a means of income generation, assurance of food security and enhanced livelihood. This study was aimed at investigating the influence of different nitrogen sources on the growth and fructification of Pleurotus ostreatus and Pleurotus pulmonarius. These mushrooms were cultivated on sawdust substrate and experiment laid out in a complete randomized design (CRD) in replicates of three. The fertilizers used were urea, liquid organic fertilizer and total plus (6-1-2 liquid inorganic fertilizer) while water served as the control. Biological Efficiency (BE) and Production Efficiency (PE) followed the same trend. The highest BE (18.75%) was recorded in inorganic fertilizer while the least was observed in the control. Furthermore, the heaviest fruit weight (65.67 g) was observed in inorganic fertilizer as the least (38.00 g) was recorded in the control. Pleurotus pulmonarius produced higher number of fruits than P. ostreatus (7.50 and 5.00 respectively). The fruit weight recorded in P. pulmonarius was heavier than that of P. ostreatus. Inorganic fertilizer was the best nitrogen source in this investigation.

Key words: Inorganic and organic fertilizer, *Pleurotus ostreatus*, *Pleurotus pulmonarius*, urea

INTRODUCTION

Cultivation of mushroom can generate income, enhance livelihood of local communities and ensure food security (Reyes *et al*., 2009). Mushrooms can be cultivated on palm-bunches, straw, corn cobs or mixtures thereof (Idowu, 2003) and on various unfermented cellulose and lignin containing wastes (Gregori *et al*., 2007). Other substrates include water hyacinth and banana leaf (Idowu *et al*., 2015). Mushrooms are non-traditional horticultural crops of high quality proteins, high fibre value, vitamins and minerals (Narayanasamy *et al*., 2009). They have nutritive values and some medicinal properties which include relief for stomach ailments, fever, asthma, smallpox, high blood pressure and cancer (Wong *et al*., 2011). They are known to promote good health in traditional Chinese medicine (Isikhuemhen *et al*., 2000). The addition of external nutrients increases the productivity of some low-yielding mushroom varieties (Carrasco *et al*., 2018). De Leon *et al*. (2017) stated that the addition of supplements will substantially increase the yield per unit weight of mushroom. Carbon and nitrogen are the two main macronutrients needed by fungi for structural and energy requirements (Carrasco *et al*., 2018). The increasing demand for dietary protein, inadequate commercial mushroom production and forest extinction gave birth to mushroom scarcity. Therefore, this investigation was aimed at exploring some sources of nitrogen to enhance the commercial production of mushroom for the availability of dietary protein.

MATERIALS AND METHODS

Mushroom spawn

The spawn of the two mushrooms (*Pleurotus ostreatus* and *Pleurotus pulmonarius*) were collected from the Mushroom unit laboratory, NIHORT, Ibadan.

Collection of substrate

The investigators sourced for the substrate (sawdust) used in this research studies at Sanngo sawmill, a major plank market within Ibadan metropolis in Oyo State, Nigeria.

Growth of the mycelia

The collected sawdust substrate was composted for a month by moistening it with water to about 65%. 1 kg of the composted sawdust was weighed into heat-resistant transparent polythene bags of size 35 x 10 cm. The neck of the bag was made of heat resistant PVC (polyvinyl choride) tube and plugged with a cotton wool. Before each of the bags was inoculated with 100 g of the mushroom separately, they were autoclaved at 121^{o}C for 15 minutes and allowed to cool to room temperature. The bags were kept in the vegetative room for about a month where the mycelia ramified in the substrates.

Preparation of the fertilizer

The following fertilizers were used in this investigation: urea, liquid organic fertilizer obtained from vegetable programme in NIHORT and total plus (6-1-2 liquid inorganic fertilizer). While 5 g of urea was dissolved in 1 litre of water, 5 mls each of liquid organic fertilizer and total plus were separately dissolved in 1 litre of water. A total of 3 litres, each of the fertilizers, was used for this research study. 3 litres of water was used as the control. The fertilizers and the water control were added to the substrate (sawdust) separately.

Experimental/ Research Design

The experiment was laid out in a complete randomized design (CRD) in replicates of three.

Data Analysis

Analysis of the data collected was done using ANOVA and significant means were separated using Duncan's multiple range test.

RESULTS AND DISCUSSION

The nitrogen sources promoted the growth and yield of the two oyster mushrooms (*Pleurotus pulmonarius* and *Pleurotus ostreatus*) on the sawdust substrate but at varying degrees. Roy *et al*., (2013) stated that phosphorus and nitrogen promote root and vegetative growth of crops. While the shortest number of days for full mycelial colonization (23.83 days) was observed in the control, the longest (25.50 days) was recorded in urea (Table 1). The highest (18.75%) Biological Efficiency (BE) was recorded in inorganic fertilizer while the least was recorded in the control (Table 1). Production Efficiency (PE) followed the same trend. The heaviest fruit weight (65.67 g) was observed in inorganic fertilizer followed by that of organic fertilizer (53.67 g) which was significantly different from what was recorded in urea (49.50 g) while the least (38.00 g) was recorded in the control (Table 1). This might be attributed to nitrogen supplied by inorganic fertilizer which aided nutrient uptake by mushroom mycelial for fruit body production. The widest width of pileus (7.75 cm) was recorded in organic fertilizer which was not significantly different from that of control (7.25 cm). The smallest was observed in inorganic fertilizer (6.37 cm). It was observed that the mycelial density of *P. pulmonarius* was heavier than that of *P. ostreatus*. Mycelial density is directly proportional to mushroom yield (Thomas *et al*., 1998). Thus, *P. pulmonarius* recorded a heavier fruit weight than *P. ostreatus* (Figure 1) and the BE recorded in *P. pulmonarius* was also significantly different from that of *P. ostreatus* (16.69% and 12.64% respectively). PE followed the same trend (Table 2).

Table 1: Effects of the various nitrogen sources on the fructification of the mushrooms on the sawdust substrate

TREATMENTS	F. COL	INI	BE	PE	NF	FW	WP	LS
Urea fertilizer	25.50	29.00	13.72	5.10	6.50	49.50	6.75	5.67
Organic fertilizer	25.00	28.67	15.33	6.07	6.33	53.67	7.75	5.50
Inorganic fertilizer	25.00	28.50	18.75	6.92	7.00	65.67	6.37	5.08
Control	23.83	28.12	10.86	4.31	5.33	38.00	7.25	5.25

Where, F. COL= Full mycelia colonization (Days), INI= Primordia initiation (Days), BE= Biological Efficiency (%), PE= Production Efficiency (%), NF= Number of fruits, FW= Fruit weight (g), WP= Width of pileus (cm) and LS= Length of stipe (cm)

Table 2: Effects of the nitrogen sources on *Pleurotus pulmonarius* and *Pleurotus ostreatus*

MUSHROOM SPECIES	Number of fruits	Width of pileus (cm)	Length of stipe (cm)	Full mycelia colonization (Days)	Primordia initiation (Days)	Biological Efficiency (%)	Production Efficiency (%)
P	7.50	7.06	5.71	24.75	28.42	16.69	6.40
OST	5.08	7.00	5.04	24.92	28.75	12.64	4.79
LSD	0.66	0.60	0.48	1.15	1.06	0.56	0.33

P= *Pleurotus pulmonarius*, OST= *Pleurotus ostreatus*

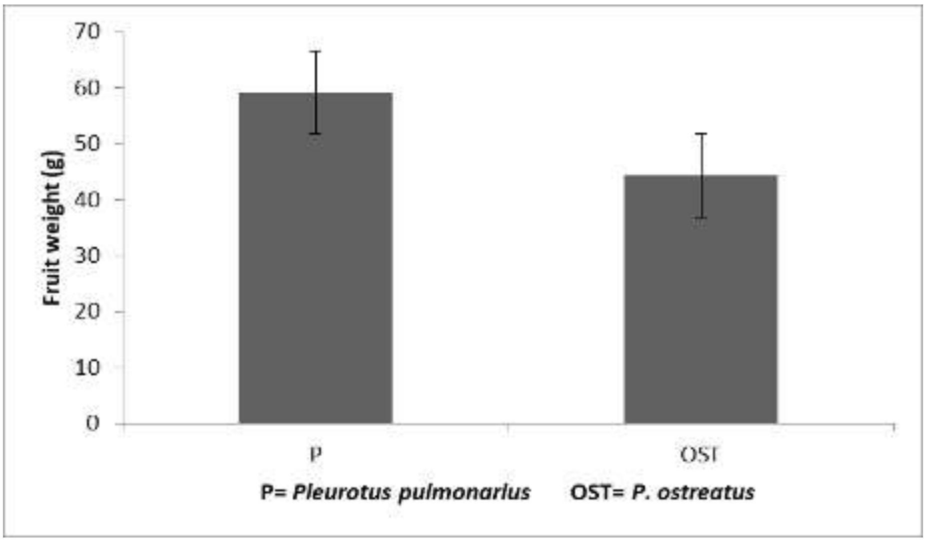

Figure 1: Effect of the nitrogen sources on the fruit weight of *Pleurotus pulmonarius* and *Pleurotus ostreatus*

CONCLUSION AND RECOMMENDATION

The highest number of fruits and heavier fruit weight were recorded in inorganic fertilizer. *P. pulmonarius* performed better than *P. ostreatus* in this investigation in terms of BE, PE, number of fruits, length of stipe and fruit weight. Therefore, total plus (6-1-2 liquid inorganic fertilizer) was the best in this investigation.

ABSTRACT

The Field trial was conducted at the Teaching and Research Farm of the Federal University of Technology, Minna (Southern Guinea Savanna ecological zone of Nigeria) during the 2019 cropping seasons. The experiment was laid out in a Randomized Complete Block Design and replicated three times. The treatments consisted of two okra varieties (NHAe47-4 and LD 88), five rates of nitrogen fertilizer (0, 30, 60, 90 and 120 kg N ha^{-1}). Each plot measures 2×5.25 m (10.5m^2) comprising of eight ridges with 3 replications. Parameters measured included Number of fresh fruits, Weight of fresh fruits, Fresh fruit diameter, Weight of seed and 100–Seed weight determination. Lab Experiment consist of treatments with factorial combinations of two okra varieties (NHAe47-4 and LD 88), and seven fruit harvesting stages (14, 21, 28, 35, 42, 49 and 56 days after anthesis) arranged in a Completely Randomized Design (CRD) and replicated four times. Seed storage and germination percentage was determined. Data collected were subjected to analysis of variance (ANOVA) using SAS Statistical package 9.2. At 5% level of probability means were separated using Student- Newman Keuls (SNK) Test. Application of 90 - 120 kg N ha^{-1} gave better fruit size and seed yield of okra. Fruits of LD88 harvested at 42 days after anthesis had a better germination percentage than fruit of other harvesting day. With the result of this study, okra growth, fruit and seed yield can be improved by application of 90 kg N/ha.

Key words: Okra, Nitrogen, Fruit and Days after anthesis

INTRODUCTION

Okra (*Abelmoschus esculentus* (L.) Moench) is a flowering plant in the Malvaceae family, commonly known by several names in different parts of the world. *Abelmoschus esculentus* and *Hibiscus esculentus* are the Latin binomial names for Okra (Kumar *et. al,* 2010). Okra is usually called "Kubewa" in Hausa, "Ila" in Yoruba and "okwuru" in Igbo speaking languages in Nigeria. Okra is also known as ladies' finger originated from Ethiopia (Sathish and Eswar, 2013) and was then propagated in North Africa, in the Mediterranean, in Arabia and India by the 12th century BC (Tripathi *et al*., 2011). It is one of the most widely known and utilized species of the family Malvaceae (Iyagba *et al*., 2013) and an economically important vegetable crop grown in tropical and sub-tropical parts of the world. The nutritional compositions of okra include calcium, protein, oil, carbohydrates, iron, magnesium and phosphorus (Omotoso and Shittu, 2007). Okra plant grows preferably in well-drained humus rich fertile soil with pH ranging from 5.8 to 6.8 (Abidi *et al,* 2014).

Nitrogen is the second most absorbed nutrient by vegetables and plays a fundamental role in their yield (Souza *et al*., 2017). In addition, N considerably mobilizes the process of flower opening, fruit setting and fruit development. Seed development influences the seed performance (Bita and Maryam 2011). Seed maturation, however, is closely associated with fruit maturation and complete fruit drying (Ashok *et al.,* 2005). The Non-availability of good seeds remains a constraint to wide cultivation of vegetables in Africa (Ibrahim and Oladiran 2011). The viability of most farmers' seeds is usually poor because of the low level of adequate production techniques (Yakubu and Abubakar 2017). The stage of harvest of okra fruit has a significant influence on the quality of its seed. Agrawal (1980) stated that okra seed pod should be harvested when they are dry (i.e. about 35 (DAA), days after anthesis). Delayed harvest may lead to low germination and vigour due to adverse weather conditions in okra (Dias *et al*., 2006). The poor germination of early-harvested seeds could have been due to the large proportion of immature seeds in these sets of seeds (Ibrahim and Oladiran, 2011). The objectives of the study were to determine the effect of nitrogen rates on fruit and days after anthesis on seed quality of two okra varieties.

MATERIALS AND METHODS

Field experiment was conducted at the Teaching and Research Farm of the Federal University of Technology, Minna (latitude 9^o 51 ^{1}N and longitude

6° 44 ¹E) during the 2019 cropping seasons (May-Sept). Soils in Minna originated from basement complex rocks and generally are classified as Alfisols (Lawal *et al*., 2012). The seed quality testing was carried out after the field work in the laboratory of the Department of Crop Production, Federal University of Technology, Minna, Niger State. Soil samples were collected from 0-15cm depth with an auger from 10 points along four diagonal transects. The samples were bulked into four composite samples. The samples were then air dried and sieved through 2mm and 0.5mm sieve. The samples were analyzed for particle size distribution, pH 1:2 (H_2O and $CaCl_2$), Organic carbon, total nitrogen, available phosphorus, exchangeable bases (Ca^{2+}, Mg^{2+}, K^+, Na^+), exchangeable acidity (Al^{3+} + H^+) and effective cation exchange capacity following the procedures described by Agbenin (1995). Seeds of two okra varieties (NHAe 47-4 and LD 88 were sourced from the National Horticultural Research Institute (NIHORT) Ibadan, Oyo State Nigeria.

The land was manually cleared followed by ploughing with a tractor. Ridges of 2m length at 75 cm apart were made in each plot. The plots size was 2m × 5.25 m (10.5m^2) comprising of 8 ridges. The treatments were a factorial combination of two okra varieties (NHAe47-4 and LD 88), Five N levels, (0, 30, 60, 90 and 120 kg ha^{-1}) laid out in Randomized Complete Block Design (RCBD) with three replications. Three seeds were manually sown per hole at 0.5m apart and later thinned to one seedling per stand at two weeks after planting (2WAP). Phosphorus and potassium fertilizer at 50 kg ha^{-1} each was applied in all the plots at 2WAP as basal application using single super phosphate and muriate of potash respectively. Urea was applied in two split doses (at 2 and 4WAP) to supply Nitrogen at different rates (0 kg N ha^{-1}, 30 kg N ha^{-1}, 60 kg N ha^{-1}, 90 kg N ha^{-1} and 120 kg N ha^{-1}). Weeding was carried out at two weeks' intervals manually. Incidence of insect pests was kept down with the application of Zap® a.i (Lambda Cyhalothrin 25g/L), at 0.005kg a.i/ha. The insecticide was applied as from 2WAP till harvesting stage.

The parameters measured/recorded includes:

1. Number of fresh fruits – Number of fresh fruits per plot was be determined by counting fruits harvested per plot, each harvest was done at five days' interval.
2. Weight of fresh fruits – Weight of fresh fruits per plot was be determined by weighing fruits at each harvest per plot using mettler weighing balance and the sum of all the weights was recorded.
3. Fresh fruit diameter- Fruit diameter per plot was determined by measuring the fruit with the use of a Vernier caliper at the point where the fruit is wider (middle).
4. Weight of seed – The Weight of seeds per fruit is aimed at determining the seed yield. This was determined by weighing the seeds on Mettler balance; the sum of all the weights was calculated and recorded per plot.
5. 100–Seed weight determination- Four replicates of 100 seed from each seed lot was counted and weighed on a Mettler balance.

Lab Experiment consist of treatments with factorial combinations of two okra varieties (NHAe47-4 and LD 88), and seven fruit harvesting stages (14, 21, 28, 35, 42, 49 and 56 days after anthesis) arranged in a Completely Randomized Design (CRD) and replicated four times.

Fruit tagging and harvesting- Flowers were date tagged on the field immediately they open on the plants daily which is an index of anthesis. Successfully tagged flowers was harvested at different maturity stages 14, 21, 28, 35, 42, 49 and 56 DAA from the first positions on the mother-plant. Seed handling - Following each harvest on the field, fruit diameter and length was measured using the venier caliper and means of the respective parameters were recorded.

Number of seeds per fruit was recorded by counting the number of seeds per fruit and means were recorded.

The weight of seeds per fruit were taken using a Mettler balance; the sum of all the weights will be calculated and recorded per plant. Fruits were broken to extract the seed.

Seed storage -Samples of seeds of each of the treatment combinations were put in small open plastic plates measuring 300 ml and then placed in an incubator at 35 °C and relative humidity of 90 %. This was aimed at accelerating the ageing of the seeds to determine the relative longevity of the seeds of the different lots (Delouche and Baskin, 1973). The seeds were stored in this environment for 4 weeks and seed samples were drawn for

ISSN: 2814-0508

germination test prior to storage and at two weeks' intervals after wards for 4 weeks.

Seed germination test - Samples were drawn from the containers in storage for germination test at 0, 2, and 4 weeks after storage. This was done by counting four replicates of 30 seeds each of the treatment combinations which was placed on filter paper moistened with distill water in plastic Petri-dishes. Germination counts was taken every-other-day and results were expressed in percentages.

The data collected were subjected to analysis of variance (ANOVA) using SAS Statistical package 9.2. At 5% level of probability means were separated using Student- Newman Keuls (SNK) Test.

RESULTS

Table 1 shows the results of the physical and chemical properties before land preparation. The soil of the site was sandy loam in texture with a moderate pH indicating the soil was slightly acidic. Soil organic carbon (SOC) was low with moderate contents of total soil nitrogen and available phosphorus. The ECEC of the soil was also found to be low.

Table 1: Physiochemical properties of the soil sample of the experimental field.

Soil Properties	Values
Particle Size distribution (g kg^{-1})	
Sand	815.5
Silt	109

In Table 2, Nitrogen significantly affected the number of fruits produced, the number of fruits produced increased with the increase in rate of nitrogen to the mother plant. However, application of 120 kg N ha^{-1} recorded the higher number of fruits while 0 kg N ha^{-1} recorded the lowest number of fruits. Variety significantly influenced fresh fruit weight as fruits from LD88 (595.28g) were heavier than fruits obtained from NHAe47-4 (447.25g). Nitrogen also significantly affected this trait as the weight of fruit increased with the increasing rate of nitrogen application with 120kg N ha^{-1} producing heavier fruits (739.90g). Variety had significant effect on fresh fruit diameter, as fruit from NHAe47-4 (10.81cm) were bigger than fruits obtained from LD88 (10.47cm). Variety also significantly affected weight of seed per fruit and 100 seed weight; seeds of fruit obtained from NHAe47-4 (3.03g) are heavier than seeds of fruit obtained from LD88 (2.92g) whereas for 100 seed weight, seeds obtained from LD88 (4.20g) are heavier than that of NHAe47-4 (3.85g). Weight of seed per fruit and 100 seed weight increased with an increase in fertilizer application.

Table 2. Effects of nitrogen application on growth and fruit yield parameters in two varieties of okra evaluated in the study

Significant variations in viability maintenance between the two varieties were recorded. At the onset and up to 4 weeks of storage, LD88 germinated significantly higher than NHAe47-4 (Table 3). Following storage for 4 weeks, germination values for the two varieties were similar. Prior to storage seed from fruit of NHAe47-4 has a lesser germination (49.21%) percentage compared to two (2) week of storage (54.9%) but higher than that of four (4) weeks storage period (33.00%). With respect to days after anthesis, there was significant effect on storage period prior to storage. At 14 days after anthesis, a significant increase in viability of seed was recorded down to (42) days after anthesis, which recorded the highest germination percentage (79.25%). It began to decline at forty-nine (49) days after anthesis (60.45%) and 56 days after anthesis (55.00%). This indicates that beyond 42 days after anthesis seed begin to lose its viability.

DISCUSSION

Maintaining optimum plant population and nitrogen fertilization dose are most important elements in improving productivity of okra. Optimum plant density is the key element for higher fruit yield of okra, as plant growth and yield are affected by nitrogen fertilization (Khan *et al*., 2013). The research conducted by Atif and Nahed (2016) revealed that increase in nitrogen fertilizer from the control (0 N) to 160 kg N ha^{-1} significantly increased total fruit yield. LD88 recorded higher seed yield compared to NHAe47-4 according to the research by Khan *et al*. (2002) that a higher okra fruit and seed yield is the function of size of the fruits and nutrition of the mother-plant during growth on the field. Rao *et al.* (2017) advised that seeds should be harvested at proper time to ensure their quality in terms of germinability and vigour. However, (Passam *et al.,* 2010) reported that fruits harvested even before physiological maturity and allowed some days of post-harvest ripening may produce good quality seeds since seed development continues in fleshy fruits owing to continuous supply of nutrients and food reserves from fruit to seed. A study conducted by (Seal *et al.,* 2013) noted that there is a positive linear correlation between fruit weight and seed dry weight on kiwifruit. They stated that flowers that open earlier have a larger ovary and set larger seeds leading to large fruits explaining that this may be because of either their innate superiority or their position on the vine. The decline in seed viability after a storage period of 49 days is indicative of seed deterioration which is linked with disruption of cell organelles due to free radical production in the cells of embryos (Bewley and Black, 2012). However, for okra seed production, fruits are left on the mother plant until they are dry before harvested. The seed crop requires the right stage of maturity followed by proper drying to ensure high germinability after harvest and storage. This is because seed longevity is known to be influenced by the initial seed quality, which is affected by the production procedure (Bortey and Dzomeku, 2016). The results of this study showed that germination, longevity and high seedling emergence were best maintained in seeds from plants to which 90 and 120 kg N ha^{-1} were applied to their mother plants during growth on the field.

CONCLUSION

It can be concluded from this study that application of 90 –120 kg N/ha gave better fruit size and seed yield of okra. Fruits of LD88 harvested at 42 days after anthesis had a better germination percentage than fruit of other harvesting day. Application of 90kg N/ha to okra is therefore suggested for good growth, improved fruit and seed yield in the studied zone.

ABSTRACT

Tomato (Lycopersicum esculentum) yields are limited by poor soil nutrition with nitrogen being the most limiting nutrient required in large quantities. The study was aim to investigate the Response of tomato fruit to varying levels of nitrogen and spacing on yield and quality in Hadejia sudan savanna of Nigeria. Plants were grown in at Department of Horticulture research and demonstration field in two consecutive years under irrigation 2019/2020 and 2020/2021, each year cultivation commenced in November to February. The nitrogen rates 0, 30, 60 and 90 kg N ha^{-1} applied in two splits. Spacing was 20x30, 30x30, 40x30 and 50x30 cm. The experimental design was a Randomized Complete Block Design, with a Split-Plot arrangement with main plots as nitrogen levels and spacing the sub plots in three replications. Fruit yield and quality data were taken after each harvesting. Number of marketable fruits was significantly affected by spacing in both seasons. Nitrogen of 60 kg ha^{-1} and spacing of 40 x 30 cm had the highest mean fruit numbers in second year. Nitrogen of 60 kg N ha^{-1} and spacing of 50 x 30 cm had the highest fruit yield in first year. Marketable unit fruit weight was highest in first year, at 50 x 30 cm. The study was significant to farmers producing tomatoes under greenhouse, to maximize on profits by scaling down nitrogen fertilizer use to attain high yields and quality of marketable tomato fruits using appropriate spacing.

Key words: Tomato, nitrogen, spacing, fertilization, yield

INTRODUCTION

Tomatoes are a vegetable crop. It belongs to the Solanaceae family. The Solanaceae family includes plants such as tomatoes, Irish potatoes, and egg plants, among others. A tomato is increasingly becoming important as a food, medicinal and industrial crop (FAO, 2001). Tomato production in Nigeria is mainly under field conditions, where changes in climatic conditions do not allow realization of economic yield. There are fluctuations in the supply of tomatoes in the market, which lead to market glut during in season and shortage during off-season (Nonnecke, 1989). Determinate cultivars may grow up to 2 m in height and are erect with restricted flowering and fruiting, and are suitable for field conditions. The stem of indeterminate cultivars grows indefinitely, reaching to more than 10 m within one year, making it ideal for long season continuous cropping as they flower and fruit regularly and evenly (Rick and Butler, 1956). Indeterminate tomatoes, vegetative growth and reproductive development proceed concomitantly during the greater part of the plant life. A strong competition between developing leaves and apical meristem influences both the earliness of harvest and total yields. High assimilate availability under high light intensity conditions stimulates both meristem activity and leaf growth (Hussey, 1963a), but when plants are source-limited (under high temperature and low light), young leaf growth is favoured at the expense of apical development. Continuous removal of young leaves counteracts this effect (Hussey, 1963b, Kinet, 1977).

With increasing plant populations, intra-plant competition becomes more important and eventually only flowers on the earliest clusters set fruits. These early yields increase as plant population increases, because there are more early clusters per unit area. Nitrogen is the most limiting nutrient to crop production (Pionke *et al.,* 1990). Like many vegetables, tomato is often heavily fertilized. Large amounts of nitrogen are often lost to leaching below the root-zone of vegetable crops (Pionke *et al.*,1990). Also, nitrogen fertilization, along with early season weed control, allows rapid crop establishment and growth, which is critical for the crop to suppress late-emergence weeds (Itulya *et al.,* 1997). Nitrogen deficiency can seriously decrease yield and crop quality. The nitrogen composition of plant tissue has important nutritional consequences, since plants are a major source of proteins in human diet (Below, 1995). Nitrogen is also a constituent of a large number of important compounds found in living cells, such as (enzymes) amino acids and nucleic acids (RNA and DNA) (Lea and Leegold, 1993). Hence, nitrogen is critical in improving growth, yield and quality of vegetable crops.

Tomato has always been a popular vegetable since its introduction in Hadejia, both in fresh market and processing industry. Tomato is the highest vegetable income earner produced annually in Hadejia (Anonymous, 2003). Most commercial tomato cultivars are selected on the basis of their yield potential over a wide range of growing conditions. Weather patterns influence tomato production in the field due to seasonality. Knowledge of optimum spacing and nitrogen fertilizer will enhance production by increasing yields and possibly improving quality of tomatoes under protected structures. Although tomato is an important crop in Jigawa state little is known of its specific nitrogen (urea) fertilizer requirement, Spacing, growth, yield and quality of tomatoes as well as pest and disease prevalence.

In this study it was assumed that high levels of urea (46:0:0) result in increased yields and quality. Intra-plant spacing of tomato influences tomato yield and quality more than inter-plant spacing. The study was aimed at determining if tomato growth, yield and quality could be increased by manipulation of nitrogen fertility levels and plant spacing under field conditions in Hadejia. Thus the specific objectives of the study were to determine: The effects of nitrogen levels on growth, yields and quality of tomatoes, the effects of spacing on growth, yield and quality of tomatoes.

MATERIALS AND METHODS

The experiment was conducted during the 2019/2020 and 2020/2021 dry season at Department of Horticulture research and demonstration field, Binyaminu Usman Polytechnic Hadejia within a latitude of 12^0 22'N and 12^0 24' N and longitude of 7^0 46' E and 10^0 E within the Sudan savanna on a sandy clay loam soil, having 0.56% organic matter, 0.06% nitrogen, 5.25ppm Phosphorus and 0.32 Potassium. The seeds were obtained at Jigawa Agricultural Supply Company (JASCO) Hadejia office. The seedling was raised in a nursery bed of 3 x 4m2 the seed were sown by drilling method. The nursery bed was watered and also kept free of weeds. Typha grass was used as mulch in preventing directs sun rays on the seedlings. Karate was used in controlling insects in the nursery at the rate of 100ml per 20 litre of water. Land was ploughed to a depth of 20 to 30 cm to kill weeds. Soils with hard pan within 150 cm of the soil layer require deep soil cultivation using a chisel plough or double digging. Well rotten farm yard manure and single super phosphate was used to improve soil organic matter and structure for effective tomato growth. The seedlings were nurtured till they attain the age of 4 weeks old and transplanted to the field using ball of earth method during transplanting at varying spacing.

Trenches 0.5 m wide by 0.8m deep lined with Polythene were used to separate the main plots to prevent nitrogen moving from one plot to another. Mulching of each plot was done on the day of transplanting by placing the polythene film and covering its sides with soil. Holes were opened at planting time on the poly film depending on the spacing recommendation for each plot. Triple supper phosphate (TSP) 23 kg P ha^{-1} was used for planting. The nitrogen: 0, 30, 60 and 90 kg N ha^{-1} inform of urea (46%) was split-applied after dissolving in water to avoid loss of ammonia to the atmosphere through volatilization due to high greenhouse temperatures. The splits of 30, 60 and 90 kg N ha^{-1} was applied two weeks after transplanting and two weeks later. All plots were applied with Muriate of Potash after two weeks at the rate of 305 kg K ha^{-1}. The inter-row and intra-row spacing (in cm) were: 20x30, 30x30, 40x30 and 50x30cm. The plots measured 3 m by 1.5 m. The experimental design was a randomized complete block design, split-plot arrangement in three replications. The main plots were nitrogen fertilizer levels, while spacing formed the sub-plots.

Tomatoes 35 cm high were trained to a single stem twisted around a sisal twine suspended from wires stretched horizontally and parallel to the tomato beds. Poles (2.2 m high) spaced at 4 m supported the wires at 35 cm apart and 2 m high. At the bottom, each string was tied directly to another wire running horizontally at 30 cm from the ground. Pruning was done regularly.

All plots received equal amounts of water, which was applied on the same day to avoid variations. Before planting, the plots were watered uniformly until field capacity was reached and thereafter plots were installed with irrigation drip tubes on the soil surface. Discharge rate for the drip lines was 2 litres per minute.

Harvesting began when first fruits reached breaker stage and done twice per week from all plants in the centre row; outer rows and plants at the end of each plot served as guard rows. All the fruits harvested per 3 x 1.5 m area were counted and weighed separately on each harvesting date. Fruits were separated into two lots of marketable and unmarketable fruits.

Fruits were graded soon after harvesting, based on size using a vernier caliper. Fruits were categorized in large (>8 cm) in diameter (Thompson, 1996). Marketable fruits were picked at breaker stage. Unmarketable fruits were those with physiological disorders such as cracks and blossom end rot or other types of blemish. Fruits from each category were counted and weighed separately. Marketable fruits were those with fruit size >4cm, without cracks, blemish, disease incidence, and other physiological disorders.

Thirty harvested fruits from each plot were randomly selected and their firmness determined using a penetrometer (Bishops Instrument, Italy). Readings were recorded in kilograms $m^{-2.}$ Fruits stored at 20^{oC} were measured every two days to determine the storage life. Fruit firmness was monitored throughout the ripening period. Total soluble solids content of the juice of 30 randomly selected, table ripe tomato fruits per plot was measured using a hand refractometer (0-30% brix). The fruit surface was cut using a knife, and juice squeezed into the refractometer. The reading was recorded and fruits with 4–9% brix were considered to have high quality.

Data Analysis

All data were subjected to the Analysis of Variance using MSTAT-C computer programme and where the F-test was significant, either Least Significant Difference or the Duncan's Multiple Range Test depending on the number of means did separations.

RESULTS AND DISCUSSION

Tomato yield and quality are affected by fertility and spacing among other factors. Nitrogen levels affect many attributes in tomato quality and yield such as fruit firmness, fruit size, total soluble solids, number of fruits per plant and marketable fruit yield. Austin (1970) showed that close spacing and high fertility levels are required to increase total yields and number of fruits per plant. Results (Tables 1) indicate that nitrogen had no significant effect on marketable fruits in both seasons. Spacing significantly affected the number of marketable fruits in both seasons.

Table1. Effect of nitrogen (N) levels and spacing (S) on number of marketable fruits per $4.5m^2$ during 2014 and 2015 season

Spacing (Cm)	Nitrogen levels (kg ha-1)							
	2017/2018 Season				2018/2019 season

* Values not followed by a letter within a factor are not significantly different according to the F-test at P <.0.05.
** Values followed by the same letter within a letter series are not significantly different at P <0.05, according to the Duncan's Multiple Range Test. a, b, c, d represent nitrogen level and e, f, g, h represent spacing.

Spacing of 50 x 30 cm had the highest significant number of marketable fruits in 2017/18 season, while spacing of 40 x 30 cm had the highest number of marketable fruits in 2018/19 season (Tables 1). The difference could be attributed to the number of early fruits produced by spacing of 30 x 30 cm which had high density. The crop was infested by bacterial wilt in 2018/19 season and the crop was not harvested to completion. Spacing of 50 x 30 cm in both seasons had the lowest number of marketable fruits. As plant density increased, the total yields were highest but the numbers of marketable yields were not as high compared to wide spacing. This is in agreement with West and Pierce (1988) who showed that total season yields increased as plant population increased to an optimum level (20,000 plants) per hectare. They pointed out that increases in density generally increase both early and total yields per hectare. Mack and Varseveld (1982) also reported that yields are greater for high population than for low populations. Mohammed and Zeineb (1988) observed that in-row spacing had no effect on marketable yield presented as percentage weight of total yield.

Tomato yields are highly responsive to the application of nitrogen (Anderson *et al.,* 1999). Nutrient requirement of the tomato is an important factor if large quantities of high quality fruits are to be produced effectively and efficiently annually. Nitrogen fertilizer levels increase total marketable yields (Wien and Minotti, 1988). In the current study nitrogen levels had no significant influence on marketable fruit yields in both seasons (Tables 1). These could be attributed to the fertilizer form used. The fertilizer used in the study was urea dissolved in water before application. Urea is well documented to be subjected to excessive nitrogen losses particularly under conditions of high soil pH, high temperature, excessive soil drying and wetting and high clay content (Ali *et al.,* 1990). High temperature conditions prevalent during season 1 of the study may have promoted measurable gaseous losses of ammonia (NH_3) and release to the atmosphere (after the application of fertilizer).

Table 2. Effect of nitrogen (N) levels and spacing (S) on fruit size (cm) during 2014 and 2015 season

Spacing (Cm)	Nitrogen levels (kg ha-1)

50x30	6.1be	6.2be	6.4ae	5.9ce	6.4f	7.1e	6.6f	6.5e

* Values not followed by a letter are not significantly different according to the F-test at $P < 0.05$.
** Values followed by the same letter within a letter series are not significantly different at $P<0.05$, according to the Duncan's Multiple Range Test. a, b, c, d represent nitrogen level and e, f, g, h represent spacing.

Spacing significantly affected fruit size, with the closest spaced plants having the smallest fruits, while the widest spaced plants had the largest fruits in both seasons (Table 2). Tomato plants in 2018/19 Season had larger fruits than 2017/18 season. The fruits harvested in 2019 season were the early fruits in the lower trusses which tend to be bigger than the later formed fruits as the crop had bacterial wilt infection. The number of fruits measured was also less compared to 2018 season, where all the fruits were harvested for the entire season, measured and the average fruit size computed. The decrease in size due to close spacing was in agreement with observations by Moore *et al*. (1957) who reported that close spacing was accompanied by a reduction in fruit size. Studies by Fery and Janick (1970) indicated that increasing plant population in the field or greenhouse increased the early and total yields per unit area, but decreased the number of fruit set per plant and fruit size.

Plots without nitrogen and those with the highest nitrogen level had the smallest fruit size (Tables 2). This was in agreement with Vittum and Tapley (1953), who observed that increasing the fertility level considerably reduced the average size per fruit. They suggested that at the high fertility level plants were able to set so many fruits per plant that the gross drain of minerals and carbohydrates was larger and resulted in smaller fruits. The decrease in fruit size was greater at low fertility level than at higher levels.

ISSN: 2814-0508

Akanbi *et al.,* (2007) stated that fruit size is genetically and environmentally controlled through successive phases of fruit development and is positively correlated with amount of N-element available for plant use during fertilization, cell mitotic activity and enlargement. N availability affect sink function of the fruit and these play a role in the control of carbohydrate accumulation in tomato. These later activity determines the number, size and chemical components of fruits. Cell numbers and size contribute to fruit size. Small fruits are related to low cells; hence a fruit with sufficient amount of nitrogen, the number and size of cells are bound to be high. In the study fruits which had no nitrogen application were small compared to those with nitrogen application. The high nitrogen level application reduced fruit size could be due to the growth of vegetative matter which might have shifted the sink to the leaves instead of the fruits.

Table 3. Effect of nitrogen (N) levels and spacing (S) on total soluble solids (TSS) during 2014 and 2015 season

Spacing (Cm)	Nitrogen levels (kg ha-1)

* Means not followed by a letter are not significantly different according to the F-Test at $P < 0.05$.
** Means followed by the same letter within a letter series are not significantly different at $P < 0.05$, according to the Duncan's Multiple Range Test. a, b, c, d represent nitrogen level and e, f, g, h represent spacing

Plant spacing in 2019 season had no significant effect on total soluble solids. During 2019 season the total soluble solids were lower than in 2018 season. This may be attributed to plant growth differences due to seasonal changes during the trial period. Solar radiation received during 2018 season influenced the supply of leaf assimilates, because when solar radiation is high, both dry matter and sugar content of the fruit are at their highest (Ho and Hewitt, 1986). Also the bacterial infection may have hindered nutrient uptake which contribute to the TSS.

In the current study, nitrogen levels applied had significant influence on the total soluble solids. Mohammed and Zeineb (1988) indicated that soluble solids contents of fresh tomato fruits were not appreciably affected by nitrogen application. This is in agreement with the study as the differences in the TSS are not very high. Garison *et al.* (1967) indicated that nitrogen tends to decrease the percent total soluble solids in the juice and increases titratable acidity.

A study carried out by Erdal *et al.* (2007) indicated that TSS contents increased with nitrogen applications. The lowest TSS values were obtained from zero N applications. Total soluble contents are an indicator of mineral nutrient concentration in fruit and these values generally increase with fertilization. Erdal *et al* (2007) also indicated that TSS was highest with fruits that have received higher N levels than other levels of N. Nitrogen being a constituent of protein and amino acids it directly affects the TSS. These indicate the reason for low TSS in the zero nitrogen application in the current study.

CONCLUSION

Based on the findings of this study, it was concluded that Heavy application of nitrogen does not necessarily increase yields of tomatoes; therefore, farmers save some nitrogen fertilizer by applying lower rates than 80 kg N ha^{-1} without adversely affecting yields. Spacing of 50 x 30 cm gave high yields and made it easier to carry out cultural and agronomic practices efficiently. Heavy application of nitrogen (120 kg ha-1) reduces fruit size and the fruit firmness. Low nitrogen levels reduce fruit total soluble solids. It is thus recommended that Nitrogen levels between 40 and

80 kg N ha-1 be applied under field condition in Hadejia and a Spacing of 50 x 30 cm should be adopted as it gives hig yields.

ABSTRACT

The field trial was conducted during the rainy season at National Horticultural Research Institute (NIHORT) Bagauda (11^0 53 N and 8^0 14 E 440 M above sea level) located in the Sudan Savanna ecological zones of Nigeria to determine the effect of nitrogen fertilizer and intra-row spacing on the yield components of Roselle (Hisbiscus sabdariffa L.). The treatments consisted of four rates of nitrogen (0, 60, 120 and 180 kg N ha$^{-1)}$ and three intra-row spacing (45, 60 and 75 cm). The treatments were arranged in a randomized complete block design and replicated three times. The results showed that the application of 180 kg N ha^{-1} and 120 kg N ha^{-1} showed significant effect on number of pods per plant, seed yield and calyx yield ha^{-1}. Intra-row spacing was insignificant on the yield components. Based on the results obtained 120 kg N ha^{-1} can best be used for the production of Roselle in Samaru.

Key words: Calyx, Components, Roselle, Nitrogen

INTRODUCTION

Roselle (*Hibiscus sabdariffa L*) belongs to the Malvaceae family and is one of the most important traditional leafy vegetable in the tropics and sub-tropics. It is believed to have originated from Africa (Grubben and Denton, 2004). It is grown in predominantly in mixture with other crops in which its specific nutrients and planting space are hardly considered, since it is considered a minor crop in the mixture the calyx and seeds yield are generally low (Fasoyiro *et al.*, 2005) therefore only a blanket Nitrogen Provision of sufficient quantities of nitrogen encourage rapid vegetative growth and regulate the uptake of P and K growth of most crops is limited more often by nitrogen deficiency than other nutrients because of the relatively large amount of required by plants nitrogen deficiency results in stunted growth, restricted, restricted root system with small yellow and chlorotic leaves. While excessive supply of nitrogen can encourage luxuriant vegetative growth, delays crop maturity and increased succulence. Nigerian Savannah is characterized by low soil Nitrogen with mean of 0.051% (John *et al.,* 2004). inter and intra-row spacing are applied by farmers since recommended planting spacing for better yield of Roselle are not available. Provision of sufficient quantities of nitrogen encourage rapid vegetative growth and regulate the uptake of P and K growth of most crops is limited more often by nitrogen deficiency than other nutrients because of the relatively large amount of required by plants nitrogen deficiency results in stunted growth, restricted, restricted root system with small yellow and chlorotic leaves. While excessive supply of nitrogen can encourage luxuriant vegetative growth, delays crop maturity and increased succulence. Nigerian Savannah is characterized by low soil Nitrogen with mean of 0.051% ((John *et al.,* 2004)).

MATERIALS AND METHODS

The field trial was conducted during the rainy season at National Horticultural Research Institute (NIHORT) Bagauda (11^0 53 N and 8^0 14 E 440 M above sea level) located in the Sudan Savanna ecological zones of Nigeria. The treatments consisted of three Intra-row spacing (45, 60 and 75 cm) and four Nitrogen fertilizer rates (0, 60, 120, and 180 kg N ha^{-1}) laid out in a randomized complete block design (RCBD) and replicated three times.

Data Collection

Data were collected on number of calyx per plant, dry calyx yield (kg ha^{-1}), 1000-grain weight (g) and seed yield kg ha^{-1}. The data collected were subjected to statistical analysis of variance (ANOVA) and treatment means were compared using Duncan's Multiple Range Test (DMRT) at 5% level of probability.

Agronomic Practices

The field for the experiment was harrowed to obtain a fine tilth. Ridges were made at the inter row spacing of 75cm. The field then sub divided into plots and replications according to the experimental layout. The seeds were dressed with Apron star at one sachet (10g) to 3kg of Roselle and were sown manually at spacing of 25, 60 and 75 cm x 75cm apart as per treatments. A pinch of seeds was dropped in each planting hole and covered lightly with soil, later they were thinned to two plants per stand at 3 weeks after sowing. Pre-emergence herbicide Atrazine + Metalochlor (Primextra Gold) at the rate of 2 kg a. i ha^{-1} was used immediately after sowing, and weeding was done manually using hoe at 3 WAS and ridge molding at 8 WAS. Basal application of phosphorous fertilizer using SSP 18 % P_2O_5 at the rate of 60 kg ha^1 and Potassium using Murate of potash K_20 at the rate of 32 kg ha^{-1} both were applied before sowing as per stands. While Nitrogen using Urea 46 % N was applied at 3 and 6 WAS as per treatment. There was incidence of pest in the experimental site and was controlled with the use of chemical as recommended (Cypermethrin at the rate of 2.1 kg ai ha^{-1}). Incidence of disease was not observed during the trial. Harvesting was done manually when the crop attained physiological maturity, the stalks were cut at the ground level with cutlass and the panicles were separated by cutting them from the stalks and were allowed to dry, threshing was done manually by beating gently with a stick and the grain were separated from the chaff by winnowing.

RESULTS

Table 1 shows the effect of nitrogen fertilizer rates and intra-row spacing on number of pods per plant of Roselle. Application of 180 kg N ha^{-1} produced the highest number of pods per plant but at par with 120 kg N ha^{-1}. Intra-row spacing and interaction did not influence number of pods per plant. Likewise, application of 180 kg N ha^{-1} produced the highest Dry Calyx Yield but at par with 120 kg N ha^{-1}. Intra-row spacing and interaction did not influence Dry Calyx Yield (Table 2).

DISCUSSION

Application of 180 kg N ha^{-1} at par with 120 kg N ha^{-1} produced the highest Seed yield and Calyx yield per hectare. This could be attributed to the fact there was translocation of assimilates from the vegetative parts to the seed and calyx. Application of Nitrogen also increased number of calyx (pods) per plant and calyx yield per hectare. The corroborated the findings by Ndayako (1997) at Samaru (Guinea Savannah) and Okosun *et al.* (2006) in the rainforest zone of Nigeria, who reported significant increase in the yield of calyces and its components with increase in Nitrogen fertilizer application. However, 1000 seeds weight were not affected by Nitrogen fertilizer rates, the increase in the number of calyces could be due to the direct effect of Nitrogen in photosynthesis to reproductive sink. Intra-row spacing did not influence seed and calyx yield per hectare from the results but Semsiri *et al.* (2000) reported that, intra-row spacing of 60cm gave the highest yield and more calyces per plant.

CONCLUSION

Based on the results obtained 120 kg N ha^{-1} can best be used for the production of Roselle in Samaru.

ABSTRACT

This research was conducted to examine the growth and yield response of sunflower (Helianthus annuus L.) varieties to varying intra-row spacing in the Sudan savannah zone of Nigeria. The trial was conducted in two different locations, Kano University of Science and Technology (KUST) research farm and Binyaminu Usman Polytechnic (BUPOLY) Hadejia practical farm during 2019 raining season. Four varieties of sunflower (SSL803, SSL806, SSL807 and SSL809) were planted at varying intra-row spacing of 20cm, 30cm, 40cm, 50cm and 60cm. Split plot design was adopted for the research, with variety allocated to the main plot while intra-row spacing to sub plots, treatments were replicated three times. The result of the experiments shows no significance statistical difference in most of the yield components between the varieties in both locations. The oil was extracted through ether extraction method and the percentage was calculated.

Key words: Yield components, Sunflower, Varieties and Spacing

INTRODUCTION

Sunflower (*Helianthus annuus* L.) originated in western North America; it is thought to have been domesticated around 1000 B.C. by Native Americans. Spanish explorers brought the sunflower to Europe in 1510. However, it was not until the late 1800, when the flower was introduced into the Russian Federation that the sunflower became a food crop. In 1860, Russian farmers made significant improvements in the way the crop was cultivated. At that time, they became the world's largest producer of sunflower seeds (Schneiter and Miller, 2010). According to Robert (2007) sunflower was probably first introduced to Europe through Spain, and spread through Europe until it reached Russia where it was readily adapted. Selection for high oil in Russia began in 1860 and was largely responsible for increasing oil content from 28% to almost 50%. The high-oil lines from Russia were reintroduced into the United State which rekindled interest in the crop.

The economic importance of sunflower cannot be over emphasized as an important oilseed crop worldwide. The fresh green plants can be fed as silage or fodder to livestock. The seed which can be eaten raw or roasted contains 36 - 45% oil depending on the variety and can be used in salad, cooking oil, margarine, lubricant, paint vanishes and soap production. The decorticated seed cake is a good source of protein (35%) for livestock, especially when made from whole seed. The crop is also a good source of nutrition which is used in food preparation, feeding livestock and poultry (FAO, 2010). Confectionery sunflower varieties have seeds that are larger, easier to dehull, lower in fat and are typically striped or white (Ford, 2011).

Sunflower oil is one of the vegetable oil in the world though it was not seen as a vegetable oil source in the U.S until the last 50 years, and really began to be significantly grown for this purpose about 25 years ago (Robert, 2007). After the oil is extracted from the sunflower seed which is about 40 to 45% of the seed by weight, the remaining seed material (meal) is fed to livestock. The nutrient value of sunflower meal depends primarily on the type of processing it has gone through. If part or all of the hulls remained on the seed prior to oil extraction, then the meal will have higher fibre content but lower protein and fat. Solvent extracted sunflower meal will have a protein percentage around 41% if dehulled, and around 28% if hulls are left on the seed. Fat content of solvent extracted meal is roughly 1%, and roughly 9% in mechanically pressed seed meal (Burton, 2008). Oil from sunflower was regarded to be cholesterol free and is valued as one of the healthy vegetable oil in the world and the sunflower seeds are used for the production of confectionaries (Berglund, 2007). This work is designed to investigate the oil content of some varieties of sunflower (*Helianthus annuus* L.) obtained from Bagauda and Hadejia locations.

MATERIALS AND METHODS

The research was conducted at Bagauda research farm at Bagauda village, Kano state which lies between latitude 11 40'N and longitude 8 16' E and BUPOLY Hadejia research farm, Hadejia town Jigawa state which lies between latitude 12 26' 59''E and longitude 10 02' 39'' E to evaluate the response of sunflower *(Helianthus annuus* L.*)* varieties to varying intra-row spacing in the Sudan savannah zone of Nigeria.

The treatments of the research consist of variety SSL803, SSL806, SSL807 and SSL809 which were allocated to the main plot and intra-row spacing of 20cm, 30cm, 40cm, 50cm and 60cm allocated to subplot. Split plot design was selected involving three replications, where each replication consists of four main plots each of 4.5m x 3m represented by 6 ridges. The method of data collection adopted was observation procedure, where 5 selected plant samples were tagged and observations were recorded as needed in the experiment. The data on growth and yield characters were collected at 4, 6, 7 and 8 weeks after sowing and also at harvest.

A sample of the threshed seeds from each subplot were cleaned and dried to reduce the moisture content. The sample seeds were crushed manually and the nuts were separated from the chaff. The nuts were then grounded into flour and wrapped with filter paper and then inserted into a soxlalet apparatus thereby adding ether solution to extract the oil through ether extraction method. This was done for each sample from all subplots in the experiment. Variety SSL809 produces higher oil at Bagauda while variety SSL807 at Hadejia. The results of the treatments were subjected to analysis of variance using SAS software. The oil percentage was calculated using the formula given:

$$\% \text{ Fat} = \frac{W1 - W2}{W1} \times 100$$

Where W1 = weight of sample before extraction (g), W2 = weight of sample after extraction (g).

RESULTS AND DISCUSSIONS

Skoric *et al.* (2007) reported that the performance of varieties tested over several environments is the best basis for selecting sunflower hybrids. The choice should consider yield, oil percentage, maturity, seed size, lodging and disease resistance. The results of the effects of variety and intra-row spacing on head diameter, number of seeds per head, grain yield and oil percentage of sunflower *(Helianthus annuus* L.*)* at Bagauda and Hadejia showed that almost all of the characters assessed during the experiment were not significantly affected by the treatments (Table 1). At Bagauda the variety SSL809 produced the highest percentage of oil when compared to the other varieties. But at Hadejia, variety SSL807 recorded higher oil percentage than the other varieties. The results revealed that oil percentage was not significantly affected by intra-row spacing at both locations of the experiment (Table 2). The findings of this work is in accordance to that of Smith (2008) who reported that sunflower grown in rows 22, 30, or 38 cm apart did not differ in seed yield, oil percentage, large seed percentage, seed weight, height, or flowering date.

CONCLUSION

Sunflower produce high quality vegetable oil and livestock feeds. After oil is extraction from the sunflower seed which is about 40 to 45% of the seed by weight, the remaining seed material (meal) is fed to livestock (Burton, 2008). This study examined the level of oil content of sunflower in percentage as affected by variety and spacing at Bagauda and Hadejia locations. Based on the findings of the study, the results showed that the effects of variety and spacing on oil contents of sunflower was not statistically significant in both location of the experiments, this implies that the differences in between is just by chance. Hence any of the variety tested can perform very well in the experimental sites with good management.

ABSTRACT

Leaching of soil nitrogen contributes to poor soil fertility. The experiment was conducted to investigate the effect of different inorganic fertilizer rates on the growth and yield of fluted pumpkin fertilizer. Ten treatments consisted of three rates of NPK 15:15:15 fertilizer (200, 400 and 600 kg ha^{-1}), three rates of NPK 20:10:10 (150, 300 and 450 kg ha^{-1}), three rates of urea (65.21, 130.44 and 175.65 kg ha^{-1}) and control (zero application). The experimental design was a Complete Randomized Design and replicated three times. The different inorganic fertilizer rates supplied 30, 60 and 90 kg ha^{-1} of nitrogen respectively. Growth and yield parameters peaked at the application of inorganic fertilizers that supplied 60 kg ha^{-1} of nitrogen and declined at 90 kg ha^{-1} of nitrogen. Application of 400 kg ha^{-1} of NPK 15:15:15 fertilizer produced highest plant yield (0.43 t ha^{-1}) followed by 130.44 kg ha^{-1} of urea (0.42 t ha^{-1}) while 300 kg ha^{-1} of NPK 20:10:10 (0.19 t ha^{-1}) produced lowest plant yield (0.15 t ha^{-1}). Therefore, for improved growth and yield of Telfairia occidentalis in Awka, the application of 400 kg ha^{-1} of NPK 15:15:15 is recommended, and in the unavailability of NPK 15:15:15, 130.44 kg ha^{-1} of Urea is recommended.

Keywords: Nitrogen content, inorganic fertilizer, fluted pumpkin

INTRODUCTION

Telfairia occidentalis is a tropical vine grown in West Africa as a leaf vegetable and for its edible seeds. *Telfairia occidentalis* is a member of the Cucurbitaceae family and is indigenous to southern Nigeria (Akoroda, 2008). The tender shoots, succulent leaves and immature seeds are cooked and consumed as a vegetable. The leaves are used alone or together with okra and *Irvingia gabonensis* or *egusi*. Soils of Awka, Nigeria are acidic, low in mineral reserves with low cation exchange capacity and base saturation (Onweremmadu *et al.,* 2006). Poor soil fertility lowers growth and yield of fluted pumpkin because nitrogen, phosphorus and potassium are the major essential elements required for physiological mechanisms for *Telfairia* growth and yield (Akanbi, 2007) and where they are deficient, *Telfairia*'s growth and yield are impaired (Ike *et al.,* 2017). Rural farmers use organic manure such as poultry droppings, pig slurry cow dung etc to improve soil productivity and yield of *Telfairia occidentalis* (Ndor *et al.,* 2013). However, organic manure cannot meet the crop requirement for the teeming Nigerian population (FPDD, 1989) and as a result there is need for the use of inorganic fertilizer for commercial *Telfairia occidentalis* production. Fluted pumpkin requires high amount of nitrogen and potassium for the production of high leaf and pod yield respectively (Vine, 2013). Olaniyi *et al.,* (2011) reported 60 kg ha^{-1} of nitrogen in combination with 45 kg ha^{-1} of phosphorus had more significant effect on the production of fluted pumpkin for optimum yield of fluted pumpkin in southwest Nigeria. Most farmers prefer the use of NPK 15:15:15 to single fertilizers in fluted pumpkin production because it is more convenient for farmers to apply fertilizer nutrients in one single formulation (FPDD, 1989). However, the use of NPK 15:15:15 in fluted pumpkin production is threatened by its scarcity. Therefore, the objective of this study is to determine other alternative nitrogen supplying inorganic fertilizer to NPK15:15:15.

MATERIALS AND METHODS

This experiment was carried out was at the Teaching and Research Farm of the Department of Crop Science and Horticulture, Nnamdi Azikiwe University, Awka during the dry season of February, 2021. The seeds of *Telfairia occidentalis* were obtained from *Mgbarimgba* market at Eke-Awka. The accession is called *ugu Mgabkwu*. Cement bags were thoroughly washed; half filled with top soil and used in planting *Telfairia occidentalis* seeds. A relatively homogenous soil was maintained by bagging a thoroughly mixed top soils from one spot. One custard bucket filled with water was used to irrigate each bag morning and evening. The same quantity of water was applied in all treatments and replications. Ten treatments consisted of inorganic fertilizers;

Urea (65.21, 130.44 and 175.65 kg ha^{-1}), NPK 15:15:15 (200, 400 and 600 kg ha^{-1}), NPK 20:10:10 (150, 300 and 450 kg ha^{-1}) and zero application of NPK fertilizer which served as the control. Each rate in the organic fertilizer supplied 30, 60 and 90 kg ha^{-1} of nitrogen respectively. The experimental design was Completely Randomized Design (CRD). The bags served as plots and were arranged in a row of 10 bags which were replicated three times making it a total of 30 bags for the experimental set up. Fertilizers were applied using ring method, placed 5 cm away from the plant stem one week after seedling emergence. Staking was done a month after planting and the trellis method of staking was adopted. The following data were collected on *Telfairia occidentalis* samples four weeks after planting; vine length, leaf area, number of leaves, girth, fresh leaf weight, fresh vine weight and fresh plant yield weight. Data were collected on a two weekly basis, from one week after the application of different fertilizer treatments. Data collected were analyzed using Genstat, 2007 software and means were separated using Least Significant Difference (LSD) at 5% level of probability.

RESULTS

The number of leaves at 4WAP was not significantly ($p < 0.05$) affected by the application of different inorganic fertilizer rates (Table 1). On mean value basis, the application of urea at the rate of 130.44 kg ha^{-1} produced highest number of leaves (11.33), followed by the application of 65.21 kg ha^{-1} of urea of ha (10.67), while 450 kg ha^{-1} of NPK 20:10:10 produced lowest number of leaves (7.67). Different inorganic fertilizers that supplied 60 kg ha^{-1} of nitrogen showed that 130.44 kg ha^{-1} of urea (11.33) produced highest number of leaves, followed by 400kg ha^{-1} of NPK 15:15:15 (10.33) while 300 kg ha^{-1} of NPK 20:10:10 (9.33) produced lowest number of leaves. Similar trend was observed at 6 and 8 WAP. The vine length at 4, 5, 6, 7, 8 and 9 WAP was not significantly ($p < 0.05$) affected by the application of different inorganic fertilizer rates (Table 1). On mean value basis, at 4 WAP, the application of urea at the rate of 130.44 kg ha^{-1} produced longest vine (27.60 cm), followed by the application of 300kg ha^{-1} of NPK 20:10:10 (23.70 cm), while 450 kg ha^{-1} produced shortest vine (7.00 cm). Different inorganic fertilizers that supplied 60 kg ha^{-1} of nitrogen showed that 130.44 kg ha^{-1} of urea (27.60 cm) produced longest vine, followed by 300 kg ha^{-1} of NPK 20:10:10 (23.70 cm) while 400 kg ha^{-1} of NPK 15:15:15 (21.00 cm) produced shortest vine.

At 6 WAP, on mean value basis, the application of urea at the rate of 130.44 kg ha^{-1} produced longest vine (42.20 cm), followed by the application of 400kg ha^{-1} of NPK 15:15:15 (40.20 cm), while 450 kg ha^{-1} produced shortest vine (12.00 cm). Different inorganic fertilizers that supplied 60 kg ha^{-1} of nitrogen showed that 130.44 kg ha^{-1} of urea (42.20 cm) produced longest vine, followed by 400kg ha^{-1} of NPK 15:15:15 (40.20 cm) while 300 kg ha^{-1} of NPK 20:20:20 (30.00 cm) produced shortest vine.

At 8 WAP, on mean value basis, the application of 400 kg ha^{-1} of NPK 15:15:15 (60.70 cm) produced longest vine, followed by the control (50.80 cm), while 450 kg ha^{-1} produced shortest vine (16.20 cm). Different inorganic fertilizers that supplied 60 kg ha^{-1} of nitrogen showed that 400 kg ha^{-1} of NPK 15:15:15 (60.70 cm) produced longest vine followed by 130.44 kg ha^{-1} of urea (49.30 cm), while 300 kg ha^{-1} of NPK 20:20:20 (32.80 cm) produced shortest vine.

Leaf fresh weight at 9 WAP was not significantly ($p < 0.05$) affected by the application of different inorganic fertilizer rates (Table 1). On mean value basis, the application of application of 400 kg ha^{-1} of NPK 15:15:15 (30.30 g) produced highest fresh leaf weight, followed by urea at the rate of 130.44 kg ha^{-1} (27.00 g), while 150 kg ha^{-1} of NPK 20:10:10 produced lowest fresh leaf weight (7.50 g). Different inorganic fertilizers that supplied 60 kg ha^{-1} of nitrogen showed that 400 kg ha^{-1} of NPK 15:15:15 (30.30 g) produced highest fresh leaf weight; followed by 130.44 kg ha^{-1} of urea (27.00 g), while 300 kg ha^{-1} of NPK 20:10:10 (10.30 g) produced lowest fresh leaf weight.

Vine fresh weight at 9 WAP was not significantly ($p < 0.05$) affected by the application of different inorganic fertilizer rates (Table 1). On mean value basis, the application of application of 130.44 kg ha^{-1} (14.70 g) produced highest fresh vine weight, followed by 400 kg ha^{-1} of NPK 15:15:15 (13.30 g), while 450 kg ha^{-1} of NPK 20:10:10 produced lowest fresh vine weight (3.00 g). Different inorganic fertilizers that supplied 60 kg ha^{-1} of nitrogen showed that 130.44 kg ha^{-1} of urea (14.70 g) produced highest fresh vine weight, followed by 400 kg ha^{-1} of NPK 15:15:15 (13.30 g), while 300 kg ha^{-1} of NPK 20:10:10 (8.70 g) produced lowest fresh vine weight.

ISSN: 2814-0508

Telfaira occidentalis yield at 9 WAP was not significantly ($p < 0.05$) affected by the application of different inorganic fertilizer rates (Table 1). On mean value basis, the application of application of 400kg ha^{-1} of NPK 15:15:15 (0.43 t ha^{-1}) produced highest plant yield, followed by 130.44 kg ha^{-1} (0.42 t ha^{-1}), while 450 kg ha^{-1} of NPK 20:10:10 (0.15 t ha^{-1}) and 600 kg ha^{-1} of NPK 15:15:15 (0.15 t ha^{-1}) produced lowest plant yield. Different inorganic fertilizers that supplied 60 kg ha^{-1} of nitrogen showed that 400 kg ha^{-1} of NPK 15:15:15 (0.43 t ha^{-1}) produced highest plant yield, followed by 130.44 kg ha^{-1} of urea (0.42 t ha^{-1}) while 300 kg ha^{-1} of NPK 20:10:10 (0.19 t ha^{-1}) produced lowest plant yield.

DISCUSSION

The application of NPK 15:15:15 fertilizer produced improved growth and yield parameters than other inorganic fertilizers used in the experiment. This could be attributed to the balanced supply of nitrogen, phosphorus and potassium from the NPK 15:15:15 fertilizer required for improve growth in fluted pumpkin. Ike *et al.,* (2017) reported that the major nutrients required by fluted pumpkin are nitrogen, phosphorus and potassium. Inadequate supply of any of these nutrients during fluted pumpkin growth is known to have negative impact on the reproductive capability, growth and yield of the plant (Vine, 2013). NPK fertilizer has been used to improve the growth and yield of *Telfairia occidentalis* (Edu *et al.,* 2015; Ndor *et al*., 2013).

CONCLUSION

From the experiment, both the growth and vegetative yield parameters were not significantly affected by the different inorganic fertilizers rates. However, observed differences confirmed earlier reports that 60 kg ha^{-1} of nitrogen produced optimum yield in *Telfairia occidentalis* in southeastern Nigeria. Application of nitrogen above 60 kg ha^{-1} declined growth and yield of *Telfairia occidentalis* irrespective of the inorganic fertilizer used to supply the nitrogen. Among the three inorganic fertilizers used in the experiment, 400 kg ha^{-1} of NPK 15:15:15 still remained the best for optimum *Telfairia occidentalis* growth and yield seconded by 130.44 kg ha^{-1} urea while 300 kg ha^{-1} of NPK 20:10:10 was the least.

ABSTRACT

An Investigation was carried out at Binyaminu Usman Polytechnic Hadejia teaching and research farm, Jigawa State within Hadejia River Valley Irrigation Project Area, in the Sudan savannah ecological zone of Nigeria during dry season of 2019/2020. The treatments were made up of four levels of NPK fertiliser (0 – 0 – 0 – 0, 80 – 40 – 40, 100 – 50 – 50 and 120 – 60 – 60 Kg/ha) and two levels of Farm Yard Manure (FYM), (0 and 2.5 tons/ha). The results indicated that application of NPK up to 120 – 60 – 60 NPK produced the tallest onion plants. Similarly, number of levels/plant was significantly higher when 120 – 60 – 60 Kg NPK/ha was applied. However, number of days to maturity was significantly delayed by application of NPK. Bulb fresh weight and yield were increased significantly up to the highest NPK applied (120 – 60 – 60). The results further showed that manure had significant effect on number of leaves and bulb fresh yield only for which higher values were recorded with the application of 120 – 60 – 60 NPK/ha.

Key words: Onion, Bulb, Fertilizer and Farm Yard Manure

INTRODUCTION

Onion is one of the most important vegetable commonly used in every household. It is used in every home in every part of the world. Its nutrient value is higher than some vegetable like carrot and cabbage. It contains edible starch but appreciable quantities of protein and vitamins A, B and C. Onion bulb can be eaten fresh of cooked. It is also used for preparing soup or stew. It is used for the treatment of several diseases. High dosage of opinion and low dosage of aspirin is good in the treatment of hypertension. It is commonly found in almost all Nigeria dishes as spice and appetizer. Onion is believed have originated in Asia, possibly in the Iran. Of the tropics very early cultivation is known to have occurred in Egypt and India. Cultivated in all parts including the drier areas were they are grown using irrigation (Tindale, 1983). The bulb is a truncated stem formed from thicken leaf base. The outer layers are thin while the inner ones are without blades and could be 10cm or more in diameter. Leaves are alternate and are produced from conical based steam. They are cylindrical in nature and becoming hollow along its upper part. The flowers are borne on scalps 30 – 100cm in height protected by terminal umbels. The inflorescence produces numerous flowers in segment with ovaries, petals and styles. Seeds are smooth, black wrinkled when dry. The embryo is curved and germination is epigeal. Approximate weight of 100 seeds is 4gm.The objective of the study is to evaluate the response of onion to NPK fertilizer and Farm Yard Manure at Hadejia Valley.

MATERIAL AND METHODS

The experiment was conducted at Binyaminu Usman Polytechnic Hadejia teaching and research farm, Jigawa State within Hadejia River Valley Irrigation Project Area. The treatments were made up of four levels of NPK fertiliser (0 – 0 – 0 – 0, 80 – 40 – 40, 100 – 50 – 50 and 120 – 60 – 60 Kg/ha) and two levels of Farm Yard Manure (FYM), (0 and 2.5 tons/ha). They were laid randomly in plots using Randomize Complete Block Design (RCBD) and replicated three times.

Nursery beds (1m x 2m) were prepared. Before sowing quantity of manure and fertilizer (NPK) was applied. The seed were drilled 5cm apart. The beds were then mulched. The mulching materials were removed after the seedlings have fully emerged. Meanwhile the beds were kept weed free and watered regularly. A local variety onion was used. When the seedlings were about 6 weeks old, they were transplanted to already prepared basins, irrigated to field capacity before transplanting. Healthy onion seedlings of about 7 – 10cm tall (6 weeks old) were selected for transplanting.

Fertilizer application: the sources of NPK fertilizer were NPK 15:15:15 and Urea (46%). All the treatments were applied in single dose at 4 weeks after transplanting. The manure treatments were applied during land preparation. The plots were irrigated to field capacity at weekly interval. Weeds were controlled manually throughout the growing period using small onion hoes.

After transplanting plant height was taken at 8 WAT (Weeks After Transplanting) from ground level to the tip of the longest leaf using a 30cm metre ruler. Mean of four plants was taken from each plot at 2 weeks' interval. Mean bulb height and diameter were determined from five randomly selected bulbs from each plot. In the same way mean bulb weight was determined. Bulb yield (kg/ha**)** was determine by expressing the bulb weight per plot into Kg/ha. The data generated was subjected to analysis of Variance (ANOVA) and where treatment means significant, values were compared using DMRT.

RESULTS

Plant weight of onion was not significantly affected by application of NPK fertilizers at 8 and 10 WAT (Table 1). However, at 12 WAT application of 120 – 60 – 60 kg/ha produced significantly taller plant treated with 100 – 50 – 50 and 80 – 40 – 40 kg/ha which were at per while plots treated with zero fertilizer had the shortest plant. At 14 WAT plant treated with NPK at rate of 0 and 80 – 40 – 40 kg/ha had similar height. However, application of 100 – 50 – 50 kg/ha produced significantly taller plants but when the dose was further increased to 120 – 60 – 60 kg/ha the difference was not significant. Although plots treated with manure had the tallest plants, the differences among the treatment were not significant across the sampling periods.

Onion leaves were not affected by application of NPK fertilizers between 8 and 12 WAT. However, at 14 WAT application of 80 – 40 – 40 kg/ha produced significantly higher number of leaves/plant which were statistically similar with plants treated with 100 – 50 – 50 kg/ha (Table 2). A further increase to 120 – 60 – 60 kg/ha however, resulted in a significant increase in number of leaves/plant. Up to 12 WAT number of leaves/plant was not significantly affected by manure application. At 14 WAT however, plants treated with manure produced significantly higher number of leaves/plant.

Table 1 Response of Onion to NPK fertilizer and Farm Yard Manure on Plant height (cm) at Hadejia

Treatment	Plant height at			
	8 WAT	10 WAT	12 WAT	14 WAT
NPK Levels				
0 – 0 – 0 kg/ha	16.77	21.12	25.27b	31.47c
80 – 40 – 40 kg/ha	17.92	24.65	31.20a	36.47b
100 – 50 – 50 kg/ha	17.52	26.00	30.83a	38.43b
120 – 60 – 60 kg/ha	20.10	28.60	34.00a	48.03a
SE±	1.23	1.78	1.08	0.91
FYM Levels				
0.0 kg/ha	18.81	25.47	30.46	37.58
2.5 kg/ha	17.34	24.72	30.19	39.62
SE±	1.30	1.03	0.50	0.86

Means followed by the same letter (s) within a column are statistically similar at 5% level of probability using DMTR.FYM = Farm Yard Manure

Plants treated with NPK fertilizers at the rate of 120 – 60 – 60 and 100 – 50 – 50 kg/ha had statistically similar and longer maturity period compared with the other treatments which were also at par. Manure application had no effect on maturity of onion. Only application of up to 120 – 60 – 60 kg/ha had significant effect on bulb height. Application of up to 100 – 50 – 50 kg/ha did not produced significantly wider diameter compared with plants that did not receive NPK treatment (Table 3). However, increasing the dose from 100 – 50 – 50 to 120 – 60 – 60 kg/ha produced significantly wider bulb diameter. Application manure had no effect on bulb diameter of onion. Application of 80 – 40 – 40 kg/ha produced bulbs which were significantly heavier than the control treatment. A further increase to 100 – 50 – 50 kg/ha did not produce a significant difference, however, at 120 – 60 – 60 kg/ha the difference was significant. Manure application had no effect on bulb weight onion. Bulb yield of onion was significantly affected by application of NPK fertilizer. Each successive increase in NPK fertiliser dose resulted in a significant increase in onion fresh yield up to the highest dose. Similarly, application of manure resulted in a significant increase in bulb fresh yield of onion (Table 3).

Table 2. Response of Onion to NPK fertilizer and Farm Yard Manure on number of leaves per plant at Hadejia

Treatment	Number of leaves per plant at			
	8 WAT	10 WAT	12 WAT	14 WAT

DISCUSSION

The growth of onion is known to be influence by application of essential fertilizers elements up to optimum levels. In this experiment onion attributes exhibited varying degree of response to fertilizer could be due to the fact that all the elements (NPK) are needed for normal growth and high yield of onion (Amans, 1982). The fresh bulb yield of onion did not increase beyond 100 – 50 – 50 kg/ha probably because the optimum requirement had been met. This result corroborated with a similar study by Mohammed and Miko (2005) in the same locality which showed that onion needed 100kg N /ha for optimum productivity.

The result indicated that manure had significant effect on the yield of onion. This is not unexpected because addition of manure to the soil helps to improve its fertility and physical properties. The lack of significant effect of manure on most of the yield attributes could be because the quantity was relatively small (2.5 tons) compared to values (4 – 10 tons) recommended by Abbey and Kanton (2003) and Sharma (2003).

CONCLUSION

The results of the present investigation indicated that application of NPK fertilizer at the rate of 100 – 50 – 50 kg/ha gave higher bulb fresh yield of onion. It further indicated that application of manure at that rate of 2.5 tons/ha supported higher productivity of onion fresh yield, thus application of NPK fertilizer and FYM, at 100 – 50 – 50 kg/ha and 2.5 tons/ha respectively, could be recommended for higher yields of onion under the climatic condition of Hadejia, Jigawa State.

ABSTRACT

In this study, response of cucumber to cow dung and NPK 15:15:15 fertilizer was evaluated during the 2020 wet season at the Horticulture Section of Samaru College of Agriculture, Ahmadu Bello University, Zaria. The treatments consisted of four levels of NPK (0, 100, 150 and 200 kg/ha) and cow dung (0, 10, 20, 30 tha^{-1} and 100kg/ha of NPK + 15 t/ha cow dung) laid out in a randomized complete block design (RCBD) with three replicates. Data collected on vine length, number of leaves, number of branches, number of fruits per plant and fresh fruit yield. Results of the study showed significant (p<0.05) differences between parameters assessed and among the cow dung and NPK fertilizer rates. Application of 30 t/ha of cow dung gave the highest fruit yield (39.33 t/ha) while combination of 15 t/ha of cow dung with 100 kg NPK (29.02 t/ha); the two treatments were thereby found to be adequate in enhancing growth and yield of cucumber at Samaru.

Key words: Cucumber, NPK 15:15:15, Cow dung, Samaru, Northern Guinea Savanna

INTRODUCTION

Cucumber (*Cucumis sativus* L.) is one of the most popular fruit vegetables in the Cucurbitaceae family (Eifediyi and Remison, 2010). Apart from its palatability, it is very important to humans for its medicinal value as diuretic and active drug for secreting and promoting the flow of urine (Nweke and Nsoanya, 2015). Cucumber also reduces the risk of heart attack and help in digestion of food (Sodimu, 2020), it promotes healthy hair growth, soften the skin and may be use for curing of skin infection such as eczema, weight loss and to expel intestinal worm (Shrivastava and Roy, 2013). Cucumber production requires fertile soil of moderate to high nutrient levels in order to achieve high yields (Nweke and Nsoanya, 2015). Although the use of inorganic fertilizer has associated with soil degradation, nutrient imbalance, acidity apart from its high cost and unavailability to resource poor farmers (Ojeniyi, 2000). On the other hand, organic manure can sustain crop production through better nutrient recycling and soil physical improvement (Maritus and Vleic, 2001) but is usually requires in a larger quantity and slow in releasing nutrients (Khalid *et al*., 2014). Against this background, there is need to study the effect of different rates of cow dung and NPK fertilizers on cucumber production with view of making appropriate recommendation(s) to cucumber farmers in Samaru metropolis.

MATERIALS AND METHODS

Site Location and Climate

The experiment was conducted during 2020 wet season at the Horticulture Section, Samaru College of Agriculture, Ahmadu Bello University, Zaria. The study area lies within latitude 11°09'52'' – 11°10'22'' N and longitude 07°38'05'' – 07°38'22'' E with 684 – 697 m above sea level. The area is situated in the Northern Guinea Savanna ecological zone with a mono-modal rainfall pattern and a long term mean annual rainfall of about 1,011± 161 mm concentrated entirely in five months (May/June–September/October) and mean daily temperature of 24°C (Oluwasemire and Alabi, 2004).

Treatments and Experimental Design

The treatments consisted of four levels of NPK (0, 100, 150 and 200 kg/ha) and cow dung (0, 10, 20, 30 tha^{-1} and 100kg/ha of NPK with 15 tha^{-1} of cow dung) laid out in a randomized complete block design (RCBD) replicated three times.

Land preparation, planting and fertilizer application

The experimental site was cleared, ploughed, harrowed to fine tilth and ridged with a plot size 3 m x 2 m. The inter- and intra-row spacing was 0.75 m and 0.5 m respectively. Two seeds of 'market-moore' variety were planted per hole and later thinned to one per stand. The cow dung was applied according to the respective rates per plot and left to thoroughly decomposed for two weeks before planting. The NPK 15:15:15 fertilizer was applied at two weeks after planting using band placement method. Weeding, application of insecticides and other cultural practices were done as at when required. Trellising was done to support the cucumber vine by fastening it to stakes; this also help to keep cucumber fruit off the ground (to prevent rotting).

Pre-planting soil sampling, cow dung and analysis

The soil samples were collected using soil auger at 0 – 20 cm depth. The samples collected were bulked to obtain a composite sample. The soil composite and cow dung samples were air dried, crushed, screened through a 2-mm sieve and prepared for manure and soil characterization following standardized procedures described by Okalebo *et al.* (2002).

Data collection and Statistical analysis

Data on vine length (cm), number of leaves per plant, number of branches per plant, number of fruits per plant and fresh fruit yield (t/ha) were recorded. The data collected were subjected to statistical analysis of variance (ANOVA) and treatment means were separated using new Duncan Multiple Range Test (SAS Institute, 2000).

RESULTS

Characteristics of the study soil

Initial physical and chemical properties of the experimental soil used in the study are presented in Table 1. The soil type was sandy loam; the soil reaction (pH) in water was slightly acid (6.5), low in organic carbon content (11.24 g kg^{-1}) and total nitrogen (0.98 g kg^{-1}). The available phosphorous (8.00 mg kg^{-1}) and exchangeable bases were relatively moderate according to FMARD (2012) rating.

Table 1: Initial soil properties at Experimental site in Zaria and Cow dung used in 2020 cropping season

Parameter	Clay	Silt	Sand	Textural class	pH water	O.C	T.N	A.P	K^+	Ca^{++}	Mg^{++}
	← (g kg^{-1}) →					← (g kg^{-1}) →		(mg kg^{-1})	← (cmol kg^{-1}) →		
Soil	80	200	720	Sandy Loam	6.5	11.24	0.49	96.54	0.11	1.79	0.74
Cow dung	n. d	n. d	n. d	n. d	n. d	n. d	0.98	1,133	0.3%	n. d	n. d

O. C = organic carbon, T.N = total nitrogen, A.P = available phosphorus, n. d = not determined

Effect of NPK fertilizer and Cow dung at different levels on Growth and Yield of Cucumber

Vine length (cm)

The effect of NPK 15:15:15 and cow dung at different levels is as presented in Table 2. Application of (100 kg NPK/ha with cow dung at 15 t/ha) significantly produced the highest length (139.97 cm) closely followed by cow dung at 30 t/ha while the lowest mean was produced by the control treatment (0 kg NPK/ha or 0 t/ha of cow dung). Successive addition of either NPK fertilizer or cow dung significantly led to increase in vine length.

Number of leaves per plant

Table 2 shows that there was a significant difference ($p<0.05$) between the means, due to application of NPK fertilizer or cow dung at different levels. The control significantly produced the lowest mean at maturity (23.53), while application of cow dung at 30 t/ha produced the highest mean (85.07). An increase in either NPK fertilizer or cow dung significantly led to increases in number of leaves per plant.

Number of branches per plant

The effect of NPK fertilizer and cow dung on number of branches per plant is as presented in Table 2. It shows significant difference ($p<0.05$) among the different rates of NPK fertilizer and cow dung. The control treatment (0 kg N/ha) produced significantly the least number (1.30) while application of cow dung at 30 t/ha produced the highest mean values (10.17) and this is closely followed by combined application of (100 kg NPK/ha with cow dung at 15 t/ha).

Means followed by the same letter (s) in the column are not significantly different using DMRT at $p \leq 0.05$

Number of fruits per plant

N fertilizer significantly influenced total fresh fruit weight as presented in Table 2. The 100 kg N/ha produced significantly the highest (20.27 kg/ha) followed by 200 kg N/ha (18.60 kg/ha) and the control treatment recorded the least mean values (14.58 kg/ha).

Fresh fruit yield (t/ha)

Table 2 shows a significant difference ($p<0.05$) among the NPK fertilizer and cow dung rates on fresh fruit yield per hectare of cucumber. The control treatment (where neither fertilizer nor cow dung) was applied gave significantly lowest mean values (7.17 t/ha) on fresh yield per hectare. On the other hand, application of cow dung at 30 t/ha gave significantly the highest mean values (39.33 t/ha) in fresh fruit yield per hectare of cucumber. This is followed by the combined application of NPK fertilizer at 100 kg/ha with cow dung at 15 t/ha.

DISCUSSION

The soil of the experimental site is generally low in fertility status especially organic carbon, total nitrogen and available phosphorus which are usually due to low clay content coupled with rapid mineralization, continuous cultivation as common to soils of northern guinea savanna (FMARD, 2012). The significant response of the observed parameters to N, P and K application could be attributed to the role of N, P and K play in enhancing vegetative development in crops especially in soil with low nutrient status similar to the report by Ikeh *et al*. (2012) who claimed that low nutrient status might have contributed to the good performance of the crop.

Generally, the parameters observed significant increased with increasing levels of NPK fertilizer and cow dung in this study. Similar findings were also reported by Nweke and Nsoanya (2015) and Ikeh *et al*., 2012 on cucumber. They reported the maximum vine length was recorded due to enhanced synthesis and availability of sufficient growth nutrients from inorganic fertilizer. The result showed that cucumber responded well and better to the application of cow dung than NPK fertilizer in all parameters observed and this could be due to high nutrient content in cow dung especially organic matter, total nitrogen (N), phosphorus (P) and exchangeable potassium (K) which are higher than those in mineral fertilizer (NPK). This conform with the work of Ewulo (2005) who reported that poultry dropping contain high amount of N and P which are required for healthy growth, development and yield of crops. In addition, combined effect of cow dung and NPK fertilizer appears to be the second best in all the parameters observed in this study and this is similar to the study conducted by Nweke and Nsoanya (2013) who reported highest leave area index and grain yield when combined poultry manure and NPK fertilizer on maize.

CONCLUSION

Based on this research finding, it can be concluded that application of 30 t/ha of cow dung is adequate in enhancing growth and yield of cucumber. However, integrating cow dung at 15 t/ha with 100 kg NPK 15:15:15/ha will assist cucumber farmers at Samaru.

ABSTRACT

Saba Senegalensis is a fruit producing plant still in the wild; it has the potential of contributing to nutritional and food security of the rural populace as well as enhancing their economy. Two experiments were carried out to determine early growth response of the seedlings to different poultry manure rates in pot and ground nurseries. The experiments were conducted at the teaching and research farm of the Department of Crop Science, University of Nigeria, Nsukka. Seedlings were previously raised in a pre-nursery experiment conducted in a high tunnel. Topsoil amended with poultry manure (PM) at six different rates (0, 10, 20, 30, 40 and 50 t/ha) constituted the pot experiment. In the ground nursery seedlings were transplanted and two weeks later treated with five (0, 10, 20, 30, 40 t/ha) PM rates. The experiments were laid out in a complete randomized design (CRD) with 10 replications per PM rates. Periodical data on the number of leaves, vine length and the number of branches were taken after application of PM. Application of 30t/ha showed a substantial increase in all growth parameters by the 34th week in the pot nursery while for the ground nursery it was 40t/ha that showed a massive improvement in all morphological characteristics by the 34th week. Optimum PM rate for growing certified seedlings of Saba Senegalensis for plantation establishment was 30t/ha for pot nursery and 40t/ha for ground nursery.

Key words: Nursery method; Poultry manure; Seedlings growth differential

INTRODUCTION

Saba senegalensis is a fruit producing plant of the Apocynaceae family native to the Sahel of sub Saharan Africa. It grows wild in the forests of western Africa. It is called Saba, Zaban or Weda depending on the region. It grows predominantly in Burkina-Faso, Senegal, Nigeria, Cote d'ivoire, Gambia, Guinea, Mali, Niger, Guinea-Bissau and Ghana (AFTD-Agro forestry tree, 2011). Its fruit is highly valued in Senegal and Gambia. The fruit of Saba is very rich in antioxidants especially vitamin C. The fruit is tasty and sweet sour with yellow pulp when ripe (AFTD-Agro forestry Database, 2011). The latex of Saba is used to treat pulmonary diseases and tuberculosis. The leaves can cure chronic headache, wounds, food poisoning and vomiting. Fula of Senegal use the leaves in preparation of sauces and condiments (Kerharo et al, 1964).

Saba grows predominantly on Riverbanks and in Woodlands (Burkill, 2013). It is propagated through seeds though in some cases the vines are used. Deforestation and the degradation of the natural habitats of Saba plants are threatening its existence. The fruit is highly prized and in parts of Africa, they are important to the rural economy and many are trucked or carried in baskets to sell in the cities (Burkill, 2004). Despite the rural importance of the fruit of *Saba senegalensis* for food security and ethno-medicine the fruits are still harvested from the wild often times in competition with monkeys that consume the fruit. This crop still grows in the wild and there are needs to make attempts to bring it to regular cultivation culture.

Currently, there are no organized horticultural standards for raising healthy and well-grown seedlings for transplanting into the field in Nigeria. Thus, the objective of this experiment was to evaluate the early growth response of *Saba senegalensis* to six different poultry manure rates.

MATERIALS AND METHODS

Two experiments were carried out at the Teaching and Research farm of the Department of Crop Science, University of Nigeria, Nsukka, located in the derived savanna zone (Latitude 7.4, Longitude 6.9 and 475m altitude) of Nigeria.

Fully ripe Saba fruits were acquired from Kogi State in the middle belt of Nigeria. Fruits of similar sizes, maturity and stage of ripening were selected for the study. The seeds were extracted and mucilage was removed by rubbing with sawdust. Afterwards the seeds were disinfected in 10% dilution of sodium hypochlorite. Seedlings from a pre-nursery were utilized for a pot and ground nursery experiments. The experiments were laid out in a completely randomized design with six poultry manure [PM] rates (0, 10, 20, 30, 40 and 50 t/ha) for the pot nursery and five PM rates (0, 10, 20, 30 and 40 t/ha) for the ground nursery, respectively. Data collected were number of leaves, number of branches and vine length. The vine length was measured with the aid of a measuring tape. While number of leaves and branches were count data. Data were measured two weeks after manure application and subsequently on 4-week-intervals; data collection was terminated 34 and 22 weeks after manure application for pot and ground nursery, respectively.

RESULTS

Growth performance in pot nursery (Table 1) was expectedly poorer in seedlings without manure application, however 30 t/ha PM elicited higher number of leaves and longer vines; highest number of branches was however associated with 50 t/ha. Results of these growth parameters (data not shown) indicated significant manure rates effect on number of leaves from the 14th week, vine length and number of branches from the 18th week to the 34th week when data collection was terminated.

Growth performance in ground nursery (Table 2) was also, expectedly poorer in seedlings without manure application, however 40 t/ha PM elicited higher number of leaves and longer vines; highest number of branches was associated with 20 t/ha. Data measured (not shown) revealed that in the ground nursery number of leaves varied significantly with manure rates between the 10th and 14th week; whereas significant treatment effect was recorded for vine length between the 6th and 22nd weeks, number of branches varied throughout the duration of measure.

Table 1: Effect of manure rates on Saba seedlings growth parameters 34 weeks after manure application in pot nursery

Manure rate t/ha	Number of leaves	Vine length (cm)	Number of branches
0	23.9	35.0	1.5
10	49.4	51.6	6.3
20	36.1	51.6	3.8
30	54.3	62.5	5.3
40	53.0	54.3	4.5
50	40.7	42.0	6.7
$LSD_{(0.05)}$	**12.9**	**11.0**	**3.0**

Table 2: Effect of manure rates on Saba seedlings growth parameters 22 weeks after manure application in ground nursery

Manure rate t/ha	**Number of leaves**	**Vine length (cm)**	**Number of branches**
0	19.0	24.7	2.4
10	24.2	25.9	2.7
20	23.8	36.5	4.5
30	21.3	36.7	2.8
40	24.6	44.1	2.2
$LSD_{(0.05)}$	**NS**	**8.0**	**1.8**

NS: Non-significant at 5% probability level

DISCUSSION

The application of poultry manure evidently increased the number of leaves, vine length and the number of branches in both the pot and ground nurseries. The control treatment (0t/ha) expectedly had the least values of all the morphological characteristics.

Findings of this experiment elucidated the importance of poultry manure to the production of certified seedlings of Saba. The significant poultry manure effect on the number of leaves, vine length and number of branches in these experiments is in agreement with the findings of Baiyeri and Tenkouano (2007), Ndukwe *et al.* (2011) and Aba *et al.* (2011) that animal manure is a valuable source of crop nutrients and organic matter which can improve the soil biophysical conditions making the soil more productive and sustainable for plant growth.

EVALUATION OF POULTRY MANURE APPLICATION RATES ON GROWTH AND YIELD OF TOMATO (*SOLANUM LYCOPERSICUM*) VARIETIES IN ABEOKUTA

Olaiya, A.O.
Federal University of Agriculture, Abeokuta

ABSTRACT

An experiment was carried out in 2020 at the upland section of farm of the Federal University of Agriculture, Abeokuta, Nigeria to determine the effect of poultry manure application rates on growth and yield of four tomato varieties. The experiment was arranged in a Randomized Complete Block Design (RCBD) and replicated three times. Four varieties of tomato are, Roma-VF, UC-82B, Beske, and Kerewa tested with organic fertilizer at 0t/ha, 1t/ha and 2t/ha incorporated into the soil a day before planting. Growth data were collected at two weeks' intervals on vegetative parameters of plant height, leaf area, number of leaves and stem girth for 8 weeks after planting while yield data collected at harvested were number of fruits, fruit weight and fruit size. All data collected were analyzed using ANOVA and separation of mean was done using Duncan's multiple range test at 5% level of probability. The result showed that there were significant (p<0.05) differences in growth and yield parameters in response to poultry manure rates. Variety Roma had the highest number of fruits when tested at all level of manure application rates with 2t/ha having the highest fruit weight followed by Kerewa at same rate of manure compared to other varieties. In terms of vegetative parameters, Roma had the highest values throughout the experiments. The result shows that different varieties of tomato differ from each other and outperform each other when different nutrient composition is made available, varieties Roma and Kerewa had higher nutrient use efficiency and are therefore recommended at 2 t/ha poultry manure application.

Key words: Tomato, poultry manure, vegetative parameters, growth, yield

INTRODUCTION

Tomato belongs to the Solanaceae family along with other economically important crops such as pepper, eggplant and potato. The tomato was classified by Miller (1754) as Lycopersicon esculentum and renamed by Child (1990) and Peralta and Spooner (2006) as Solanum lycopersicum (Díez & Nuez, 2008). The cultivated tomato, Solanum lycopersicum L., is the world's most highly consumed vegetable due to its status as a basic ingredient in a large variety of raw, cooked or processed foods. Tomatoes are grown both in most home gardens and commercially as one of the words most popular vegetables. The tomato crop has a great importance in the world, and its production, in 2013, reached 163.9 million tons and average yield of 34.7 tons per hectare (FAO 2013). In 2014, the global area cultivated with tomato was 5 million hectares with a production of 171 million tonnes, the major tomato-producing countries being the People's Republic of China (hereafter "China") and India (FAOSTAT, 2017).

Tomato can be grown in a variety of geographical zones in open fields or greenhouses, and the fruit can be harvested manually or mechanical means. Under certain conditions (e.g. rejuvenation pruning, weeding, irrigation, frost protection), this crop plant can be perennial or semi-perennial, but commercially it is considered an annual (Garcia et al., 2015). The tomato was cultivated and consumed in Mexico well before the arrival of the Spanish. The tomato has passed from uncertain acceptance to its arrival in Europe to occupying first place among horticultural crops at the present. Asia is by far the continent with the greatest production, producing 50% of the total, with Europe ranking as the second (17.5 %), followed by Central and North America (12.3 %), Africa (11.7 %), Latin America and the Caribbean (7.8 %) and Oceania (0.05 %). China is the main producer of tomato, followed by the US, Turkey, India and Italy (Díez & Nuez, 2008).

Tomatoes (Solanum Lycopersicum) are consumed as either fresh fruit by themselves, in salads, as ingredients in many recipes, or in the form of various processed products such as paste, whole-peeled tomatoes, diced products, and various forms of juices and soups. Tomato may contribute to a healthy, well-balanced diet as it has a few calories and is a source of vitamin A, vitamin C, and minerals. It provides small amounts of the vitamin B complex, such as thiamin, riboflavin, and niacin (Sainju and Dris, 2006). Tomato is also a source of iron. Yellow tomatoes have higher vitamin A than red ones, but red tomatoes contain lycopene, an anti-oxidant compound that may contribute to protect against cancer (Naika et al., 2005). Recent studies suggest that lycopene reduces the risk of prostate cancer (Miller et al., 2002). Consumption of tomatoes can reduce the risk of developing gastroenteric diseases, such as colon, rectal, and stomach cancer. Finally, it is easily digestible and its bright color stimulates appetite (Sainju and Dris, 2006). Then tomato is a favorite garden plant in many parts of the world, an important source of vitamins and nutrients and an economically important agricultural commodity. Food is one among the most important basic necessities of man. For Nigeria to meet the millennium development goal in food production, food including tomato must be readily available. Low soil fertility could threaten the security of food production and supply. Soil fertility is a major overriding constraint that affects all aspects of crop production (Mbah, 2006).

In the past years, inorganic fertilizer was advocated for crop production to ameliorate low inherent fertility of soils in the tropics. In addition to being expensive and scarce, the use of inorganic fertilizer has not been helpful in intensive agriculture because it is often associated with reduced crop yield, soil acidity and nutrient imbalance (Ojeniyi, 2000; Ano and Agwu, 2005; Agbede et al., 2008). The need to use renewable forms of energy and reduce costs of fertilizing crops has revived the use of organic fertilizers worldwide (Ayoola and Adeniyan, 2006). Large quantities of organic wastes such as poultry manure are available especially in urban centers and are an effective source of nutrients for vegetables such as tomato (Adediran et al., 2003). Soil fertility status varies considerably with different ecological zones. Infact, even in the same zone, there are micro-differences in soil characteristics. The crop yield response to organic waste is highly variable and depends on the types of wastes, crop type and species, soil type and climate conditions (Adediran et al., 2003).

For Nigeria to meet the millennium development goal in food production, food including tomato must be readily available. Low soil fertility could threaten the security of food production and supply. Tomato cultivars differs from one another in terms of size, color, leaves, time of maturity, resistance to diseases and several other vegetative reproduction phases. Poultry waste as an organic manure is becoming popular due to its effectiveness of solving the plant nutritional problem and also effective on the growth, development and fruit yield of crops. The main objective of this study is to increase the growth and yield of tomato while the specific objectives was to evaluate the growth and yield of both local and exotic tomato varieties in response to rates of poultry waste application at Abeokuta southwestern Nigeria.

MATERIALS AND METHODS

The experiment was carried out at federal university of agriculture Abeokuta at upland fadama site (Lat 7º15'N and long 3º 25'E). Four varieties of tomato were planted on raised bed. The varieties were sourced from OjaAgbe: the varieties are

1. Uc82b (V1)
2. Roma vf (V2)
3. Kerewa (V3)
4. Beske (V4)

The experiment was arranged in a randomized complete block design format with three replicates. These involved four varieties of tomato and manure treatment at three different rates of 0,1 and 2 tonnes/ha, this makes twelve treatment combinations as listed below

V1M1, V1M2, V1M3, V2M1, V2M2, V2M3, V3M1, V3M2, V3M3, V4M1, V4M2 and V4M3.

The land was cleared and beds were made manually using hoe and cutlass, the individual plot dimension was measured as 2m by 2m and the total plot area was 46m by 12m, which summed up to 552m2. The seeds were planted in the local nursery made under a shade closer to the allocated plot for 4weeks. The seedlings were transplanted on the beds at a spacing of 60cm by 50cm and the beds were 1m apart.

Soil sample of the experimental site was collected using soil auger at a depth of 0 to 15cm, sieved, air dried and packed before taken to the laboratory for analysis of physical and chemical properties of nutrient composition.

Cu (mg/kg)	0.024	-

Supplying for seedling that failed to survive during the first week of planting was carried out with new ones at two weeks after transplanting. Manure application was applied a day before transplanting. Side placement was used, 2cm depth was dug, the manure was placed and earth was used to cover it up. Weeding and other cultural practices were carried out as appropriate.

Data was collected at two weeks' interval starting from two weeks after transplanting. Three plants were tagged from individual plots; data was recorded on Plant height, Number of leaves, Stem girth, Leaf area, Fruit set, Average fruit weight, Friut quality and Total Fruit yield per hectare.

The data collected were statistically analysed using Analysis of Variance (ANOVA) and the treatment means were separated for each parameter using Duncan Multiple Range Test (DMRT).

RESULTS

Effect of varietal differences on plant height (cm) of tomato varieties: The effect of varietal differences on plant height (cm) as portrayed in table 2 shows significant ($p<0.05$) difference at 8WAP with Beske having the least plant height (40.09) while Roma and kerewa had the highest plant height of 60.99 and 60.24 respectively throughout the period of experiment.

Effect of varietal differences on stem girth (cm) of tomato varieties: The effect of varietal differences on stem girth(cm) as portrayed in table 3 below. There was a significant ($p<0.05$) difference at 4WAP to 8WAP. Beske has the least stem girth (60.09) while Roma has the highest value for stem girth (0.88) throughout the period of experiment.

Effect of varietal differences on leaf area (cm) on tomato varieties: The effect of varietal differences on leaf area as portrayed on the table 4 below. There was a significant ($p<0.05$) difference among the varieties at 4WAP to 8WAP with Uc82b having the highest leaf area (15.05) while Beske had the least leaf area value (7.51) throughout the period of experiment.

Effect of varietal differences on number of leaves of tomato varieties: The effect of varietal differences on number of leaves as portrayed on the table 5 below. There was a significant ($p<0.05$) difference among the varieties at 2WAP to 8WAP with Roma having the highest number of leaves (273.71) while Beske had the least value for number of leaves (106.52) throughout the period of experiment.

Effect of poultry manure rates and varietal differences on plant height of tomato varieties: The effect of the manure rate and varietal differences on the plant height is portrayed in table 6 below. There was significant ($p<0.05$) differences in plant height among the different varieties throughout the period of observation. Kerewa at given rate of 1t/ha had the highest plant height with (73.67) as compared to other varieties, however Beske at given rate of 2t/ha had the lowest plant height (35.34) as compared to other varieties during the period of observation.

Effect of Poultry manure rates and varietal differences on leaf area of tomato varieties: The effect of the manure rate and varietal differences on leaf area is portrayed in table 7 below. There was significant ($p<0.05$) differences in leaf area among the different varieties throughout the period of observation. Uc82b at given rate of 2t/ha and

Kerewa at given rate of 1t/ha had the higher Leaf area with (17.86 and 16.82 respectively) as compared to other varieties, however Beske at given rate of 2t/ha, 1t/ha and 0t/ha and Roma at given rate of 0t/ha had the lowest Leaf Area (7.20,7.19,7.35 and 7.41 respectively) as compared to other varieties during the period of observation.

Effect of Poultry manure rates and varietal differences on number of leaves of tomato varieties: The effect of the manure rate and varietal differences on number of leaves is portrayed in table 8 below. There were significant ($p<0.05$) differences in number of leaves among the different varieties throughout the period of observation. Kerewa at given rate of 1t/ha and Roma at given rate of 2t/ha had the highest number of leaves with (359.35 and 343.90 respectively) as compared to other varieties and rates, however Beske at given rate of 2t/ha, 1t/ha and 0t/ha and kerewa at given rate of 0t/ha had the lowest number of leaves (108.78, 136.44, 74.33 and 122.89 respectively) as compared to other varieties and rates during the period of observation.

Effect of poultry manure rates and varietal differences in stem girth(cm) of tomato varieties: The effect of the manure rate used on the stem girth is portrayed in table 9 below. There was significant ($p<0.05$) differences in plant height among the different varieties throughout the period of observation. Kerewa at given rate of 1t/ha had the highest stem girth with (1.10) as compared to other varieties and rates, however Beske at given rate of 2t/ha had the lowest stem girth (0.57) as compared to other varieties and rates during the period of observation.

Effects of poultry manure rates and varietal differences on number of fruits and fruit weight : The effect of manure rate and varietal differences as portrayed in table 10 below shows a significant($p<0.05$) differences in number of fruits and fruit weight, Roma variety shows high response to 1t/ha and 2t/ha of manure rate with the value 95 and 92 respectively compared to the other varieties at different rates however Roma variety given 2t/ha of manure rates shows a high response to the fruit weight with the highest value 3.35 compared to other varieties at different rates throughout the period of experiment

DISCUSSION AND CONCLUSIONS

Hidden hunger is becoming major problem in Africa and tomato is one of the fruit vegetables that contains essential nutrient that can address this problem. The fertility status of the soil is expected to benefit from poultry manure application since the manure is known to improve soil organic matter and macro-nutrient qualities of the soil. It was found that 2 t/ha poultry manure gave the most growth and highest fruit yield among all poultry manure levels. Soil pH tended to reduce with a rise in the amount of poultry manure suggesting that poultry manure lead to increased acidity in the soil. Excess N in the soil and soil acidity could cause nutrient imbalance in the tomato crop and a reduction in the uptake of certain nutrients (Ewulo et al., 2008).

The poultry manure could have supplied micronutrients which are essential for tomato growth and yield. Stephenson et al. (1990) and Oladotun (2002) reported that poultry manure contains macro and micro nutrients such as N, P, K, S, Ca, Mg, Cu, Mn, Zn, Bo and Fe. Agele (2001) also found that poultry manure litters resulted in better growth and yield of tomato than NPK fertilizer alone. In this study tomato performed well under application of poultry manure at different rates in terms of vegetation parameters. However, 1 t/ha of manure rate applied to tomato shows a great response on yield even under unfavorable climatic conditions.

This study showed that application rate of poultry waste had significant effect on growth and yield of tomato varieties especially Roma and Kerewa, hence the two rates and varieties are recommended to farmers in Abeokuta for tomato cultivation with higher yields.

ABSTRACT

Field trials were conducted during the 2017 wet season at the Research farms of the Institute for Agricultural Research, Samaru and Kadawa to assess the response to application of poultry manure at different rates on growth and yield of three selected kenaf varieties. The treatment consists of four poultry manure rates (0, 2, 4 and 6 t ha^{-1}) and three kenaf varieties- Ifeken 400, Ifeken D1 400 and Girin danani. The trial was a 4 × 3 factorial laid out in a randomized complete block design and replicated three times. Plots supplied with 6 t ha^{-1} poultry manure significantly produced (p< 0.05) taller plants, higher shoot dry weight, seed weight plant^{-1}and seed yield. Although no statistical difference was observed among varieties during the growth stages (plant height and shoot dry weight) across sampling periods except in Samaru, at 3 and 6 weeks after sowing (plant height), where Girin danani produced significantly taller plants than other varieties. The interactions between varieties and poultry manure was significant on shoot dry weight in Samaru. However, Girin danani variety significantly produced (p <0.05) higher seed weight plant^{-1} of (125.88 and 135.92 g ha^{-1}) and seed yield of (209.7 and 226.5 kg ha^{-1}) in both locations, compared with Ifeken 400 and Ifeken D1 400 varieties. Based on the results obtained from this trail, the application of 6 t ha^{-1} poultry manure and Girin danani variety resulted in higher growth and seed yield in both locations. Therefore, the use of Girin danani variety and 6 t ha^{-1} poultry manure can be adopted by farmers in the Northern guinea and Sudan Savanna agro ecological zones to enhance the growth and seed yield of kenaf.

Key words: Growth, Seed Yield, Poultry manure, Kenaf and Varieties.

INTRODUCTION

Kenaf (*Hibiscus cannabinus* L.) also called Bimly, Bimlipatum, Jute and Deccan Hemp is a member of the Hibiscus family (*Malvaceae*) and indigenous to Africa. It is an annual fibre crop (Alexopoulou *et al.*, 2000). The name kenaf is of Persian origin and is used to signify both the tall annual plant (*Hibiscus cannabinus* L.) with large flowers, characteristic of the Mallow family, and the bast fibre obtained from its stem (Angelini *at al.*, 1998). The genus Hibiscus is widespread, comprising of some 200 annual and perennial species. Francis *et al.*, (2010) reported that kenaf is closely related to cotton (*Gossypium hirsutum* L.) and okra (*Hibiscus esculentus* L.). Manzanares *et al*. (1997) reported that kenaf is one of the important fibre crops next to cotton and is cultivated for its core and bast fibres. Recently, the interest in growing kenaf has been increasing throughout the world for its elevated fibre content (Alexopoulou *et al.*, 2000). It is a fast growing crop and has high potential as an industrial crop (Manzanares *et al.*, 1997). The residual core fraction is used as biomass for energy production (Danalatos and Archontoulis, 2005). Kenaf is traditionally grown in east-central Africa, west Asia and in several southern states of America for fibre and seed oil production. It is also an excellent forage crop (Muchow and Wood, 1980), containing 18-30% crude leaf protein and stalk protein 5.8-12.1% (Ogbonnaya *et al.*, 1997). Investigations have indicated that Nigerian savanna soils are largely deficient in major essential nutrients like nitrogen, phosphorus and potassium. Making it necessary to supply and enrich the soil with applied nutrients using inorganic and organic sources such as poultry, cow and goat manure. The use of inorganic fertilizer is constrained by factors such as unavailability of the right type, at the right time, and at affordable cost, as well inadequate credit facilities for the farm inputs (Chude, 1999). Hence organic manure is a better alternative and a necessary option for improved crop production especially in the Guinea Savannah of Northern Nigeria. Poultry manure is relatively cheap, readily available to small holder farmers and improve soil physical properties compared to inorganic fertilizers, similarly the increasing demand for poultry manure was due to its health benefits and risk-free characteristics especially in vegetables and fruits production. Poultry manure has been found to have higher nutrients concentration (Iken and Amusa, 2004). Although in Nigeria research work on poultry manure recommendation for kenaf production is not available, however improve and high yielding kenaf varieties have been developed such as Ifeken 400 and Ifeken D1 400 through conventional breeding by the Institute of Agricultural Research and Training Ibadan, Oyo State which is affiliated to Obafemi Awolowo University. Research work on these varieties was mostly conducted in the rainforest agro ecology and derived Savanna agro ecological zones of the country. There is the need to extend the cultivation of these varieties in the northern and Sudan Savanna agro ecological zones of Nigeria, hence the use of Ifeken 400 and Ifeken D1 400 to investigate their adaptability in the zones. Based on this, the present study was conducted to determine the appropriate rate of poultry manure and suitable variety in growing kenaf for seed in the Northern guinea and Sudan savannah agroecological zones of Nigeria.

MATERIALS AND METHODS

The experiment was conducted at the Institute for Agricultural Research (I.A.R) Farm, Samaru, (Latitude 110 11N Longitude 07' 38 E, 686m) above sea level in Kaduna State and at Kadawa, (Latitude 110 39 N Longitude 08' 27 E, 500m) above sea level in Kano State, in the northern Guinea and Sudan savannah ecological zones of Nigeria, respectively during the 2017 wet season (Kowal and Knabe, 1972). The treatments consisted of four rate of poultry manure (0, 2, 4 and 6 tons ha^{-1}) and three varieties of kenaf (Ifeken 400, Ifeken D1 400, and Girin danani). The treatments were factorially combined and laid out in a Randomized Complete Block Design (RCBD) and replicated three times. The gross plot size was 4m x 3 (12m^2) while the net plot was 2 x 3 (6m^2).

The experimental field was cleared and harrowed twice, and raised seed beds were constructed according to plot size above. The poultry manure was applied 7 days before planting by mixing the manure thoroughly with the soil with a hoe in each plot as per treatment basis. Seeds were sown manually on 26th July, and 2nd August, 2017 wet season at the rate of 3 seeds per hole, at an intra-row spacing of 25cm and inter-row spacing of 50cm. Sowing was done on flat land after harrowing and the plants were thinned to 2 plants per stand at 3 weeks after sowing. Data was collected on plant height, shoot dry weight, seed weight plant^{-1} and seed yield were subjected to statistical analysis of variance (F-test) as described by (Snedecor and Cochran, 1967) to test significance of treatment effects. The treatment means were compared using Duncan's Multiple Range Test (DMRT) (Duncan, 1955).

RESULTS

Plant Height

The effects of varieties and poultry manure rate on the mean height of kenaf during the 2017 wet season at Samaru and Kadawa is presented in Table 1. A significant difference between varieties at 3 and 6 WAS in Samaru. At 3 WAS, Girin danani significantly produced taller plants, than Ifeken D1 400 and Ifeken 400 which were statistically similar. At 6 WAS the production of tall plants by Ifeken 400 was significant, while Girin danani significantly produced taller plants than Ifeken D1 400. At Kadawa, no significant difference was observed between varieties on plant height of kenaf at all sampling periods. Application of poultry manure significantly influenced the height of kenaf at 3 and 6 WAS in Samaru and 3-12 WAS at Kadawa. Where the application of 6 t ha^{-1} poultry manure produced taller plants than other rates. The interactions between varieties and poultry manure rate on the mean height of kenaf was not significant throughout the period of study.

Shoot dry weight

The effects of varieties and poultry manure rate on the mean shoot dry weight of kenaf during the 2017 wet season at Samaru and Kadawa is presented in Table 2. No significant difference between varieties was recorded at all sampling periods in all locations. Application of poultry manure significantly influenced shoot dry weight of kenaf at 9 WAS in Samaru where the application of 4 t ha^{-1} poultry manure produced a significantly higher shoot dry weight than at 0 t ha^{-1}; but statistically at par with plots applied with 2 and 6 t ha^{-1}. The least shoot dry weight was recorded on plots with 0 t ha^{-1}poultry manure application. There was a significant difference on the application of poultry manure on the shoot dry weight of kenaf at all sampling periods in Kadawa. At 3 WAS, the application of 2 t ha^{-1} poultry manure produced significantly higher shoot dry weight than plots with 0 t ha^{-1}; but statistically at par with plots applied that had 4 and 6 t ha^{-1} poultry manure application. However, at 6, 9 and 12 WAS, shoot dry weight of kenaf generally increased with increasing rate of poultry manure from 0 to 6 t ha^{-1}. Shoot dry weight was significantly higher in plots with 6 t ha^{-1} poultry manure than on those with 0 t ha^{-1}. There was no significant difference on shoot dry weight from plots with 6 t ha^{-1} of poultry manure application and those applied with 2 and 4 t ha^{-1}. The lowest shoot dry weight was recorded on plots with 0 t ha^{-1}.

The interactions between varieties and poultry manure rate on the mean shoot dry weight of Kenaf was significant at 9 and 12 WAS in Samaru is presented in Table 3. At 9 WAS, the combination of poultry manure rate and varieties had a significantly higher shoot dry weight with Ifeken 400 and 2 t ha^{-1} poultry manure; and was statistically similar with the variety Girin danani applied with poultry manure at 2 and 4 t ha^{-1}. The lowest shoot dry weight was recorded with Ifeken D1 400 which had 2 t ha^{-1} poultry manure. At 12 WAS, Ifeken 400 applied with 2 t ha^{-1} poultry manure applicationproduced the highest shoot dry weight; but was statistically at par with Girin danani which had poultry manure at 2 and 4 t ha^{-1}poultry manure applicationand Ifeken D1 400 at 0 t ha^{-1}. The lowest shoot dry weight was recorded with Ifeken 400 at 0 t ha^{-1}.

Seed weight plant^{-1}

The effects of varieties and poultry manure rate on mean seed weight per plant of Kenaf at Samaru and Kadawa during the 2017 wet season is presented in Table 4. A significant difference was recorded between varieties at both locations. At Samaru, Girin danani produced significantly higher seed weight of Kenaf than Ifeken 400, butwas statistically at par with Ifeken D1 400. Similarly, Ifeken D1 400 recorded statistically the same seed weight per plant with Ifeken 400. However, at Kadawa, Girin danani significantly recorded the highest seed weight per plant over Ifeken D1 400 and Ifeken 400. Ifeken D1 400 recorded significantly higher seed weight per plant compared to Ifeken 400. The application of poultry manure significantly increased the seed weight per plant at both locations. At Samaru, the application of 6 t ha^{-1} poultry manure significantly produced the highest seed weight per plant of Kenaf. The application of 2 and 4 t ha^{-1}, recorded seed weight per plant that were statistically at par with each other; while the least seed weight per plant was observed on plots applied with 0 t ha^{-1}.

At Kadawa, seed weight per plant significantly increased with poultry manure rate from 0 to 6 t ha^{-1}. The interaction effect between varieties and poultry manure rate on seed weight per plant of Kenaf was not significant in both locations.

Seed yield

The effects of varieties and poultry manure rate on the mean seed yield per hectare of kenaf at Samaru and Kadawa during the 2017 wet season is presented in Table 5. A significant difference was observed between varieties at both locations, in which Girin Danani produced higher seed yield ha^{-1} than other varieties that were tested. Application of poultry manure significantly influenced seed yield at both locations. The application of 6 t ha^{-1} poultry manure significantly showed the highest seed yield against other treatments.

DISCUSSION

The positive response of growth components such as (plant height and shoot dry weight) to poultry manure application from 2 to 6 t ha^{-1} at both locations could be attributed to the beneficial role of manure in providing soil nitrogen, phosphorus, potassium and other essential nutrients, which in turn improved growth and development of the plants during the trial. This is in consonance with the findings of Adekunle et al. (2014) who reported that the application of manure from 10-20 t ha^{-1} significantly increased the growth attributes of kenaf. The interaction between varieties and poultry manure was significant on shoot dry weight, where the combination of Ifeken 400 and 2 t ha^{-1} poultry manure produced higher shoot dry weight in Samaru. This could be probably due to the morphology of the variety and its ability to utilize the nutrients supplied by the poultry manure for rapid growth and development. This is in agreement with the findings of Mubarak (2014b) who reported that higher shoot dry weight was obtained in clemson spineless variety of okra as a result of the morphology of this variety which was taller than Ex Samaru 4 and it contributes to the weight of the variety (clemson spineless). Seed yield ha^{-1} was observed to increase significantly with the application of 6 t ha^{-1} of poultry manure at both locations. This could be due to the appreciable amount of essential nutrients in the poultry manure (N, P, K, Ca and Mg) and the favourable weather conditions during the 2017 wet season that favored the quick decomposition of the manure. This result conforms to earlier findings by Atif et al. (2015) who reported a higher yield of jute mallow when poultry manure was applied. The significant differences recorded among the three kenaf varieties in terms of their growth and yield such as plant height, shoot dry weight, seed weight plant^{-1} and seed yield of kenaf is attributed to differences in the genetic composition of the varieties used. This is in line with the study of Akinfasoye et al. (1997) who reported that the differences in yield parameters of crops are attributed to the cultivars grown and their genetic make-up.

Girin danani produced higher seed weight plant^{-1} and seed yield than Ifeken 400 and Ifeken D1 400 at both locations. Apart from the genetic composition of the variety which plays an important role in the potential yield of the crop, the differences in the rate of nutrient absorption and utilization among the three varieties and environmental variations could greatly influence the yield of kenaf. This result agrees with the finding of Williams (2004) who observed differences in yield of kenaf varieties due to different genetic make-up of these varieties.

CONCLUSION

Kenaf variety Girin danani showed superiority over Ifeken 400 and Ifeken D1 400 on all the growth and yield components in this study. The study further confirmed the valuable contribution of poultry manure, where the application of 6 t ha-1 poultry manure had the best results of all parameters in both locations.

ABSTRACT

A field study was carried out at the experimental site of National Horticultural Research Institute, Idi-ishin, Ibadan, Oyo State, Nigeria, to assess the heavy metals concentration in cucumber planted using organic fertilisers to enhance its production and determine its health risk index (HRI) and target hazard quotient (THQ) if consumed. There were four treatments: Poultry manure (PM), Composted cow dung (CCD), Liquid Organic fertilizer (LOF) and the control (CTR) which were laid out in a randomised complete block design replicated three times. Heavy metal analyses were determined in all the samples of the fertilisers and the soil before use as well as the cucumber after harvest using standard procedures. Results were analysed using ANOVA at p<0.05. LOF and CTR had the least values of heavy metals (0.08 and 0.00) mg/kg while others ranged from 0.30 and 0.31 mg/kg. The CCD had the highest value (Chromium (Cr): 110.27 mg/kg) while the CTR had 0.00 mg/kg of Lead (Pb). All fertilisers treatments had higher values of heavy metals above FAO/WHO standard. The heavy metals concentration ranged from 12.9 mg/kg of Pb to 3.0 mg/kg of Cadmium (Cd) in the soil and 145 mg/kg of Zinc (Zn) to Not Detected (ND) in both Cd and Pb (for PM and LOF) in the fertilisers. HRI and THQ for heavy metals in the fertiliser treatments for cucumber were <1 although Pb was highest 0.45 and 0.88 for both HRI and THQ. Consumption of cucumber grown with the fertiliser treatments could not have health impact (HRI and THQ <1) but continuous consumption could lead to bioaccumulation of heavy metals especially Pb in the consumers. It is however suggested that liquid organic fertilisers should be used in other to have safe and quality cucumber.

Key words: Health risk, Hazard Quotient, Soil, Cucumber

INTRODUCTION

Cucumber (*Cumunis sativus* L.) is one of the main fruit that is eaten raw, cooked or in salad. The presence of terpenoid, a main phytochemical constituent in cucumber possesses medicinal effectiveness against malaria, viral, bacterial and fungal agents (Egwaikhide, 2010) as obtained from its extract (Ankita *et al*., 2012). Soils are enhanced by applying fertilisers that supply additional plant nutrients and also boost the plant growth. Organic fertilisers (OFs) are composed mainly of plant and animal waste. Application of OFs to the soil has shown a positive influence on the growth and yield of crops (Udoh *et al*., 2005); alongside a slight increase in human food chain toxicity (Brady and Weils, 2002). This is because they contain not only major elements necessary for plant nutrient but other variable qualities of heavy metals (Ali *et al*., 2013) which increase up the food chain. Heavy metals become toxic when they are not metabolised by the body and accumulate in the tissues. These pollutants cannot be excreted efficiently in the human body hence they build up (Godfrey *et al*., 2003) leading to ill health, diseases and finally death. This study was therefore conducted to assess the heavy metals concentration in cucumber, associated with the health risk index and target hazard quotient.

MATERIALS AND METHODS

Experimental Site Description

The experiment was carried out at the National Horticultural Research Institute (NIHORT) Jericho, Ibadan, Oyo State, Nigeria. The area lies between Latitude 7^0 54^1 N, Longitude 3^0 54^1 E and 213m above sea level in the Greenwich meridian, its average rainfall is about 1250 mm, while average mean temperature is 26 ^{0}C. The average relative humidity is 74.53%

Treatments and Experimental design

Seeds of cucumber (NAGANO F1) and LOF were purchased from Agrotropics Seed Company Bodija, Ibadan. The PM was collected from NIHORT poultry farm while the CCD was purchased from Aleshinloye Fertiliser Company, Ibadan. The treatments were: LOF at 500 ml/ha, CCD at 20 tons/ha, PM at 20 tons/ha as recommended by Adeniyi (2014) and the CTR (without organic fertiliser). The experiment was laid out in a randomised complete block design with each of the four treatments replicated three times.

Analysis of Heavy Metals in Samples

Heavy Metals Determination in Cucumber and Soil

Maturity of cucumber fruits were determined from very greenish colour to yellowish green and were harvested by plucking randomly at 6-8 weeks after sowing. Harvested fruits were collected together to form a composite sample. Soil samples were randomly collected from the depth of 0-15 cm using calibrated soil auger. They were randomly looped together to form a composite and taken to the Toxicology Research Laboratory of Crop Protection and Environmental Biology, University of Ibadan for air drying and digestion using the AOAC, 2005 and taken to the multidisciplinary central research laboratory for heavy metals determination using Atomic Absorption Spectrophotometry (AAS) using the Roychowdhury and Tah (2011) method.

Determination of Health Risk Index and Target Hazard Quotient

DIM = (C_{metal} × C_{factor} × $D_{food\ intake}$) ÷ ($B_{average\ weight}$) (Rattan *et al.*, 2005; USDA, 2007). Where C_{metal} = Conc. in plants (mg/kg), C_{factor} = Conversion factor (0.085) (Sajjad Khan *et al.*,2009). $D_{food\ intake}$ = Daily intake of vegetables (kgd^{-1}), 100g was used (Lanre-Iyanda and Adekoye, 2013). $B_{average\ weight}$ = average body weight (kg), 60kg (ESFA, 2012). HRI = DIM ÷ RfD (US-EPA, 2013).

$$THQ = \frac{EF \times ED \times FIR \times C}{RFD \times WAB \times TA}$$

Where: EF = Exposure Frequency $350\frac{days}{year}$ ED = Exposure Duration = 54 years (average life time of Nigerian Population) FIR = Food Ingestion Rate (vegetable consumption values for South western adult in Nigeria is 60g/person/day) WAB = Average Body Weight = 60 Kg for adult TA = Average exposure time for non-carcinogens (ED × $365\frac{days}{year}$ (Oguntona, 1998). If HRI and THQ is <1, the exposed population is said to be safe and if ≥1, the population will experience health risk (IRIS, 2003).RfD = Oral Refence Dose

Statistical Analysis

Results were analysed using analysis of variance and means were separated at a probability of five percent (5%) level of significance using Duncan Multiple Range Test

RESULTS AND DISCUSSION

Heavy metals in Organic Fertilisers before planting

The range of heavy metals in the fertilisers were from ND in both LOF and PM in Cd and Pb; 349.78 in Cr (Table 1). This is in consonance with Ogabiela *et al.*, 2009 that organic fertilisers had the highest Cr value although its uptake could be within the permissible limit. Cd and Pb was only detected in CCD while Zn and Cr occurred in all the fertilisers.

Table 1: Comparison of some heavy metals concentration in the Fertilizers Used

Fertilizer	mg/kg Cu	mg/kg Zn	mg/kg Cr	mg/kg Cd	mg/kg Pb	mg/kg Ni
Compost	23.00	145.00	310	3.00000	80.0000	11.0000
Poultry	15.00	106.00	16	ND	ND	5.0000
Liquid	216.025	60.625	349.175	ND	ND	15.625
WHO	90.260	800-1200	--	15-40	200-400	--
EPA	1500	--	1200	--	300	--

Heavy metals present in soil samples ranged from 12.9 in Pb to 3.0 in Cd (Pb>Cr>Zn>Cd) and were above the WHO/FAO2001 standard this is in line with Olatunji*et al.*, 2013 and Radwan and Salama, 2006 which carried out a survey of various fruits and vegetables for heavy metals in the soil (Table 2).

Table 2: Some heavy metals concentration in the soil sample before fertilizer application

No	mg/kg Cr	mg/kg Zn	mg/kg Cd	mg/kg Pb
SOIL	12.80	5.856	3.0	12.9
WHO	-	0.3	-	0.1
EU (2001)	-	-	3.0	300

Heavy Metals Concentration in Cucumber

The CTR had the highest Zn values (9.17 mg/kg) which varied from other fertilizer treatments (4.39-5.35 mg/kg). LOF had the lowest Cd (0.15 mg/kg) while the control had the highest value (0.47 mg/kg) with significant difference amongst the treatments (Table 3). CCD had the highest value for Cr (110.28 mg/kg) while the CTR had 92.86 mg/kg as the lowest with significant difference. The sample trend was observed in the value of Pb (3.66 mg/kg) in CCD while it had 0.00 mg/kg in the CTR. Dotse *et al*., 2010 investigated Pb, Cu, Cr, Zn and Cd in different vegetables, cucumber included and found that Pb contents exceeded the permissible limit which is in consonance with the CCD.

Table 3: Some heavy metals concentration in the Cucumber

Fertilizer	mg/kgZn	mg/kgCr	mg/kgPb	mg/kg Cd
Compost	5.01	110.27	3.66	0.30
Poultry	4.39	109.85	1.12	0.31
Liquid	5.35	103.52	0.08	0.15
Control	9.17	92.86	0	0.47
EU	50	1	0.43	0.2
NAFDAC	50	-	2	-
FAO/WHO, 2016	9.4	2.3	0.1	-

Result on the HRI and THQ revealed all heavy metals less than 1 (<1) below the tolerable limit as presented in figure 1-4. The high transfer values for Cr from soil to fruit indicates a strong accumulation of the receptive metals in the region as reported by Fayinminnu and Adekunle-Jimoh (2015). Pb indicated the highest value for its HRI and THQ which if accumulated could be detrimental. An important aspect of assessing risk to human health from potentially toxic metals is the knowledge of the dietary intake of the metals (DIM) (Cherfi *et al*., 2014; Chery *et al*., 2008). Health quotient has been a useful parameter for evaluation of risk associated with consumption of metal contaminated food crops (Chary *et al*., 2008 and Zhuang *et al*., 2009). The existential potential for chromium and lead contamination and toxicity raises the issue of future monitoring (Udousoro and Essien, 2015).

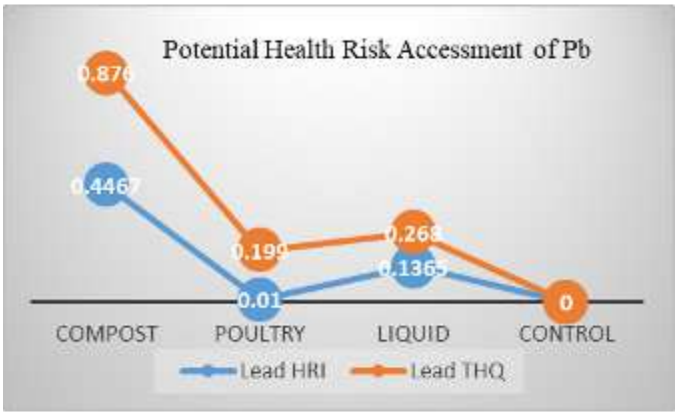

Figure 1. Potential Health Risk Assessment of Lead (Pb) through ingestion of *Cucumis sativus* fruit

Footnote: HRI = Health Risk Index and THQ = Target Hazard Quotient.

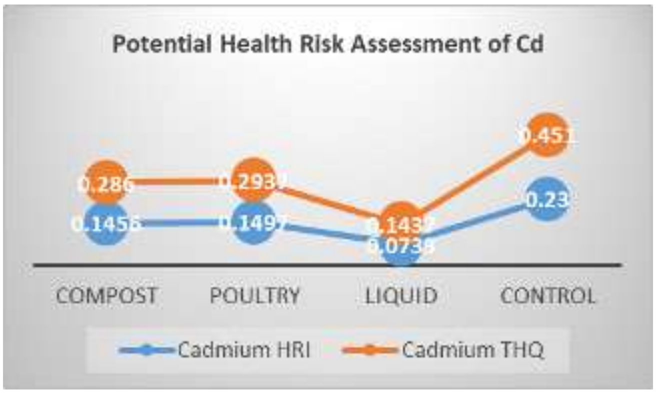

Figure 2. Potential Health Risk Assessment of Cadmium (Cd) through ingestion of *Cucumis sativus* fruit

Footnote: HRI = Health Risk Index and THQ = Target Hazard Quotient.

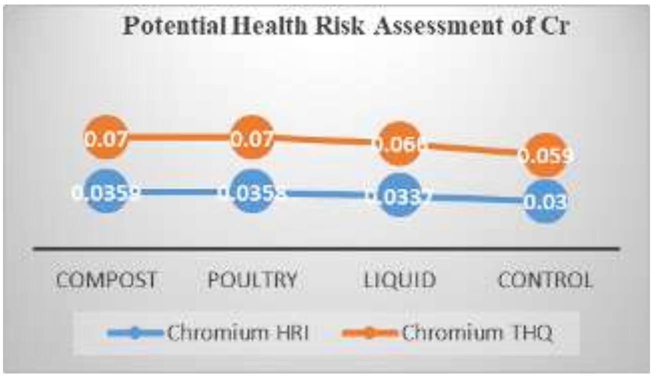

Figure 3. Potential Health Risk Assessment of Chromium (Cr) through ingestion of *Cucumis sativus* fruit

Footnote: HRI = Health Risk Index and THQ = Target Hazard Quotient.

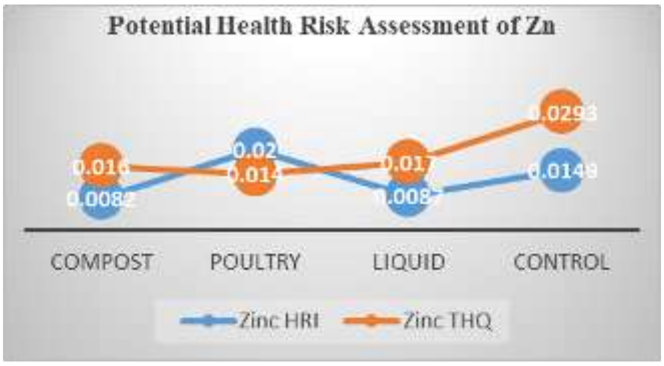

Figure 4. Potential Health Risk Assessment of Zinc (Zn) through ingestion of *Cucumis sativus* fruit

Footnote: HRI = Health Risk Index and THQ = Target Hazard Quotient.

CONCLUSION AND RECOMMENDATION

Cucumber fruit could contribute to bio-accumulation magnification of cadmium and chromium in humans. Although the human health risk and target hazard quotient associated with cucumber fruit production were negligible (health quotient<1), it was observed that Pb in the fruit presented the highest values for the THQ and HRI in the study area. Also instances where cucumber is planted for the influx harvesting of fruits at a short period of time, LOF be used at the recommended rate of 500ml/ha which was best suitable for tolerable heavy metals in cucumber fruits a unique significant difference in output.

ABSTRACT

Lycopene, a red pigment carotenoid is one of the most important antioxidants that is contained in ripe tomato fruits. Field experiments were conducted to investigate the effects of NPK 15-15-15 fertilizer and poultry manure on the lycopene content of two tomato varieties. The study was conducted at the National Horticultural Research Institute, Ibadan, (Lat. 7^0 30'N; Long. 3^0 50'E) during the 2011 and 2012 cropping seasons. The experiments were design as 2x2x5 factorial in Randomized Complete Block and arranged in Split–Split plots, comprising of two cropping systems two tomato varieties (Uc82B and Ibadan local) and soil amendments (0, 60, and 120 kg N/ha NPK 15-15-15 and 10 and 20 tons/ha poultry manure). The application of 20 t/ha poultry manure showed the highest value of lycopene while the non application of any form of soil amendment resulted in the lowest.

Key words: Lycopene. Intercropping, NPK 15-15-15 fertilizer, poultry manure, Uc82B, Ibadan local.

INTRODUCTION

Consumption of tomato products has been associated with decreased risk of some cancer types (Vinson *et al.,* 1996), because of the nutrients contained it. Tomatoes have been reported to be an important source of many nutrients such as lycopene. Lycopene is the red pigment carotenoid which is also responsible for the characteristic red colour of most tomato varieties (Rahayu et al., 2018). Intercropping tomato with appropriate crops, would lead to increased productivity and reduced risk of total crop failure, it may also affect the fruit quality, although according to (Woese, 1997), differences between varieties and other environmental conditions had greater influence on fruit quality than did the different cultivation systems. Adoption of improved varieties and agro technique also makes increased productivity attainable. Tomato responds well to additional fertilizer applied and it is reported to be a heavy feeder of NPK (Hebbar *et al*., 2004), deficiency of which is a major production constraint in some soils (Lester, 2006). Different kinds of fertilizer and application methods are reported to have different effects on the yields and quality of tomato fruits (Lester, 2006). Therefore, the objective of this research work is to determine the effects of intercropping system and application of organic and inorganic soil amendments on the yield and Lycopene content of two varieties of tomato (Uc82B and Ibadan local).

MATERIALS AND METHODS

Soil and Poultry Manure Analysis

The soil sample and cured poultry manure were analyzed for total nitrogen, pH, organic carbon, available P, exchangeable Ca, K, Mn, Na, and Mg. Total N. Analyses were carried out using the standard analytical laboratory procedure of IITA (IITA, 1994).

General Treatments and Experimental Design

The study was conducted at the National Horticultural Research Institute (NIHORT), Jericho, Idi-Ishin, Ibadan. NIHORT is located in the rainforest savanna transition zone and falls approximately on latitude 7^0 30'N and longitude 3^0 50'E. It is at altitude 168m above sea level. Two varieties of tomatoes :(Uc82B and Ibadan local) were intercropped with maize cultivar SAMMAZ 14.

The experiments were design as 2x2x5 factorial in Randomized Complete Block and arranged in split–split plots and replicated three times. The experimental factors include; cropping system (Sole and Intercrop), variety (Ibadan local and Uc82B) and soil amendment which consisted of 0, 60 and 120kg N/ha NPK 15-15-15, 10 and 20t/ha of Poultry Manure. Incorporation of organic manure into soil involved digging the poultry manure into the soil using spade fork two weeks before planting. The NPK 15-15-15 fertilizer was applied by ring placement into drills 5 cm deep and 7.5 cm away from the plant and covered with soil, 3WAT.

Lycopene

The milled tomato samples were reconstituted in distilled water and mixed thoroughly. Lycopene in the samples was extracted by hexane-acetone-ethanol (2:1:1, v: v: v) mixture, following the method of Sharma and Le Maguer (1996). The absorbance of hexane solution containing Lycopene was measured at 472nm on a Spectrophotometer (Unikon 930, Kontron, Italy). Using hexane as a blank. The Lycopene concentration was calculated using its specific extinction coefficient (E 1%1cm) of 3450 in hexane. Data were subjected to analysis of variance using GenStat Discovery Edition 4 (2011). Significant means separated by the least significant difference at 5% probability level ($LSD_{0.05}$).

RESULTS

Effects of cropping system, soil amendment and variety on tomato fruits yield.

The results of the pre-treatment soil analysis of the experimental site of this study also indicated low N, P, and K: Total N (0.30, 0.65 g/kg); Available P (8.09, 12.5); Exchangeable K(0.23, 0.13cmol). The poultry manure used contained N (2.90, 2.92g/kg); Ca (3.55, 2.57g/kg); Mg (0.55, 0.43g/kg); P (1.65, 1.55g/kg) and K (1.80, 1.83g/kg) in 2011 and 2012 respectively.

Effects of cropping system, variety and soil amendments on tomato Lycopene content

The results show that Ibadan local tomato variety produced significantly higher lycopene contents than Uc82B in the two years of the study, while the antioxidant varied significantly with the application of the different forms and rates of soil amendment with the application of 20 t/ha poultry manure showing the highest value and non-application of any form of soil amendment resulting in the lowest value (Table 1). The application of 0 and 120 kg N/ha NPK and 10 t/ha PM resulted in significantly higher lycopene contents in Ibadan local than in Uc82B, while the application of 60 kg N/ha NPK and 20 t/ha PM resulted in similar lycopene contents in the two tomato varieties (Table 2). However, under the intercropping system (Table 2), the application of 0 and 120 kg N/ha NPK and 10 t/ha resulted in significantly higher contents of lycopene in the Ibadan local than in Uc82B which variety showed higher lycopene content with the application of 60 kg N/ha NPK, while the application of 20 t/ha PM showed similar lycopene contents in the two varieties. In 2012 (Table 2) revealed that when the tomatoes were planted as sole crops, the application of any form and rate of soil amendments resulted in significantly higher lycopene contents in the Ibadan local than in the Uc82B, with the exception of the application of 60 kg N/ha NPK with higher lycopene content in Uc82B than in Ibadan local. Although under the intercropping system (Table 2), the application of the soil amendments resulted in significantly higher lycopene contents in Ibadan local than in the Uc82B, with the exception of the application of 20 t/ha PM which resulted in similar lycopene contents in the two varieties.

Table 1. Main effects of cropping system on tomato fruits Lycopene content in 2011 and 2012

		Lycopene content (mg/g)

PM=poultry manure, least significant difference at 5 percent probability level ($LSD_{0.05}$)

DISCUSSION

The low nutrient content of the soil especially in the year 2011 may be attributed to the established fact that plant nutrient is limiting in most of the Nigeria farmlands as observed (Obigbesan, 2000). The nutrients composition of the poultry manure used for this study suggested that it was adequate to improve the soil fertility, thereby enhancing the performance of the tomato crop. The two tomato varieties responded differently to the different soil amendments, confirming their different genetic background as Passam *et al*. (2007) observed that tomatoes' response to a particular nutrient vary with cultivars. The results obtained in this study also suggested that there are no appreciable evidences for cropping system effect on Lycopene content in contrast to the report of Barrett *et al*. (2007) who found significant impacts of production system on lycopene. But its levels varied significantly with the different variety of tomatoes in agreement with the previous findings in which Lycopene content of tomatoes were found to vary between cultivars which may be due to their genetic background and differences, (Rahayu *et al.* (2018), Helyes *et al.*, 2012, George *et al*., 2004). Toor *et al*., (2006), had noted that fertilizer sources can have a significant effect on tomato quality; in affirmation this study showed some significant differences in value. that the application of 20 t/ha poultry manure gave the highest value, similar values have been reported even with lower quantity (10.0 t ha^{-1}) by Yadava *et al*. (2012), indicating that organic manure is an effective source of antioxidants especially lycopene.

CONCLUSION

Ibadan local tomato variety is a better source of lycopene content than Uc82B; poultry manure as an organic fertilizer supplied better lycopene than the inorganic fertilizer. In conclusion, in addition to other benefits of organic manure antioxidant content of tomato fruits may be improved by its application.

ABSTRACT

The significance of organic and inorganic nutrients for crop growth and productivity cannot be overemphasized. Pot and field trials were carried out in the department of crop science university of Nigeria, Nsukka. The Pot experiment was laid out in a completely randomized design (CRD) in 15 replications while the field experiment was laid out in a randomized complete block design (RCBD) in 3 replications. These studies were designed to compare the effect of organic and inorganic fertilizers on the performance of Moringa oleifera in pot and field. Human urine, poultry manure and pig manure were applied as organic sources while NPK 15:15:15 served as inorganic fertilizer. Poultry manure and pig manure were incorporated into the soil at the rate of 10t/ha according to their appropriate requirements, 4 weeks before planting. Similarly, 4 parts of water was mixed with 1 part of human urine and 240t/ha of NPK 15:15:15 was applied in two split doses as well as a control experiment. Two seeds of Moringa.oleifera were planted for both pot and field trials. Results of the Analyses of variance (ANOVA) indicated significance ($P<0.05$) among treatments with respect to most of the component traits measured. Poultry manure significantly ($P<0.05$) influenced the morphological, physiological and yield parameters of Moringa oleifera compared to other treatments used in both experiments. Poultry manure gave the highest plant height of 103.0 cm and 133.4 cm for experiments 1 and 2, respectively while its application also gave the highest stem girth of 5.11 cm and 4.9 cm in both experiments 1 and 2 respectively, compared to human urine, pig manure and NPK 15:15:15, which gave relatively lower values. The control had the least plant height and stem girth in both experiments. However, results from these experiments affirmed that the use of both organic and inorganic fertilizer could positively enhance crop growth, yield and productivity. It also confirmed the use of human urine as a substitute for nitrogenous chemical fertilizers.

INTRODUCTION

Moringa oleifera is a evergreen, fast growing and drought resistant plant which belongs to the *Moringaceae* family. It can reach a maximum height of 7-12 m and a diameter of 20-40 cm at chest height additionally, it is perennial in nature. The stem is normally straight and branches at a height of 1.5 to 3 m (Fuglie and Sreeja, 2011). *M. oleifera* is a highly nutritious and medicinal plant with great agricultural, industrial and domestic uses (Moyo *et al*., 2011, Ndubuaku and Ndubuaku, 2011). Almost every part of moringa tree has been consumed by humans' overtime. It has been used for various domestic purposes as well as alley cropping, animal forage, water purification, machine lubrication (oil), manufacture of perfume, and hair care products. Besides culinary and other domestic uses, several biological properties ascribed to various parts of this tree have been reviewed in the past. It grows best in loamy or sandy loam soil and can tolerate poor but not water-logged soils.

Due to its popularity and the increasing demand for organically grown food products, the prospect of using organic fertilizer in growing this crop is very bright as the application of organic fertilizers not only produces high and sustainable yield, but also improves soil fertility and productivity (Sanwal *et al.,* 2007). One of such organic fertilizer which is in abundance and at the same time, if not properly disposed, poses health hazard is human urine. Urine is an aqueous solution, made up of more than 95% water, with the remaining constituents made up of urea, creatinine, dissolved ion (chlorine, sodium, potassium etc) inorganic and organic compounds or salts (Richert *et al*., 2010). It is a liquid product of the human body that is secreted by the kidneys which contains large amounts of soluble nutrients – macro and micro nutrients (Gensch *et al.,* 2011).

Human urine makes an excellent high nitrogen liquid fertilizer for crop growth. It is rich in nitrogen and can be used to fertilize numerous crops. Human urine contains other nutrients like phosphorus, potassium, magnesium, calcium.

Thus, these nutrients present in urine could be useful as fertilizers. In general, pure human urine contains very few enteric microorganisms if there is no faecal contamination ((Höglund, 2001). Urine has been successfully used to fertilize other crops like cucumber, cabbage, lettuce, maize, wheat and tomatoes in addition to okra. The use of urine as a fertilizer is not a new phenomenon. Therefore, human urine can go a long way to assist in the growth, yield and production of okra in both small and large scale.

Despite its numerous uses and benefits already mentioned, human urine still remains unpopular in Nigeria and has not been fully exploited, it is sometimes neglected as a result of lack of awareness which formed the basis for this study. More so, much emphasis has been on the use of organic manure and chemical inorganic fertilizers in enhancing the growth and yield potentials of *Moringa oleifera*. Little or poor attention so far has been given to the use of human urine as an organic fertilizer on the growth and performance of perennials like *Moringa oleifera* Lam, owing to its poor knowledge and utilization. This thereby formed the backbone of this study for which the objectives were to compare the effects of human urine, poultry manure, pig manure, NPK 15:15:15 and control on the growth and performance of *Moringa oleifera* in both pot and field trials.

MATERIALS AND METHODS

Two experiments were conducted in the research farm at the Department of Crop Science, University of Nigeria, Nsukka. Nsukka is situated on latitude $06^0$51'E, longitude $07^0$29'N and altitude 475m above sea level. It is characterized by lowland humid conditions with bimodal annual rainfall distribution of about 1500mm. The mean annual temperature ranges from 20^0C to 30^0C and relative humidity from 70% to 80% (Baiyeri *et al*., 2008). It has a derived savanna ecology.

Urine Collection and Treatment

Human Urine was collected from a private home with no form of faecal cross contamination, stored for a period of three months, and then treated by two methods which were extended storage and solar inactivation (GTZ, 2009). These treatment methods entailed the storage and exposure of collected urine samples to solar radiation for a period of three months (WHO 2016). This was necessary to inactivate pathogens, degrade micropollutants and also remove pathogenic microorganism. (Rainey*, et al.,* 2005, GTZ, 2009)

Soil and manure analyses

Samples of soil were collected from different mapped spots on the experimental field from where soil used for the potted trials were collected to a depth of 20 cm. The collected soil samples were made into a composite mix. A phsico-chemical analysis was carried out on sub-sample taken from the composite mix to determine the particle sizes (clay, silt, fine sand and coarse sand). Additionally, samples of collected human urine, pig manure and poultry manure was analysed for the determination of nitrogen, phosphorus, potassium calcium, and magnesium content. The soil pH was determined using a Beckman's zeromatic pH meter. Analyses were carried out at the labouratory of the Department of Soil Science, University of Nigeria Nsukka, Enugu State, Nigeria.

Pot Trial

This experiment was laid out in a completely randomized design (CRD) with five treatments. Each treatment was replicated 15 times. 75 poly bags were perforated at the bottom and both sides, filled with 10 kg of top soil. Two seeds of *Moringa oleifera* were planted in each of the poly bags already filled with soil. These Moringa plants were thinned to one plant per bag at two weeks after seedling emergence. 12 litres of water was mixed with 3 litres of human urine in a calibrated bucket. One litre of the urine-water mixture was used to fertilize the Moringa in the poly bags for urine treatment three, six, and nine weeks after planting in three split doses. This was applied 5 cm away from the plant**.** 10 t/ha each of poultry manure and pig manure was incorporated into the soil in the polybags according to their respective treatments. This was done four weeks before planting. 240 kg/ha of NPK 15:15:15 was applied per bag to the Moringa plant in a ring form three, six and nine weeks after planting in three split doses.

Field Trial

This experiment was laid out in a randomized complete block design (RCBD) with three replications. Two seeds of *Moringa oleifera* were planted at a plant spacing of 80 cm x 80 cm, these Moringa plants however, was thinned to one plant at two weeks after seedling emergence. Each treatment plot measured 2.8m x1m.

One litre of human urine was mixed with 4 litres of water in a calibrated bucket. One litre of the urine-water mixture was used to fertilize the Moringa plants three, six and nine weeks after planting in three split doses. This was applied 5 cm away from the plant**.** 10 t/ha of poultry manure and pig manure was incorporated into the soil according to their respective treatments. This was done four weeks before planting. 240 kg/ha of NPK 15:15:15 was applied to the Moringa plant in a ring form three, six and nine weeks after planting in three split doses.

Growth and yield parameters

Morphological, physiological and yield data were collected on stem girth, plant height, number of leaves, number of fruits, number of seeds, harvest dry weight, and seed weight of *Moringa oleifera* in both the pot and field trials.

Statistical analyses

Data generated were subjected to analysis of variance (ANOVA) following procedures outlined for a randomized complete block design and a complete block design using GenStat Discovering Edition 4 (GENSTAT 2011). Significance of the treatment means were separated using Fisher's least significant difference (F-LSD) at 5% probability level as described by Obi (2002). Yield parameters were further modeled with genotype-genotype-environment (GGE) biplot analyses (Yan 2001)

RESULTS AND DISCUSSIONS

The textural class of the experimental site was sandy loam, the soil was acidic and basically had low essential plant nutrients. More so, the poultry manure and pig manure used were high in pH, while the organic carbon and organic matter content in poultry manure were relatively higher than that of pig (Table 1). The physico-chemical analyses depict that human urine is alkaline with a pH of 9.8mg/l (Table 2).

Exchangeable magnesium	9.60 (mg/l)
Available phosphorus	10.01 (mg/l)

Analysis of human urine (table 2) further showed the presence of organic matter, carbon and nitrogen. Human urine is a rich source of plant-available nitrogen with appreciable amount of phosphorus, potassium, magnesium, calcium, zinc and iron. Therefore, it can substitute for inorganic fertilizers (Kirchmann and Pittersson, 1995). It is a mixture of more than 200 organic and inorganic compounds that include nitrogen, phosphorous, and sulphur elements in various vitamins, hormones, organic acid and salts. Most of these compounds have concentrations higher than 10mg/L, and correspond to a mass of about 36.8 g/L. The remaining compounds only represent approximately 0.25 g/L (Putnam, 1971).

The availability of nutrients in the soil could be greatly influenced by soil pH and the proportionality of the physicochemical properties of the soil. The soil physical and chemical properties are shown in Table 1. Results depict that the soil acidity was high and there was deficiency in nitrogen and organic matter. This development could be attributed to the continuous erodibility of the top soil. This agrees with the work of Yusulf *et al.* (2017) which explained that the variation in soil structure and the removal of topsoil as a result of erosion could lead to nutrient removal and environmental degradation in a long run.

Nsukka is generally notable for its acidic soils (Baiyeri *et al*., 2007), which impedes nutrient availability to plants (Baiyeri *et al.,* 2006). The total nitrogen from analysed soil was very low compared to the critical level of 0.1% in Nigeria (FMANR, 1990) as this suggests the need for increased supply of N in the soil to enhance growth and yield. This prospect was met with the application of both organic and inorganic fertilizer types which led to increased yield potentials of M*oringa oleifera* both in pots and on the field (Tables 3 and 4).

The variation in fertilizer types had a great influence on the growth response of *M. oleifera* and the quality of fruits produced thereof. Among the fertilizer types, poultry manure exhibited the highest performance with respect to the morphological, physiological and yield traits measured compared to other treatments utilized in both experiments. This was closely followed by pig manure and human urine which also influenced the growth and yield component traits measured in both experiments compaired to NPK 15:15:15 and control (Tables 3 and 4).

The biplot however, explained 96.1% of the total existing variation depicting that deductions from it are reliable. Poultry manure greatly influenced the number of seeds, harvest dry weight, seed weight and number of fruits in both pot and field trials. This was distinctly revealed from the biplot that the application of manure could improve greatly the yield of *Moringa oleifera* (Figure 1). This agrees with the work of Adebayo *et al.* (2011) who stated that the vegetative and dry matter yield of *M. oleifera* was substantially enhanced through the application of organic amendment. In a study of the efficacy of different levels of poultry manure on the growth and yield of *Citrillus lanatus*, in Nigeria, it was observed that the application of poultry manure significantly enhanced growth parameters, vigor and number of fruits during two seasons (Dauda *et al.,* 2008).

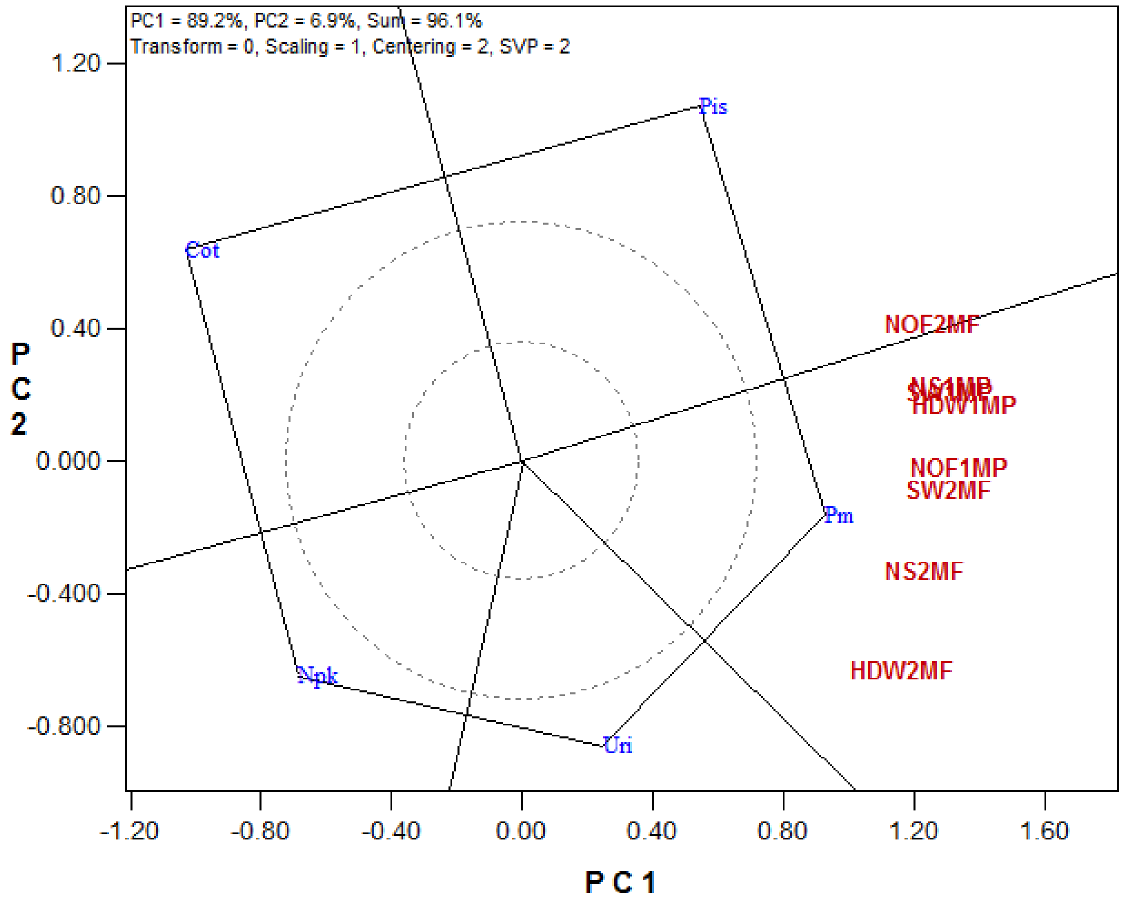

Fig 1: Bi-plot analyses of effect of fertilizer types on yield of moringa Pot and sole

CONCLUSION

The growth and productivity of *M. oleifera* could be subject to the application of organic and inorganic amendments to enhance their growth and productivity. Organic fertilizers mainly poultry manure, human urine and pig manure portrayed superiority in their morphological, physiological and yield performances compared to inorganic fertilizers (NPK 15:15:15) as well as control. Results obtained suggest that human urine could serve as a good substitute for nitrogen enriched chemical fertilizers in acidic soils because of its alkaline nature.

ABSTRACT

Jute mallow though an indigenous vegetable is now gaining more recognition especially because of its medicinal value. It therefore becomes imperative to give more attention to the production of the crop in an appropriate soil environment for it optimum yield. A field experiment was conducted at the experimental site of Federal College of Agriculture Moor Plantation Ibadan to determine the effect of different soil amendment on the growth and yield of Corchorus olitorius. Randomized complete Block Design was used for the experiment with four treatments replicated three times. The treatments used were Urea, NPK 15: 15:15, poultry manure all at the rate of 20 kg N /ha and no treatment. Parameters taken were plant height, number of leaves, leaf area and fresh weight of harvested Jute mallow. Result obtained showed that treatment had effect on plant height of jute mallow as from 5 weeks after sowing, (WAS) in which plants treated with poultry manure were taller than control although statistically similar with those of urea and NPK. Also, the plants responded positively to fertilizer application where poultry manure significantly gave higher value of leaf area (42.53cm²) which was comparable with those of NPK and urea but higher than the control (15.46cm²). Number of leaves were significantly higher with plants treated with urea at par with those of NPK and poultry manure while control had the least significantly. Urea produced the highest fresh weight of Jute mallow (1777.78 kg/ha) which was not significantly different from the plants treated with NPK and poultry manure while control has the lowest yield (188.89kg/ha). With the world campaign of organic food, this study recommends the use of poultry manure at the rate of 20 kg/N / ha for optimum production of jute mallow since it competes favourably with the use of urea and NPK.

Key words: Jute Mallow, Poultry Manure, Urea, fresh Weight, *Cochorous olitorius*

INTRODUCTON

Jute mallow an important leafy vegetable is found in wild and cultivated forms in many tropical countries of Africa and Asia (Schippers, 2000). The leaves are rich in minerals like calcium, glucose, Magnesium and Iron. It also contains high percentage of vegetable protein. It prevents anemia, and can be used as effective alternative drug to treatment of chronic cystitis, fever, gonorrhea and tumor (Gruben 2004). Jute fibre can also be gotten from the stem due to its strength, and durability (Edmunds 1990). The composition of *Corchorus olitorius* leaves per 100 g of fresh edible portion is: 80.4 g water, 58 kcal of energy, 4.5 g protein, 0.3 g fat, 12.4 g carbohydrate, 2.0 g, fibre, Ca 360mg, P 122mg, Fe 7.2 mg beta carotene 6410µg, thiamin 0.15 mg, riboflavin 0.53 mg, niacin 1.2 mg ascorbic acid 80 mg. the leaves also contains vitamins A, C, and E which are antioxidants and protects the body from degenerative diseases. Vitamin E slows down aches and pains associated with aging and increases stamina. (Leung et al. 1968). Jute mallow, being a leafy vegetable, require nitrogenous fertilizer for its vegetative growth and yield (Tisdale and Nelson, 1990). Jute requires 20 kg/ ha of N (Whitlock et al., 2003).

The use of inorganic fertilizer to increase the use of crops has been found to be effective as a short term solution which demands consistence use on a long term basis (Waswa et al., 2007). The composition and especially micro nutrient content of *Corchorus olitorius* are strongly influenced by external factors such as soil fertility and fertilization. Nitrogen fertilizer greatly improves the micro nutrient content especially that of Fe, P, Ca, carotene and vitamin C (Leung et al. 1968). On the other hand, organic waste has been seen as a viable alternative to chemical fertilizer since it has a long term productivity in soil conservation and improvement in soil fertility for sustainable food security (Akanbi, 2003).

Nitrogen is present in so many inorganic fertilizers in different proportions for instance, ammonium nitrate has NPK rating of 34-0-0, Urea on the other hand has an NPK rating of 46-0-0 (Bot and Benites, 2005). Therefore, looking at the appropriate source of nitrogen for the production of jute mallow becomes necessary. Also, the limitation of inorganic fertilizer and the effect it has on the soil makes it to become imperative to look at other sources of fertilizing the soil. This drive motivates this work which aimed at determining the effect of different soil amendment on the growth and the yield of jute mallow (*Corchorus olitorius*)

MATERIALS AND METHODS

Study area

A field experiment was conducted at Federal College of Agriculture, Ibadan South West of Nigeria (Latitude 7° 22°N; Longitude 3° 58"E and 275 m above sea level). The experiment was carried out in 2019 cropping season. After land preparation by ploughing and harrowing, the plot was marked out and site laid out in a randomized completely block design with four treatments replicated three times.

The experimental site was 13.5mx11m while the plot size was 3x3m^2 with 0.5m between plots and 1m between replicates. The treatments consist of four levels of zero application of fertilizer, urea, NPK, and poultry manure all at the rate of 20kg/ha. The poultry dung was applied a week before sowing; NPK and Urea fertilizer were applied two weeks after sowing. The quantity of each fertilizer used was based on the quantity of nitrogen (N) present in each material used as treatment. Urea has 46 % N so; 43.48 kg/ha was used. NPK contains 15% N, hence 133.33kg/ha was used. The quantity of N in the poultry manure was 0.0168 % hence 1190.76kg/ha was used. The seeds were sown by broadcasting.

Five plants were randomly sampled and tagged for observation for growth and yield parameters at 4, 5 and 6 weeks after sowing. The parameters taken were: plant height (cm), number of leaves, leaf area (cm^2), and fresh weight of *Corchorus olitorius* (kg).

Data collected were statistically analyzed using ANOVA to test the level of significance of treatments on the measured parameter and the significant means were compared and separated using Duncan Range Multiple Range Test (DRMRT) at 5% level of significance.

RESULTS AND DISCUSSION

The result of the pre cropping soil in table 1 showed that the soil is slightly acidic with a pH of 6.24, total Nitrogen is very low hence the soil needs more N for the production of the test crop, available Phosphorus of relatively okay, exchangeable bases are equally low. The nutrient composition of the poultry manure is shown in table 2 below and it was discovered that the nitrogen content was low.

Table1. Physical and Chemical Properties of Pre Cropping Soil

Parameters	Values
pH	6.24
Total carbon g/kg	1.57
Total nitrogen g/kg	0.157
Available Phosphorus mg/kg	10.63
Exchangeable Cation cmol/kg	
Sodium Na+	0.49
Potassium K+	0.31
Calcium Ca2+	2.90
Magnesium Mg2+	2.83
Exchangeable acidity H+ (cmol/kg)	0.10
CEC (cmol/kg)	4.63
Particle size distribution (g/kg)	
Sand	667.6
Clay	124.8
Silt	207.6
Textural class	Sandy loam

Effect of treatment on plant Height (cm), number of leaves, leaf area (cm^2) and fresh weight (kg) of *Corchorus olitorius*.

It was observed that at 5 and 6 WAS, treatment effect was significant on the plant height of *Corchorus olitorius* (table 3). Plants treated with poultry manure were significantly (<0.05) taller than zero application but were not statistically different from those treated with urea and NPK. This result underscores the fact that Jute mallow responds well to fertilization, particularly nitrogen (Ogunrindé and Fasinmirin, 2011).

Table 2: Chemical Properties of Poultry Manure

Properties	Value
Calcium (%)	4.20
Magnesium (%)	1.96
Potassium (%)	0.18

Copper (mg/kg)	28700
Zinc (mg/kg)	200
Manganese (mg/kg)	410
Total Nitrogen (%)	0.017
Phosphorus (%)	0.75
Iron (mg/kg)	4800

Table 3: Effect of different Soil amendment on plant height (cm), number of leaves and leaf area (cm²) of *Corchorus olitorius*

Treatment	4WAS	5 WAS	6 WAS
Plant Height (cm)			
Urea	12.35a	23.82a	29.93a
NPK	11.51a	20.99a	29.45a
Poultry	13.51a	24.09a	31.21a
Control	10.72a	19.70b	23.53b
Number of leaves			
Urea	12.50a	16.34a	19.00a
NPK	11.50a	15.66a	17.34a
Poultry	10.84a	15.5a	18.84a
Control	5.42b	9.17b	11.08b
Leaf area (cm²)			
Urea	6.80a	27.59a	36.53a
NPK	8.46a	28.08a	38.01a
Poultry	8.31a	27.81a	42.53a
Control	6.75a	14.63b	15.46b

Means followed by the same letter are not significantly different from each other at 5% level of probability using DMRT, WAS= weeks after sowing.

At 5WAS, *Corchorus olitorius* responded to the treatment applied with respect to the number of leaves produced in which it was observed that plants treated with urea produced the highest number of leaves which was at par scientifically with those treated with NPK and poultry manure but significantly (<0.05) different from those with zero application (Table 3). This also reconfirmed the role of nitrogen in promoting vigorous vegetative growth in leafy vegetables (Tisdale and Nelson, 1990).

Effect of treatment on leaf area of *Corchorus olitorius* revealed that at 5WAS, plants treated with NPK produced wide leaves which are statistically the same with those of urea and poultry manure but are significantly (<0.05) different from zero application. At 6 WAS, treatment of *Corchorus olitorius* with poultry manure produced plants whose leaves are wider (<0.05) than zero application but were at par with those treated with urea and NPK (Table 3). This also showed that nitrogen stimulates formation of new leaves and increases the size of plant. Other reseachers have also discovered that chicken manure contains basic nutrients required for enhancing growth and yield of crops (Sharpley and Smith 1991). Also, application of chicken manure increases carbon content, water holding capacity, aggregation of soil, and decreases bulk density (Egerszegi, 1990). Poultry manure also increases the water soluble and exchangeable potassium and magnesium which enhance crop yield (Jackson, 1999).

Table 4 showed the effect of treatment on the yield of fresh weight of *Corchorus olitorius*. It was observed that plants treated with urea produced yield which was significantly (<0.05) higher than that treated with zero application but was at par statistically with those treated with NPK and poultry manure. The reasons for increased leaves yield could be due to the increased solubilization effect of urea which makes the nitrogen available to the crop which could lead to the built up of sufficient food reserves for the developing sinks and better portioning towards the developing leaves. This result corroborates the work of Emuh (2013).

Table 4: Effect of different Soil amendment on fresh weight of *Corchorus olitorius* (kg/ha)

Treatment	Fresh weight (kg/ha)
Urea	1777.78a
NPK	1366.67a
Poultry	1388.89a
Control	188.89b

Means followed by the same letter are not significantly different from each other at 5% level of probability using DMRT, WAS= weeks after sowing.

CONCLUSION AND RECOMENDATION

The result of this study showed that *Corchorus olitorius* responded well to application of nitrogen fertilizer either in the organic or inorganic form. It was also discovered that, poultry manure, though with the least percentage of N in this study, produced the same result statistically with those of inorganic fertilizer. Application of poultry manure is therefore recommended in this study for optimum yield of *Corchorus olitorius* since it competes favourably with urea in yield and it is purely organic.

ABSTRACT

The cultivation of Pleurotus tuberregium with Guinea grass (Panicum maximum) in comparison to rice (Oryza sativum) without nutrient supplementation was investigated. The effect of straw type on mycelia growth, sclerotial yield, biological efficiency (BE) and nutritional quality were determined. Two types of straws, Guinea grass and rice straws were compared, Rice straw recorded higher sclerotia yield (81.63g) than the Guinea grass (75,32g). Days to substrate colonization and sclerotial initiation were shorter by by two and eleven days respectively. Mushroom yield () and BE () were higher on rice straw (). However, it was found out that from the proximate content (protein, fat, ash, potassium, sodium, phosphorus and zinc) were also higher in mushroom sclerotia harvested from Guinea grass than those obtained from the rice straw based substrate. Comparing the rice straw with the guinea grass, rice straw yielded about 4% more sclerotia under the same cultivation condition than Guinea grass.

Key words: *Pleurotus tuberregium,* ricestraw, guinea grass, yield and nutritional analysis

INTRODUCTION

Mushrooms are believed to be nature's gift for mankind, highly nutritious with high culinary value. Mushrooms are believed to be a bridge between plant and animal kingdom and believed not to be plant or animal. Their cell wall contains chitin instead of cellulose and they lack the green pigment (chlorophyll) as found in other green plants. The quality of their protein is equivalent to that of animal protein containing all the essential amino acids (Quimio *et al,* 1990). The medicinal value of mushrooms made them important in the modern day medicine as most species are medicinal. In recent times, people are now very conscious of their health and mushrooms being an health food, is gaining ground more than ever before (Adrock, 2019). This made it imperative to popularize its cultivation on readily available agro- industrial wastes in the country. Mushroom cultivation is becoming popular because of its low inputs; its cultivation can be highly profitable because of the tropical climate which is suitable for the cultivation of tropical varieties especially the oysters, shiitake reishi mushrooms (). Mushroom production can be profitably considered in areas where land is a limiting factor especially in the peri-urban and urban areas. Among the available mushrooms species that can be grown in Nigeria, is *Pleurotus tuberregium,* which can grow on a wide variety of agro-industrial wastes with considerable lignocellulose content. This work was undertaken because of the need to identify suitable and abundantly available growth media for the production of *P. tuberregium' Panicum.* Guinea grass (*panicum maximum*), also known as panic grass is a tropical pereniall turft grass that is rhizomatous at the base. It is used as forage for animals. It is usually found growing luxuriantly by the road sides abandoned farm lands especially in the rain forest belt of Africa. This study evaluates the productivity and nutritional quality of *P. tuberregium* on Guinea grass (*Panicum maximum*) in comparison to its growth and nutritional quality on rice straw (*Oryza sativum*).

MATERIALS AND METHODS

Pure culture of the mushroom (*P. tuberregium*) was obtained by tissue culture isolation from a young and healthy fruiting body which was placed on prepared potato dextrose agar (PDA) medium and incubated at room temperature for seven days to allow the fungal mycelium to grow out of the basidiocarp. This was subcultured into fresh PDA medium which was incubated and after it was fully ramified, it was refrigerated until needed (Raguphati *et al,* 2016).

Mother spawn was prepared by soaking sorghum seeds overnight. The soaked seeds were drained and filled in 200ml capacity bottles which were plugged with cotton wool, wrapped in aluminum foil. The prepared bottles were sterilized at 121^{0}C for fifteen minutes. After cooling down to ambient temperature (25^{0}C), The bottles were inoculated with the freshly prepared culture above to give the mother spawn. Sorghum seeds were prepared as outlined above, and were inoculated with the mother spawn to generate the planting spawn.

Substrate preparation

Luxuriantly growing Guinea grass were harvested, chopped into sizes of about 3-5cm and air dried. Rice straw was also collected from International Institute of Tropical Agriculture, Ibadan, Nigeria. These were also chopped (3-4cm) and dried. The chopped substrates were separately soaked and added with 1% calcium carbonate. These were stuffed into heat resistant polyethylene bags (300g/bag) held in place with polyvinyl rings and plugged with cotton wool with eacc treatment replicated seven times. The bags were pasteurized (70^0C for five hours), cooled overnight and inoculated with the freshly prepared planting spawn of *P. tuberregium* the following day. After inoculation, the bags were moved to the incubation room to allow for its vegetative growth. At the expiration of twelve weeks' incubation period, the fully ramified bags with balls of sclerotia of the mushrooms were opened and sclerotia were separately harvested from the bags and weighed. Some of the harvested sclerotia were dried and powdered for proximate content analysis.

The experimental design was a completely randomized design with seven replications. The following data were collected: mycelial growth/day, the number of days required for the initiation of scleroium, the number of days required for total harvest, sclerotial yield, and biological efficiency. The data were analyzed using the SAS statiscal package. Means were compared using Duncan's multiple range test. Biological efficiency was measured using the formula below:

Biological efficiency (%) = total sclerotial yield/ substrate dry weight × 100

RESULTS AND DISCUSSION

Optimum daily mycelia growth (0.71cm), shortest time required to complete mycelia colonization (28.33 days) and days to sclerotia initiation (64.67days) were observed on rice straw based substrate which are statistically higher than that obtained on Guinea grass, 0.60, 29.67, 75.33 respectively. Comparing the rice straw with the Guinea grass straw, the rice straw yielded about 8% more sclerotia (81.63g) than the Guinea grass (75.32%) This result was similar to earlier findings by Tupatler (2006) who reported higher oyster mushroom yield on rice straw than wheat. The biological efficiency also followed the same trend with higher efficiency on rice straw (66.63%) and lower (61.48%)on Guinea grass. (Table1).

Table 1: Effects of different straw types on growth and yield of *Pleurotus tuberregium*

Treatment	Mycelia extension/ day (cm)	Days to media colonization	Days to sclerotia initiation	Sclerotia yield (g)	Biological Efficiency (%)
Rice straw	0.71	28.33^{b}	64.67^{b}	81.63^{a}	66.63^{a}
Grass straw	0.60	29.67^{a}	75.33^{a}	75.32^{b}	$61..48^{b}$

This also agrees with earlier studies by Somashekha, *et al, (*2020) who evaluated different agricultural wastes including rice straw and guinea grass for mushroom cultivation. His results indicated higher mushroom yield and biological efficiency on rice straw than guinea grass. The nutritional quality of the mushroom's sclerotia harvested from Guinea grass based substrates were observed to be better interms of the macro nutrient contents. The most abundant of the macro-nutrients was potassium (Table 2).

Table 2: Macronutrient composition of *Pleurotus tuberregium* grown on rice and grass straw

Treatment	K (%)	Na (ppm)	Mg (%)	Ca (%)	P (ppm)
Grass straw	0.33^{a}	102.88^{c}	0.09^{b}	0.15^{b}	0.24^{a}
Rice straw	0.26^{c}	90.22^{d}	0.12^{a}	0.24^{a}	0.20^{b}

The proximate content (protein, fat ash and phosphorus) of the sclerotia harvested on guinea grass were found to be better than those from rice straw (Fig. 1). Zinc content was also more on scerotia from Guinea grass, the copper was comparable to that obtained on rice straw sustrate (Fig. 2).

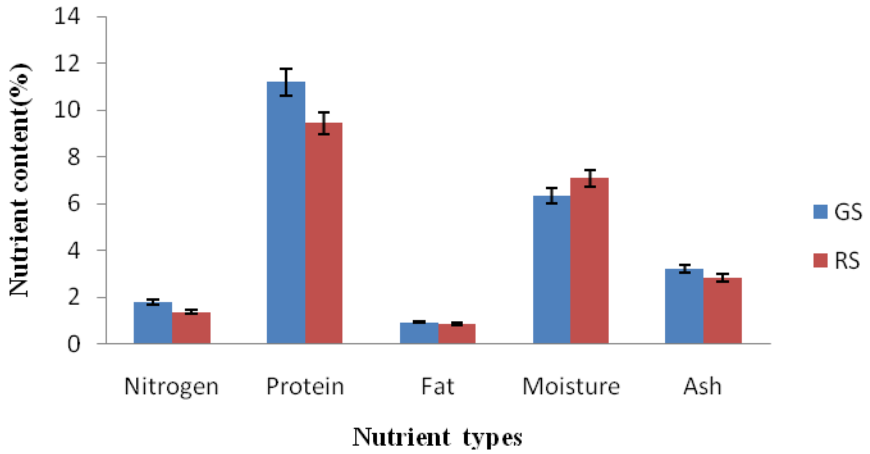

Fig 1: Proximate composition of *P. tuberregium* grown on rice and wheat straws

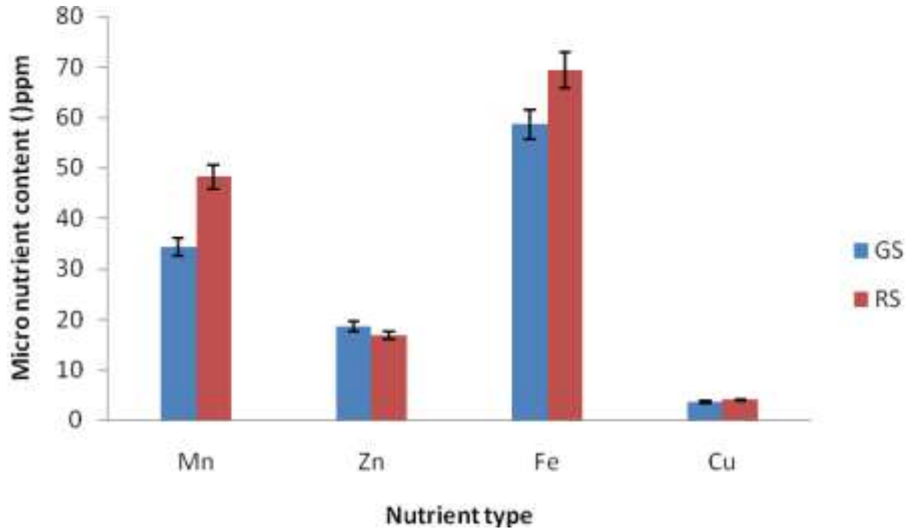

Fig 2: Micronutrient composition of *P. tuberregium* grown on different agricultural wastes

CONCLUSION

In conclusion, the major findings in this work indicated rice straw to be the best substrate for the cultivation of *Pleurotus tuberregium* in terms of mycelia growth rate, time required for substrate colonization, sclerotia yield and biological efficiency. The nutritional quality of mushroom harvested from Guinea grass were higher than those harvested from rice straw.

ABSTRACT

A study on the effect of different levels of pig manure and poultry litter at (0,5 and 10t/ha) was carried out at the Teaching and Research farm of the Plateau State College of Agriculture, Garkawa during the 2019 cropping season. Application of the organic manures had significant effects (P≤ 0.05) on the number of leaves, plant height, stem diameter, number of seeds per plant and seed yield t/ha. The use of poultry litter significantly increased seed yield (5.00 – 5.10 t/ha) compared to the control (0 t/ha). Hence application of 5t/ha of poultry litter and pig manure was recommended for optimum yield of millet in Garkawa.

Key words: Pig manure, Poultry litter, Millet, Garkawa

INTRODUCTION

Millet is one of the cherished drought resistant cereals in Nigeria (Aduna, 2011). Millet is grown extensively in Nigeria due to its low requirement for the major needed elements (Gupta, 2010). It is consumed fresh, roasted, boiled, sundried or pounded as "fura" "dambo" or fermented "Akamu" (Agbato, 2003). The production of millet in Nigeria is declining due to poor soils and unpredictable weather conditions (Badi 2019). While there is a decline in food production, particularly with staple crops like millet, the population of the country is increasing geometrically (Batino, 2004). This is basically due to land degradation and soil infertility. Use of organic manures is one of the ways of addressing this situation as they are cheap availability, within the reach of a common farmer, less toxic and with no negative effect on the environment. The objective of this study therefore is to look into the effect of pig manure and poultry litter on the yield of millet.

MATERIALS AND METHODS

The experiment was conducted during the 2019 cropping season at Garkawa (latitude and longitude east of the equator at the experimental and Research Farm of the Plateau State College of Agriculture, Garkawa. Pig manure and poultry litter at 0,5, and 10t/ha were used for the study. Millet seeds were obtained from National Seeds Council, Jos. The experiment was laid in a Randomized Complete Block Design with 3 replications. The land was harrowed and then ridged at 75cm apart. Intra-row spacing was at 20cm. weeding was done manually at 3 and 6 WAS. Similarly, other management practices like thinning, supplying, application were done according to Oduori, (2005). Growth and yield characters like plant height, number of leaves, stem diameter, number of heads, number of seeds and 1000 seed weight were taken. The data collected were subjected to Analysis of variance. Significant means were separated using least significant difference (LSD) as recommended by Gomez and Gomez, (1984).

RESULTS AND DISCUSSION

There was significant difference (P≤0.05) in plant height, stem diameter and number of leaves than the control (Tables 1-3). This could probably be due to the fact that poultry litter and pig manure contains all the available nutrients needed for the growth and yield of millet, which are readily available to crops. Camberdella (2004) reported that organic manures contain the essential elements required for the growth of cereals.

Similarly, organic manure had significant effect on yield characters like: Number of heads, number of seeds and 1000 seed weight (Table 4). This is probably because organic manures stay in the soil for a long period of time (Murray, 2008).

ABSTRACT

A field trial was conducted in Federal College of Horticulture Dadin kowa Gombe State to determine the effect of manure rates on growth and yield of two cucumber varieties during 2020 Wet Season in Dadin kowa. It consisted of two (2) varieties of cucumber (market more 76 and market more D.O.T) and four (4) levels of manure rates (0t/ha, 12t/ha, 18t/ha and 24t/ha). The treatment was combined in factorial and laid in a Completely Randomized Block Design (RCBD) with three replications making up a total of twenty-four plots. The plots size was 3x3 with 1m space between replication and 0.5m between plots. The result of the research showed that, there was no significant difference between the two cucumber varieties throughout the study period. On the other hand, the results for the manure rates had indicated that there were highly significant differences among the manure rates used for the study. It is clear that, the higher the rate the higher the performance on all the parameters measured (vine length, number of leaves, number branches, and fruit weight). However, it is suggested that similar research be conducted in the study area and other places to ascertain this fact.

Key words: Cucumber. varieties, vine

INTRODUCTION

Cucumber (*Cucumis sativus* L.) belongs to the family of Cucurbitaceae. It is ranked the eighth most grown vegetable crop around the world; after maize, sugar beet, cassava, tomatoes, watermelons, sweet potatoes, and dry onions (Edom 2017). It is an important vegetable that is cultivated globally. It has creeping vine that bears large leaves, which form canopy above the cylindrical fruits. In African including Nigeria, it is unranked probably due to inadequate production volume when compared to other European countries Ume 2017). It is cultivated in almost all the agro-ecological zones of Nigeria ranging from coastal to savannah zones. The savanna zone of Nigeria has the greatest potential for its production due to moderate rainfall. However, research has proved that it can grow in some southern parts of Nigeria that had moderate rainfall (Enujeke 2013). The importance of cucumber to mankind can be categorized into three namely: food, medicine and industry. Like food, it is either eaten raw or prepared in various forms especially as components of the vegetable salad. In medicine, it is used to fight against cancers (breast-ovarian, uterine and prostate); treatments for diabetics, skin irritations; rehydrate the body and regain one's self from dryness (Omeh 2017 and Shetty. 2002). Its benefits concerning other health and medical conditions are widely documented (Olorun; 2017, Holmes 2000 and Edom 2017) noted that it is important in cosmetic industry for the manufacture of soaps, lotions, shampoos and fragrant. Three major cucumber varieties widely grown are slicing, pickling, and burpless (Wikipedia. 2017). However, there are different cultivars found in the market globally, and they emanate from these three major varieties (Wikipedia. 2017). Despite the importance of this vegetable crop, lack of specific rate of sheep and goat manure and high cost of inorganic fertilizer had constituted a major constraint to its production in the study area. Therefore, this study was conducted to with objective in mind to determine the effect of different rate of sheep and goat manure on growth and yield of cucumber and also to determine the best variety of cucumber in the study area for recommendation to the farmers

MATERIALS AND METHODS

Site Characteristics

The experiment was conducted at Teaching and Research Farm of Federal College of Horticulture Dadinkowa, Gombe State. The area lies approximately 260 m above sea level is located between latitude 10°15' North and longitude 11°15' East. The climate of the area is semi-arid zone, which is characterized by a wet and dry season. October to March is the major dry season. The mean annual rainfall is 1,500mm and the mean temperature is 35°C. (URBDA,2015)

Treatments and Experimental Design

The experiment consisted of two factors: variety (Market more 76 and Market more D.O.T) and the manure rates (0t/ha, 12t/ha, 18t/ha and 24t/ha). The two factors and their levels gave 8 treatment combinations which were laid out in a randomized complete block design (RCBD) and was replicated three times.

The land was cleared and harrowed twice to obtain a fine tilth. Beds were marked out using a measuring tape, rope and pegs. Each plot measured 3 x 3m (9m^2) in size with a distance of 0.5m between the plots and 1m between replicates. Six plots were obtained in a replicate, given a total of 18 plots. Before sowing the crop, soil samples were taken in a "Z" shape within the experimental area following the procedure of IFDC (2003) at a depth of 0-30cm using a tubular auger.

The plants were sown at the rate of three to four seeds per holes at a spacing of 30cm by 0.5m. Weeds were controlled at regular intervals after planting. The crops were staked and insecticide was also applied to control insect pest. Data was collected on vine length, number of leaves, number of branches, number of flowers, fruit and weight of fruits. All the data collected were subjected to analysis of variance (ANOVA) using Genstat statistical package and least significant difference (LSD) was used where there was significant difference to separate the means.

RESULTS AND DISCUSSION

The result in Table 1 indicated that there was no significant difference ($P< 0.05$) between the two cucumber varieties used throughout the study period on all the characters measured. This might be due to similarities of varieties in term of morphology, nutrients and environmental requirement of the crop. The results corroborate with the findings of Imran *et al*., (2017) who work on six varieties of cucumber at the Department of Horticulture, Rajasthan College of Agriculture, Maharana Pratap University of Agriculture and Technology, Udaipur, Rajasthanand and found that, there was no significant different between the varieties used. The manure rates on the other hand indicated a significant difference throughout the growing period on all the characters measured. This had indicated the importance of organic manure in term of growth and yield of cucumber. The result is in line with the findings of Funch *et al*., (1998) who reported that vine length increased to addition of organic matter. The result had also corroborated with the findings of Abdulkadir *et al.,* (2020) and Henry (2000) whose all reported that, the application of sheep and goat manure significantly ($P>0.5$) increased the number of branches per plant over the control. Similarly, this finding is in line with the findings of Jilani *et al.,* (2009), Ayooba and Adeniran (2006) and Deksissa *et al.,* (2008) who reported that increase in manure rate can lead to increase in cucumber yield.

CONCLUSION

It could be concluded that application of organic manure to Dadin kowa soils can be sustain and enhance cucumber production especially 24t/ha. This is similarly applicable not only to Dadin kowa land but other areas with similar soil types.

ABSTRACT

Cucumber (Cucumis sativus L.) is a widely cultivated plant which belongs to the family Cucurbitaceae (gourd family). It is an annual, creeping vine that grows up on trellis or other supports, wrapping around them with thin, spin tendrils. The objective of this study was to evaluate the growth and yield of cucumber in response to varying combination ratio of two plant based fertilizer. The plant based organic fertilizer (Tithonia diversifolia leaves and Azardirachta indica leaves) collected at NIHORT Research farm Ibadan, Oyo state, air dried and milled separately into powder form, different ratios were weighed for each organic fertilizer, combined and incorporated into the soil 2 weeks before planting. The experiment was laid out in a factorial arrangement fitted into randomized complete block design with three replicates. The trial consisted of 2 varieties of cucumber (Marketer and Market more) and 6 treatments comprising Mexican sunflower and Neem leaf at combination of 100%T + 0%N, 75%T + 25%N, 50%T + 50%N, 25%T + 75%N, 0%T + 100%N and Control (no plant extract) making 12 treatments. Results obtained showed that all the growth and yield parameters measured were significantly influenced by application of the fertilizer, significant differences (P <0.05) was observed among the cucumber varieties. Fertilizer combined at 25%N + 75%T applied to marketer had significant (p <0.05) effect on yield components of cucumber. However, application of 100%T significantly (P <0.05) produced the highest fruit yield (14.65 kg).

INTRODUCTION

Soil fertility depletion among the small holder production in Africa is one of the causes of the reduction in per capita food production. Tanimu *et al.* (2007) reported that shortage and high cost of inorganic fertilizers have limited its use among small holder farmers in Nigeria. To this Ogbonna (2008) reported that organic fertilizer contributes to the increase in yield of crop by up to 80% as this also depends on the rate of application of the organic fertilizer. Also the use of organic manures on agricultural lands has been reported to have great advantages in nutrient recycling, improving soil structure and promoting biological activities of the soil which in turn improves the overall soil health, enhance the growth and productivity of the crop (Arisah *et al*., 2003). Idem *et al*. (2012) has it that sometimes, application of organic manure serves as an alternative practice to inorganic fertilization and this in turn improves the soil structure. In most tropical soil, organic manure has been known to become the determinant for improving soil fertility (Ikpe and Powel, 2002; Uwa, 2013). However, the increasing demand and consumption of cucumber has become quite necessary to identify potential plant materials as alternatives to inorganic fertilizer. The trial was done to assess the influence of Neem and Mexican flower organic manures as soil amendment on growth, yield and yield component of cucumber.

MATERIALS AND METHODS

A field trial was conducted between September and November 2018 at the Vegetable Research Farm of National Horticultural Research Institute (NIHORT), Ibadan, Oyo state located in the rain-forest agro-ecological zone ($7^{0}33^{1}$N and $3^{0}56^{1}$E 168 m above sea level). Mexican sunflower leaves [*Tithonia diversifolia (*Hemsl.) A. Gray] and neem [*Azardirachta indica* A. Juss] were air dried and milled separately as each treatment was weighed at 100% (2kg), 75% (1.5kg), 50% (1kg), and 25% (0.5kg) which was combined at different ratios for varying combinations these was incorporated into the soil and left for 2 weeks to decompose before planting. The experiment comprised of twelve (12) treatments laid out in a factorial arrangement and replicated three times. The field was disc-ploughed twice, harrowed and sprayed with systemic herbicide force-up (a.i glyphosate) at the rate of 250 ml to 18 liters of water using a knapsack sprayer before planting two weeks after. Plot size was 2m x 2m ($4m^2$) while the experimental field size was 17m x 17m ($289m^2$). Boarder was raised at the sides of each plot to avoid washing away of the treatments by rainfall. Seeds of two cucumber hybrids; (Marketer and Market more (Technisem company) were planted at a spacing of 50cm x 50cm giving rise to 25 plants per plot with a corresponding population of 1156 plants. Weeding was carried out manually with hoe at 3 and 6 weeks after sowing, vines were staked using bamboo tree cuttings at 4 weeks after sowing. Data collected included: plant height (cm), leaf area (cm), stem diameter (cm), number of leaves per plant while at harvest fruit yield, fruit length (cm) and fruit weight (g) were determined. The data were subjected to analysis of variance, and where appropriate, means separated using Duncan multiple range test

RESULTS

The varietal differences were observed as marketer performed better than market more. Also among the organic fertilizer used, it was observed that 100% Tithonia (T) significantly (P <0.05) influenced the Leaf Area, stem diameter, number of leaves, fruit width and the fruit yield of cucumber (Table 1). However, 75% T and 25% N also significantly (P <0.05) influenced plant height (67.86 cm), LA (129.12) stem diameter (7.2 cm), though this was not significantly (P <0.05) different from 100%T and fruit width (44.2 cm) in table 1. Also the performances of the varieties on the organic fertilizer showed that marketer performed better with organic fertilizer than the marketmore (Fig 1). The interaction effect of the varieties against the organic manure on yield components and yield of cucumber shows that marketer significantly (P <0.05) performed better than marketmore (Table 2). The use of 100%T on marketer showed that it influenced the stem diameter (7.8 cm), number of leaves (23) and fruit width of cucumber (49.60 cm). while 25%T x 75%N significantly (P <0.05) produced the highest fruit yield (20kg) of marketer. Also from table 2 it showed that with marketmore under the organic manure combination with 100%N it influenced the stem diameter of cucumber (7.44 cm) though this was not significantly (P <0.05) different from 100%T, 57%T + 25%N, 50%T + 50%N with marketer and 100%T, 75%T + 25%N with marketmore. Also in it was observed that 100%T with marketmore gave significantly (P <0.05) higher fruit yield (11.23 kg) when compared with other combinations with market more.

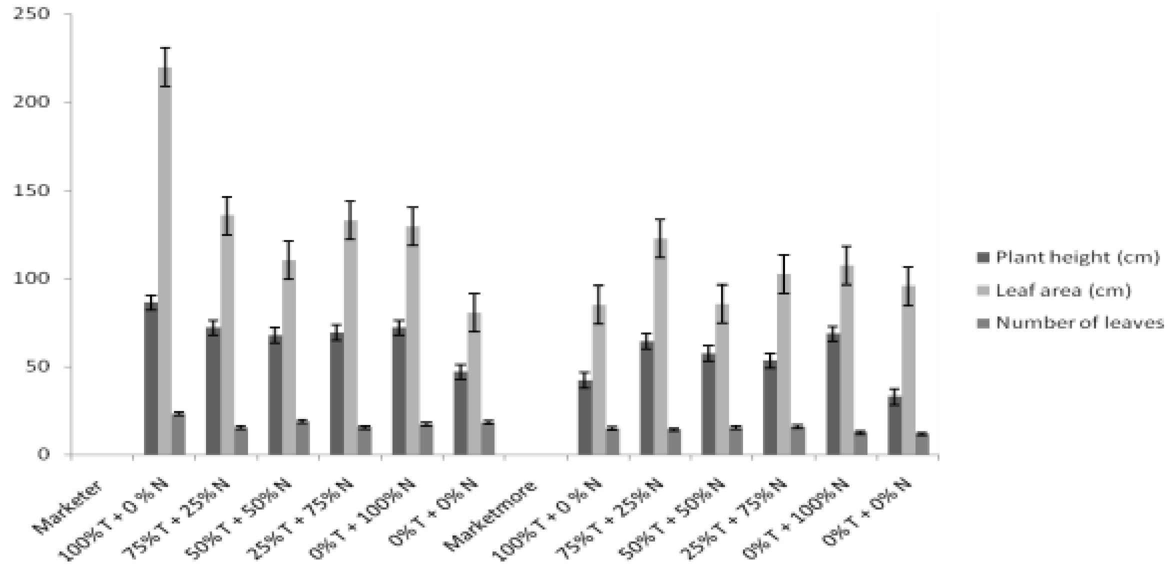

Figure 1: Interaction effect of Neem and Mexican Sunflower manure on the growth of cucumber

DISCUSSION

Neem leaves as manure could be used for the preparation of vermin-compost having both fertilizer and pesticidal potential (Oyekunle and Abosede, 2012). This is in agreement with our finding as 25%T and 75%N as organic manure had significant (P <0.05) influence on the fruit yield of cucumber. However, it was observed that the complete usage of Mexican sunflower gave higher fruit yield than when mixed with 25% Neem and when 50% of each was used. This is also in line with the finding of James *et al.* (2000) who reported that Mexcan sunflower can increase the yield of crops. With the findings of the trial it has shown that its use as green manure can increase the production of vegetable crops as it will maintain soil moisture, fertility and productivity. Lokanadhan *et al.* (2012); Oyekunle and Abosede (2012) also reported that neem leaf manure is gaining popularity amongst small holder farmers in Nigeria as this is because it is observed to be environmentally friendly, has pesticidal potential and could increase the nitrogen and phosphorus in the soil. The result has shown that plant products are non-polluting, less toxic and biodegradable with no hazardous residues in the soil, water and air. Generally, the response of the crops showed that the soil responded better when the organic manure was applied (Moyin-Jesu *et al.,* 2012), as this corresponded with our findings as better performance of cucumber treated with the organic manure in the field against zero plots. Also the trial is in support with the reports of Schipper (2000) and Awodun (2007) that the application of organic manure significantly influenced the growth and yield of fluted pumpkin.

ABSTRACT

An experiment aimed at determining the organic fertilizer rate that will optimize growth and yield of two cultivars of long cayenne pepper was carried out at the National Horticultural Research Institute (NIHORT), Ibadan between 2007 and 2008. The experiment was a 2 × 4 factorial arrangements in RCBD with three replications comprising of two pepper cultivars (NHV-1A and NHV-1F) and four rates of Tithonia compost (0, 45, 90, 135 kg N/ha). Seedlings were transplanted six weeks after sowing at a spacing of 0.5 m × 0.5 m. Five plants were randomly selected and tagged for data collection on growth, yield and yield components. Data collected were subjected to analysis of variance and significant means were compared with LSD (P< 0.05). Results from this study showed that no significant difference existed between the accessions of pepper used in terms of plant height but there was significant difference in terms of number of leaves, branches and leaf area. Varying rates of tithonia compost significantly affected growth of long cayenne pepper. Number of leaves and leaf area decreased with decreasing rate of tithonia compost. Tithonia compost significantly affected fruit yield and yield components of long cayenne pepper except mean fruit weight. Long cayenne pepper with tithonia compost application rate of 90 kgN/ha had significantly higher number of fruit/plant, fruit weight/plant and fruit yield (158, 790.3 g and 30.25 t/ha respectively). It can then be concluded that for optimum performance of long cayenne pepper 90 – 135 kg N/ha from Tithonia compost organic fertilizer should be applied.

INTRODUCTION

Pepper production and its consumption have consistently increased annually worldwide dating back to the 20 century because of its importance as vegetable, spice and industrial raw materials (Wien, 1997). Pepper is usually cultivated as annual vegetable crop all over the world, but it grows and yields better in the tropical region of the world. Pepper forms a major integral part of our daily diet and a vital component of stew and soup consumed by all and sundry in Nigeria. Pepper fruits are consumed fresh, processed or dried (Grubben and El-Tahir, 2004). Pepper production requires high level and readily available soil mineral nutrients for optimum growth and yield. The primary nutrients considered essential for optimum growth and yield of pepper species includes nitrogen, phosphorus and potassium (Grubben and El-Tahir, 2004). All these nutrients listed are inherently low in tropical soils as a result of low organic matter content, especially in Nigeria. However, this can be improved through some agricultural practices such as application of fertilizers among others. Inorganic fertilizers are costly (especially to the low resource farmers), not easily accessible and often unavailable at critical time when it is most needed couple with the fact that the negative environmental effect limits it use. Moreover, the application of inorganic fertilizers could not replenish soil micro nutrient that often become depleted by growing crops consequently causing reduction in the crop productivity and yield (Sikora and Szmide 2001).

The nutrients content in various organic fertilizers are released gradually unlike inorganic fertilizers; make nutrients available in every developmental levels of pepper. In the recent time, farmers use organic fertilizers because of the potential advantages ascribed to organic based fertilizers. Moreover, some of the inorganic fertilizers applied are absorbed by plants while the left over dissolved into the environment (surface water, atmosphere and ground water) as pollutants, affecting the ecosystem. Organic wastes that exist in Nigeria varied from domestic waste, industrial waste to farm left overs (plant and animal residues) (Adediran *et al.* 2003). Organic fertilizers have been reported to improve soil structure, enhance long-term productivity as well as plant biodiversity and provide essential nutrients to plant, leading to better quality of plant and fruits, especially of *Capsicum annuum* (Enwall *et al.,* 2005; Alabi, 2006). The objective of this study was to determine the organic fertilizer rate that will optimize growth and yield of two cultivars of long cayenne pepper.

MATERIALS AND METHODS

This study was conducted at the National Horticultural Research Institute (NIHORT), Idi-Ishin, Jericho, Ibadan (7° 33´ N; and 3° 56´ E 168 m above sea level) between 2007 and 2008. The site, lies within savannah: forest transition ecology of Nigeria. Pre-cropping soil sample was randomly taken at the depth of 0-15 cm for the analysis of its physical and chemical properties. Seeds of the two accessions of the two long cayenne pepper cultivars (NHV-1A and NHV-1F) used in the study were high yielding and early maturing cultivars developed in NIHORT. Nursery trays were filled with sterilized and sieved, well mixed component of organic manure, rich virgin soil and gutter sand devoid of pebbles in a proportion of half top soil, one quarter manure and one quarter gutter sand. (NIHORT, 1986). Seeds of the two cultivars were sown in separate trays and watered once daily for the first 14 days, and once in two days thereafter till the time of transplanting at six weeks after sowing (WAS).

The experiment was a 2 × 4 factorial arrangements in RCBD with three replications comprising of two pepper cultivars (NHV-1A and NHV-1F) and four levels of Tithonia compost (0, 45, 90, 135 kg N/ha contained in 0, 2.81, 5.6, 8.43 t/ha respectively) of the compost material. Each replicate consisted of eight plots of 3 m × 2 m (6 m^2) each resulting in total experimental area of 23 m × 13 m (299 m^2). The plots were 1 m apart while replicates were separated 2 m apart. Vigorous and healthy seedlings of the crop were transplanted at one plant per stand using a distance of 0.5 m × 0.5 m which was equivalent to 40,000 plants per hectare. Tithonia based compost fertilizer were applied to each plot one week before pepper seedlings were transplanted. Weeding was done by hoe weeding and harvesting of ripe fruits was carried out twice a week. Five plants were randomly selected and tagged for data collection on plant height (cm), number of leaves, branches, stem diameter (cm), leaf area (cm^2), mean fruit weight (g), fruit diameter (cm), fruit length (cm), number of fruits/plant, fruit weight/plant (g), number of seeds/fruit, 1000 seed weight (g) and fruit yield (t/ha). Data collected were subjected to analysis of variance and significant means were compared with LSD ($P< 0.05$). Leaf area was calculated using linear regression equation estimator model $Y = 0.60 \times L \times B$ (where Y = leaf area, L = leaf length from apex to base and B = leaf breath at the widest part) (Salau *et al.,* 2008).

RESULTS AND DISCUSSION

Results from this study showed that no significant difference existed between the accessions of pepper used in terms of plant height but there was significant difference in terms of number of leaves, number of branches and leaf area. NHV-1F had significantly higher number of leaves than NHV-1A while NHV-1A had significantly higher number branches and leaf area than NHV-1F (Table 1). Furthermore, varying rates of tithonia compost significantly affected growth of long cayenne pepper used in this study. Plants with application of 45 kg N/ha significantly increased in height than 0, 90 and 135 kg N/ha. Moreover, plants treated with 45 kg N/ha produced the tallest plants followed by those treated with 135 kg N/ha and 90 kg N/ha (Table 1).

Number of leaves and leaf area decrease with decreasing rate of tithonia compost in order of 130 kgN/ha > 90 kgN/ha > 45 kgN/ha > 0 kgN/ha (Table 1). Number of branches per plant increased with increase in fertilizer rates except that the effects of 135 kg N/ha and 90 kg N/ha were not significantly different. Fertilizer rates of 135 kg N/ha, 90 kgN/ha and 45 kg N/ha were significantly better than the control while the least occurred when plants were not fertilized (Table 1).

The long cayenne pepper accessions used in this study were significant different from each other only in terms of fruit length, fruit diameter and number of fruits per plant while no significant difference existed among the pepper accessions in terms of 1000 seed weight, fruit weight per plant, mean fruit weight and fruit yield. Accession NHV-1A produced significantly thicker and longer fruits than accession NHV-1F while accession NHV-1F produced significantly higher number of fruits per plant than NHV-1A (Table 2). Tithonia compost significantly affected fruit yield and yield components of long cayenne pepper except mean fruit weight (Table 2). Fruit diameter and fruit length increase with increasing rate of tithonia application in the order of 0 kgN/ha < 45 kgN/ha < 90 kgN/ha < 135 kgN/ha. There was no significant difference in the 1000 seed weight of long cayenne pepper with tithonia compost application at any of the rates used but all these produced fruits with significantly higher 1000 seed weight than those with no tithonia compost application (Table 2). Long cayenne pepper with tithonia compost application rate of 90 kgN/ha had significantly higher number of fruit/plant, fruit weight/plant and fruit yield (158, 790.3 g and 30.25

t/ha respectively) than pepper with other rates of tithonia compost application and those without application of tithonia compost. Pepper without application of tithonia compost had the least number of fruit/plant (114), fruit weight/plant (595.7 g) and fruit yield (21.23 t/ha) while no significant difference existed between pepper with no application of tithonia compost and those with 45 kgN/ha in terms of fruit weight/plant and fruit yield. Roy *et al*. (2011) observed that length of fruit and breadth, and average fruit weight of pepper respectively increased with organic fertiliser rates to 100 and 150 kg N/ha. Additionally, this could be a pointer that high rate of tithonia based organic fertiliser may be needed for pepper growth and yield in soils used. Kathrin *et al*. (1998) recommended the use of high organic fertiliser rates on tropical soils for high performances of crops due to poor nutrient status of the soils.

CONCLUSION

Tithonia compost fertilizer at 90 kgN/ha and 135 kgN/ha gave similar but significantly higher pepper yield than other lower fertilizer rates. Hence, 90 kgN/ha is recommended for economics of production of the long cayenne pepper used in this study. It is concluded that for optimum performance of long cayenne pepper 90 – 135 kg N/ha from Tithonia compost organic fertilizer should be applied.

ABSTRACT

A field experiment was conducted at National Horticultural Research Institute, Ibadan to evaluate the influence of integrated nutrient management on growth performance of African breadfruit seedlings in the orchard. The treatments consisted of (1) NPK I5:15:15 (0.45 t/ha), (2) Compost (15 t/ha), (3) Sawdust (25 t/ha), (4) Plastic mulch (1,632 kg/ha), (5) NPK + Compost, (6) NPK + Sawdust, (7) NPK + Plastic mulch, (8) NPK + Sawdust + Plastic mulch, (9) NPK + Compost + Plastic mulch, (10) Control (No fertilizer application). These treatments were applied to the transplanted seedlings at three Months After Transplanting (MAT). The experimental design was Randomized Complete Block Design (RCBD) in three replications. Data were collected on plant height (PH), number of leaves (NL), and weed dry weight (WDW). Data collected were analysed using descriptive statistics and ANOVA at $\alpha_{0.05.}$ *Results obtained revealed that, significantly taller plants above 2m was recorded from plots treated with NPK+sawdust+plastic mulch, sawdust, and NPK+compost, while the shortest plant was recorded from plots treated with NPK+compost+plastic mulch. Highest NL (105.3) was observed from plots treated with NPK+sawdust+plastic mulch and was not significantly different when compared with other treatments. The WDW ranged between 40.0 g/m2 (plastic mulch) to 180 g/m2 (sawdust). However, plastic mulched plots recorded the least WDW, which was significantly lower when compared with other treatments. Combination of appropriate and compatible different nutrient sources enhanced the growth performance of african breadfruit in the orchard.*

INTRODUCTION

African breadfruit, the nutritious fruit is an energy-rich food, high in complex carbohydrates and rich in dietary fibre, Ca, K, Mg, thianin and niacin. Some varieties are also a good source of antioxidants and carbohydrates. A balanced fertilizer programme can add to soil fertility and prevent nutrient deficiencies and excess stress during the growing season. Using conventional NPK fertilizer and organic fertilizer reduce nutrient leaching, which often takes place in time of high rainfall. The most economically important product of the breadfruit tree is the fruit which is a nutritious, high energy food. A 100g edible portion of boiled breadfruit flesh provides 114 kcal, mainly from carbohydrates, 4.9g of dietary fibre, and appreciable amount of minerals such as calcium, the B vitamins and essential fatty acids. Breadnut seeds are also nutritious because they have a high content of both carbohydrate and approximately 8g fat, 17g protein, 3.2g dietary fibre and useful amounts of minerals, including potassium and phosphorous (Breadfruit Production Guide FAO, 2015).

With the view of an increase in land scarcity and water shortage, most of the agriculture plans depend on the use of chemical fertilizers and the production of new high-yielding crop varieties. Yet, both components are much expensive and do lead to higher pressure and more responsibilities for the financial investments and consequently lead to an increase in the total costs. Meanwhile, the price of fertilizers increases, year by year, due to the higher amount of fertilizers needed in the second and third seasons as compared with that in the first season to maintain the current yield production at economical level.

Integrated nutrient management (INM) is a scheme that refers to a safest way to dispose off crop residues and produce high-quality compost by a balanced and integrated use of both sources of fertilizers together in combinations (organic and inorganic fertilizers) for maintaining soil fertility and providing plants with an optimum level of nutrients required over all of cycle life to sustain the yield productivity. The key component of the INM goal is to reach the most effective and homogeneous combination that could lead to good management and be an effective target of the fertilizers, sufficient and balanced use of their quantity and quality, and be straightforwardly up taken by plants for higher yield without jeopardizing soil native nutrients or polluting the environment. It is ultimately viable to achieve such a target through the wise application of integrated nutrient management (INM) approach, which is known as a balanced mixture of organic, inorganic, and bioorganic microorganisms in combinations in different practices (Janssen, 1993).

Moreover, application of inorganic fertilizers is not a pragmatic option for many poor farmers in different regions worldwide, because many poor farmers do not have enough money to pay the claim of fertilizer price, besides its scarcity and unavailability in times of need.

Integrated nutrient management is also described as the technique of using minimum effective dose of suffcient and balanced quantities of organic and inorganic fertilizers in combination with specific microorganisms to make nutrients more available and most effective for maintaining high yields without exposing soil native nutrients and polluting the environment. Furthermore, many benefits can also be gained from using integrated nutrient management. INM can act as the driving forces, able to support the plans of converting marginal lands into productive ones, therefore fulfilling the strategy agenda of increasing cultivated land.

Furthermore, integrated nutrient management is a tool which can offer good options and economic choices to supply plants with suffcient amounts of most macro- and micronutrients and also can reduce the dose of chemical fertilizers, create favourable soil physiochemical conditions and healthy environment, eliminate the constraints, safeguard the soil nutrient balance in the long run to an optimum level for sustaining the desired crop productivity, and find safety methods to get rid of agriculture wastes (Selim and Al-Owied, 2017; Selim, 2018)

Therefore, it is inevitable to properly manage the nutrient balance and weed infestation in breadfruit orchards in order to protect the trees from nutrient in-balance and competition with persistent/pernicious weeds. More so, there is dearth of information on performance of breadfruit trees to different nutrient sources. It is against this background that this study was proposed. Therefore, the objective of this study is to determine the influence of different nutrient sources on the growth performance of juvenile african breadfruit trees in the orchard.

MATERIALS AND METHODS

The study was conducted at National Horticultural Research Institute (NIHORT), Ibadan, N7°24ꞌ23.50872ꞌꞌ LAT, LONG E3°50ꞌ32.08884ꞌꞌ LONG 213 meters above sea level, Ibadan lies in the derived savannah of South west Nigeria. The area is characterised with bimodal rainfall distribution, which peaks in July and September. The early rains occur between April and July, while the late rain occurs from September to November. The soil in the experimental area belongs to the main soil series of Egbeda, Olorunda, , Iwo, Makun, Etioni and Iregun (Smyth and Montgomery, 1962). They are classified as Alfisols (Soil Survey Staff, 1990) and Lixisols (FAO/UNESCO, 1986).

The treatments consisted of (1) NPK I5:15:15 (0.45 t/ha), (2) Compost (15 t/ha), (3) Sawdust (25 t/ha), (4) Plastic mulch (1,632 kg/ha), (5) NPK + Compost, (6) NPK + Sawdust, (7) NPK + Plastic mulch, (8) NPK + Sawdust + Plastic mulch, (9) NPK + Compost + Plastic mulch, (10) Control (No fertilizer application). These treatments were applied to the transplanted seedlings at three Months After Transplanting (MAT). The experimental design was Randomized Complete Block Design (RCBD) in three replications. Data was collected on plant height, number of leaves, number of branches, collar diameter, and weed dry weight. The treatments were applied once in a year and repeated in the second year. All data collected were subjected to SAS programme using Analysis of Variance, and the means were separated using Duncan Multiple Range Test (DMRT) at ($p<0.05$) probability level.

RESULTS

Breadfruit plots treated with NPK + Sawdust + Plastic mulch recorded significantly taller plants of 2.1m. This was significantly higher when compared with other treatments. The plots treated with NPK + Compost and plots treated with NPK + sawdust produced similar results (1.5m) which was not significantly different from each other. The least plant height (0.7m) was recorded from plots treated NPK during the first cropping season. At the second cropping season, taller plants above 2m (208.7m, 206.3m, 204.7m) were recorded NPK + sawdust + plastic mulch, sawdust and NPK + compost respectively. Breadfruit trees with the shortest height was recorded from plots treated with NPK + compost + plastic mulch. This was not significantly different from other treatments (Table 1).

Table 1: Effects of integrated nutrient and weed management on growth parameters and weed dry weight in juvenile african breadfruit orchard

Treatments	PH 1	PH 2	NB 1	NB 2	WDW
NPK 15:15:15	0.7d	120.7a	4.0a	8.7bc	150.0a
Compost	1.6ab	68.0a	8.7a	18.0a	156.7a
Sawdust	1.4abc	206.3a	8.4a	13.0abc	180.0a
Plastic mulch (PM)	1.0bcd	149.7a	9.0a	10.7abc	40.0c
NPK + Compost	1.5abc	204.7a	10.3a	12.7abc	143.7ab
NPK + Sawdust	1.5abc	195.3a	4.8a	23.7a	126.7ab
NPK + PM	1.3bcd	190.3a	7.3a	7.0bc	86.7bc
NPK + Sawdust + PM	2.1a	208.7a	11.0a	10.7abc	85.0bc
NPK + Compost + PM	0.8cd	119.3a	7.3a	9.7bc	63.3c
Control	1.4abc	128.3a	9.7a	13.0abc	126.7ab

Means followed by the same letter in a column are not significantly different by DMRT at ($p<0.05$)
PH = Plant height. NB = Number of branches. WDW = Weed dry weight.

Significantly more branches (11.0) was recorded from plots treated with NPK + sawdust + plastic mulch and this was not significantly different from other treatments, while plots treated with NPK 15:15:15 recorded the least number of branches during the first cropping season. during the second cropping season, a significantly higher number of branches (23.7) was observed from plots treated with NPK + sawdust, while the lowest was recorded from plots treated with NPK + plastic mulch (Table 1). Highest number of leaves (105.3) was recorded from breadfruit plots treated with NPK + Sawdust + Plastic mulch and was not significantly different from other treatments and the control (Figure 1). No significant difference was observed among the treatments for collar diameter (Figure 2). The observed increase in the height of trees can be attributed to the synergistic relationship, slow release of nutrients, availability and eventual uptake by the trees. The usage of compost and sawdust conserves moisture and the nutrients therein while, the plastic mulch prevents leaching and volatilization.

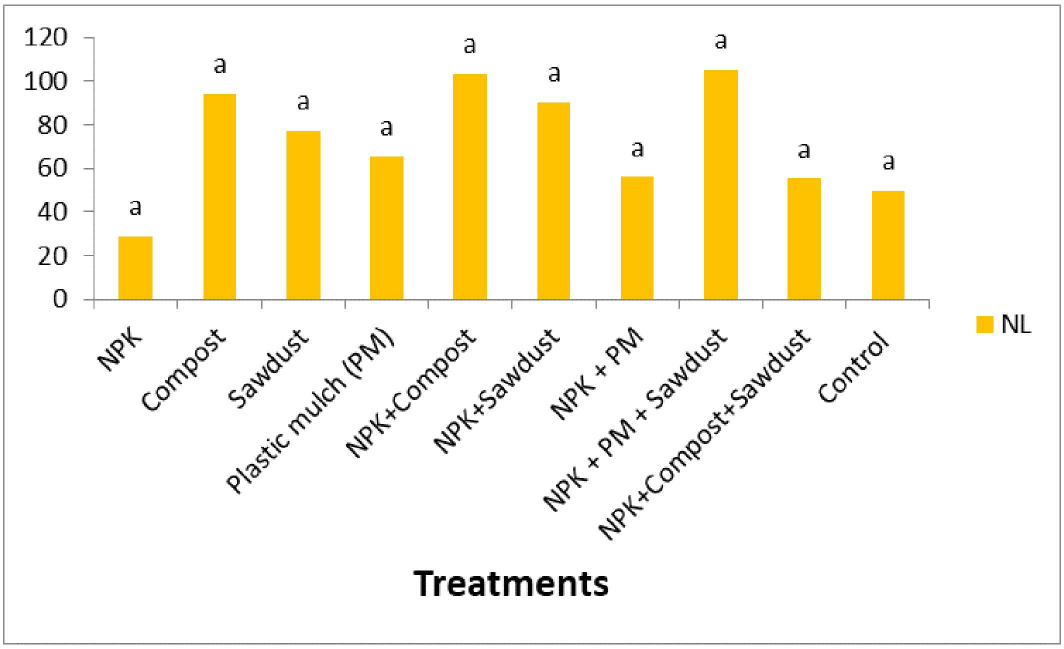

Figure 1: Effects of integrated nutrient management on number of leaves of juvenile breadfruit trees in the orchard

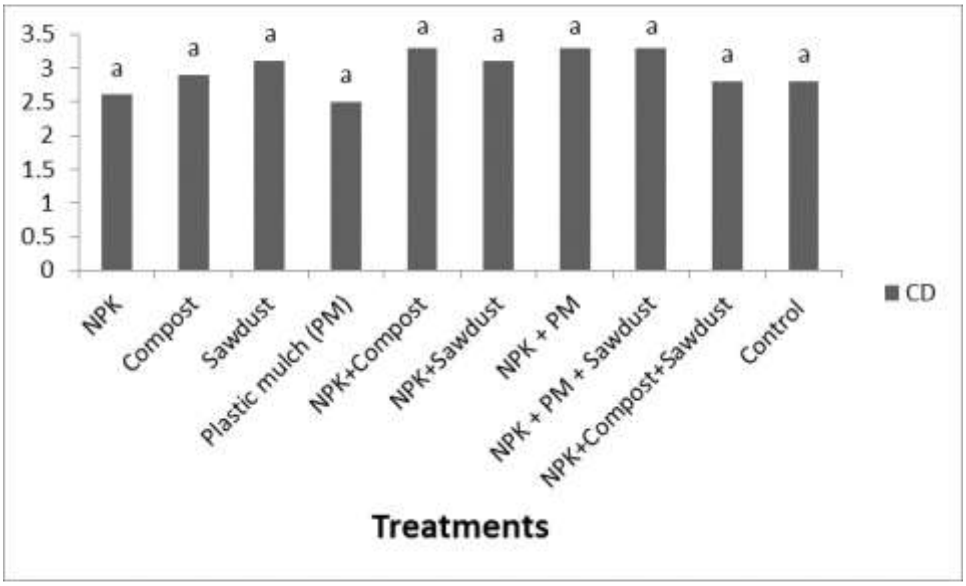

Figure 2: Effects of integrated nutrient management on collar diameter of juvenile breadfruit trees in the orchard

The weed dry weight ranged between 40.0 g/m^2 (plastic mulch) to 180 g/m^2 (sawdust). However, breadfruit plots mulched with plastic mulch recorded the least weed dry weight which was significantly lower when compared with other treatments. The observed decrease in the performance of trees treated with NPK alone can be attributed to the presence of weeds as reflected in the weed dry weight. Akobundu (1987), noted that NPK fertilizer application encouraged more weed growth. The author also noted that NPK application coupled with weed's inherent competitive ability results in more weed growth, as well as the control. Also, Alamu *et al*, (2012), reported that citrus plots that received 0.45 tha-1 NPK 15:15:15 recorded the highest weed density.

CONCLUSION

Breadfruit plots treated with NPK + Sawdust + Plastic mulch performed better than other nutrient source and combinations, while plots treated with NPK 15:15:15 alone gave the lowest performance and this may be attributed to effects of weed pressure on the trees as it is reflected in the weed dry weight.

ABSTRACT

Field experiment was conducted during the dry season at the Demonstration Farm of the Department of Agricultural Education Federal College of Education (Technical), Gombe to evaluate the effect of plant spacing and organic manure rate on the growth and yield of waterleaf. Treatments included three intra row spacing (5cm, 10cm and 15cm) and four cow dung levels (0,1,2 and 3 t/ha) which were laid in a randomised complete block replicated three times. Data collected were subjected to analysis of variance (ANOVA) using STAR statistical package. The results on plant height, plant girth, leaf area, number of flowers per plant, total fresh and dry weights showed there was no significant difference (P ≤ 0.05). However, number of leaves per plant and number of branches per plant were significant (p<0.05). Waterleaf intra row spaced at 5cm and applied 3t/ha cow dung produced highest number of leaves per plant (67) and number of branches (17) respectively. Therefore, for optimum production of waterleaf, spacing of 25cm x 5cm and cow dung rate of 3t/ha should be used and hereby recommended for farmers in the study area.

Key words: plant spacing, cow dung, growth, yield, waterleaf

INTRODUCTION

Waterleaf (*Talinum triangulare*) is a cosmopolitan non – conventional invasive plant (Souza and Lorenzi, 2012) adapted to hot and humid climate and poor quality soil (Amorim *et al*., 2013). It belongs to the Portulacaceae family which is a relatively small family (30 genera and 400 species) of the Caryophyllales order, but it has widespread distribution (Amorim *et al*., 2013). In the southern part of Nigeria, it is used singly in the preparation of sauces and stews and in mixed vegetable soups in combination with other vegetables; in the later it serves as softener of other vegetable species (Aja *et al*., 2010).

Talinum is adaptable throughout the country. It is best suited in a wet tropical environment with partial shade (Fontem, 2014). It is well adapted to the hot and humid climate and the poor quality soil, which makes its cultivation an important economic activity for small growers (Amorim *et al*., 2013). Waterleaf is eaten as a vegetable throughout the tropics including many countries in West and Central Africa and it is cultivated abundantly in Nigeria and Cameroon (Akachuku and Fawusi, 2015).

Talinum is said to stimulate egg production in fowls (Irvine, 2010). According to Leung *et al.* (2018), the leaves of waterleaf contain per 100 g edible portion: water - 90.8 g, energy – 105 KJ (25 kcal), protein - 2.4 g, fat - 0.4 g, carbohydrate - 4.4 g, fibre - 1.0 g, calcium – 121 mg, phosphorus - 67 mg, iron - 5.0 mg, thiamin - 0.08 mg, riboflavin - 0.18 mg, niacin - 0.3 mg, ascorbic acid – 31 mg. Sridha and Lakshminarayana (2013) also gave a report on high total lipids, essential oils, and alpha-tocopherols and beta-tocopherols in waterleaf. Water leaf is highly riched in crude proteins, crude fibres (Enete and Okon, 2010). And the minerals present contribute to high anti-oxidant values of water leaf (Enete and Okon, 2010). Medicinal properties of water leaf have been ascertained by many researchers to contain chemical substances like (flavonoids, alkaloids and tannins) that help in the management of cardiovascular diseases, such as Stroke, Obesity (Aja *et al*., 2010).

Farmers find it difficult to maintain a standard fertilizer regime in the cultivation of water leaf as they often supplement organic manure with mineral fertilizers. Cow dung is rich in minerals and ranges from greenish to brackish, often darkening after exposure to the air; it contains high level of ammonia (Braadbaart *et al*., 2012 and Dittrich and Helden, 2012). The increasing demand for waterleaf due to urbanization has therefore pushed farmers into small and medium scale production of waterleaf in Akwa Ibom State. Consequently, to obtain optimum yield, organic fertilizers are being developed by farmers from farm and city wastes for vegetable production. Also, organo-mineral fertilizers (OMF) in which organic wastes are fortified with inorganic N or NP fertilizers are being utilized by crop farmers. Organic and organo-mineral fertilizers have been reported to significantly increase yield of vegetables such as pepper (*Capsicum annum*), tomato (*Lycopersicon esculentus*), okra (*Abelmoschus esculentus*), egusi-melon (*Cucumeropsis mannii*) and amaranthus (*Amaranthus cruentus*) (Oluwole *et al*., 2019).

Plant spacing is a very important measure a farmer can employ to optimize yield of crops, yet this is often neglected by the local farmers. It has been shown that one of the most critical aspects of optimizing crop growth and indeed yield is maintaining adequate crop geometry in terms of spacing. According to Schippers (2013) proper spacing allows for less competition from weeds. Schippers (2013) also suggested that in waterleaf, if the soils are fertile or when manure is used in such a way that plants develop rapidly with large leaves, spacing should be increased to about 25 cm x 25 cm. According to Nadi and Lal (2013) lower densities encourage weed growth, reduce production and have less beneficial effects on the soil.

Plant spacing and organic manure rates affect the growth and yield components of water leaf Orluchukwu and Poripo (2014). Various spacings 25cm x 10cm, 25 x 20cm, 25 x 30cm and 3cm x 5cm depending on organic manure rates and the ecological zone had been recommended for waterleaf production (Orluchukwu and Poripo, 2014 & Aniefiok *et al*., 2013). The dry matter yield of waterleaf decreased as the spacing increased with 25cm x 30cm spacing giving the lowest dry matter yield and the closest spacing of 25cm x 10cm giving the highest dry matter yield (Orluchukwu and Poripo, 2014). Most research efforts on waterleaf production in the study area have focused on resource utilization (Udoh *et al,* 2015). There has been a paucity of information on the effect of plant spacing and organic manure rate on the growth and yield of waterleaf (*Talinum triangulare*) in the study area. Hence this study is being conducted to evaluate the effect of plant spacing and organic manure rate on the growth and yield of waterleaf (*Talinum triangulare*).

MATERIALS AND METHODS

The experiment was conducted at the Students' Demonstration Farm of Federal College of Education (Technical) Gombe Latitude 12^0 30´N and longitudes 8^o 45´E) between the months of June and September, 2019. The state climate is generally warm, with temperatures not exceeding 40^o C during the months of March – May. The topography is mountainous, undulating and hilly to the south east and flat opens plains in the North central. The vegetation is generally sudan savannah grassland with concentration of wood land in the South east and South West and annual average rainfall is 850mm.

Treatment consists of four rates of cow dung (0, 1, 2, and 3 tonnes/hectare) and spacing (25cm x 5cm, 25cm x 10cm and 25cm x 15cm) to give treatments combinations of twelve. The treatments were laid out in a Randomized Complete Block Design (RCBD) replicated three times. The plot size 3.94m x 0.3m with spacing within and between plots 25cm and 50cm respectively. Prior to planting, soil sample were randomly collected at 0 – 25cm, bulked and mixed thoroughly for physical and chemical analyses. Two weeks old Water leaf seedlings were obtained from the market and transplanted to the plots according to the treatment spacing, while the cow dung treatments were applied two weeks before transplanting. Weeding and other agronomic practices were promptly carried out. At maturity stage, the waterleaf plants were harvested by hand pulling. The growth and yield parameters collected were plant height, number of leaves per plant, leaf area (cm^2), number of branches per plant and total fresh weight. Data obtained were subjected to statistical analysis of variance (ANOVA) using STAR software and the means were separated Least Significance Difference (LSD) at 5% level of probability ($p<0.05$).

RESULTS

Physical and Chemical Properties of the Experimental Site and Cow Dung Used

The physic-chemical analysis of the soil (Table 1) showed that the soil was sandy loam in texture with 82.80%, 4.56% and 12.64% of sand, silt and clay respectively. It is slightly acidic with a pH of 6.72, low in available phosphorus (9.25 mg/kg), total nitrogen (0.06) and organic carbon (0.56 %). The soil is also low in most of the exchangeable bases, calcium (2.83 cmol/kg), magnesium (0.72 cmol/kg), sodium (0.11 cmol/kg) and potassium (0.28 cmol/kg). These values imply that the soil used for the trial was low in most of the nutrients which were beyond the critical levels (Enwezor *et al*., 1989) and at such will lead low fertility.

Table 1: Physical and Chemical Properties of the Experimental Site during the Experiment

Soil Properties	Values
Physical Composition (%)	
Sand	82.8
Silt	4.56
Clay	12.64
Textural class	Sandy loam
Chemical composition	
pH in water	6.72
Organic carbon (g/kg)	0.56
Total nitrogen (g/kg)	0.06
Available phosphorus (mg/kg)	9.25
EC (dS/m)	0.116
Exchangeable bases (cmol/kg)	
Ca^{++}	2.83
Mg^{++}	0.72
K	0.28
Na	0.11
Base saturation (%)	0.116

The composition of the cow manure is indicated on Table 2. The results showed that the pH value is slightly alkaline (7.86), organic carbon (32.1 %) total nitrogen (1.87 %), available phosphorus (1.16) and exchangeable bases (Ca 0.33; Mg 0.04; K 0.26).

Table 2: Chemical composition of cow manure used during the experiment

Chemical composition	Cow
pH in water	7.86
Organic carbon (%)	32.16
Total nitrogen (%)	1.87
Available phosphorus (%)	1.16
Potassium (%)	0.26
Calcium (%)	0.33
Magnesium (%)	0.04
Iron (%)	4.29
Manganese (mg/kg)	2.11
Copper (mg/kg)	0.27
Zinc (mg/kg)	0.48

Results on number of leaves per plant showed no significance difference ($P \leq 0.05$) at week 1, 2 and 3 weeks after transplanting (WAT) while there was significant difference ($p<0.01$) and ($p<0.05$) at 4 and 5 WAT respectively (Table 3). At 4 and 5 WAT, plants spaced at 25 x 5cm and applied with 3t/ha cow dung recorded the highest number of leaves per plant of 52 and 67.33 respectively. The least number of leaves per plant were obtained from plants intra row spaced at 15cm and 10cm applied 0 t/ha with 30.00 and 50.67 for 4 and 5 WAT respectively. Results on plant height showed no significant difference ($P \leq 0.05$) throughout the measuring periods. Nevertheless, plants intra row spaced 5cm and applied 3t/ha cow dung appeared to be tallest (Table 4). Plant girth showed no significant difference ($P \leq 0.05$) throughout the measuring periods (Table 5). Nevertheless, plants intra row spaced 5cm and applied 3t/ha cow dung appeared to be thickest. Number of branches shows no significant difference ($P \leq 0.05$) at week 1, 2, 3 and 4 WAT but showed significance difference ($p<0.05$) at 5 WAT (Table 6). Plants intra row spaced at 5cm and applied 3t/ha recorded highest number of branches per plant (17.33) followed by those intra row spaced of 15cm and applied 3t/ha with 17 branches per plant, while branches were obtained from those spaced at 10cm with zero cow dung. The results on leaf area showed there was no significant difference (P ≤ 0.05) throughout recording periods (Table 7). Results on the effect of plant spacing and organic manure rates on the number of flowers per plant, fresh yield and total dry weights are presented on Table 8. The results indicated no significance difference (p>0.05) on the number of flowers per plant, total fresh and dry weights.

DISCUSSIONS

The highest number of leaves per plant recorded for intra row spaced of 5 cm applied 3t/ha cow dung indicated that close spacing with adequate manure enhanced growth of waterleaf. This finding is in agreement with those of Schippers (2013), Orluchukwu and Poripo, 2014 and Aniefiok *et al*. 2013 who found that close spacing and adequate manuring enhanced more leaves production and dry matter in waterleaf. Similar result was presented by Ndaeyo *et al.,* (2013) shows that at 3, 6, 9 and 12 WAP, the leaf area of waterleaf differed significantly (P < 0.05) among the different fertilizer treatments. Furthermore, the result showed closely spaced plants with adequate manuring enhance good growth and more branches per plant. This is because as more leaves are active photosynthetically, more assimilates are produced enhance growth and more branches per plant. This is in agreement with the findings of Ndaeyo *et al.,*

(2013) who stated that at 3, 6, 9 and 12 WAP, there were significant differences in the number of branches per plant (P ≤ 0.05) among the different fertilizer treatments. He also stated that at 9WAP, 5tha-1 poultry manure (PM) produced 24-75% more branches than other treatments whereas at 12WAP, the number of branches from the 300kgha-1 NPK + 1.25tha-1 PM plot superseded other treatments by 52-78%. The control treatment had the least number of branches per plant. This finding is contrary to those of Malik *et al*. (2016) who found that more branches were produced at wider spacing in waterleaf.

CONCLUSION

The result of this study indicated that plant spacing and cow dung affects growth dry matter yield of waterleaf. Optimum growth and leaf production were recorded from plants intra row spaced at 5 cm and applied 3t/ha cow dung. Therefore, for optimum production of waterleaf spacing of 25cm x 5cm is recommended for the farmers in the study area.

A REVIEW OF SOILS AND FERTILIZER MANAGEMENT RESEARCH ON COCOA (*THEOBROMA CACAO* L.) PRODUCTION IN NIGERIA

Ogbeide, C.E and Ibiremo, O.S.

Soils and plant Nutrition, Cocoa Research Institute of Nigeria. P.M.B. 5244, Ibadan, Oyo State, Nigeria

ABSTRACT

Cocoa (Theobroma cacao) an important economic crop in Nigeria, contributes significantly to the Gross domestic product (GDP) of the nation. The productivity had been variously affected by soil fertility status and fertilizer management. This paper reviewed the soil requirements and characterization of cocoa, fertilizer management for cocoa and agronomic practices for growing sustainable cocoa as well as some gaps were identified for further research. Research revealed that cacao requires a deep well drained soil with a high nutrient content, rich in organic matter. Recommended fertilizer for cocoa on land cleared from forest are 4g P/tree. For land previously cropped with cocoa or other arable crops, the recommended fertilizer applications are: 10Kg N+4Kg P+4Kg K per tree in the first year. In the second and third year after planting, 10g P per tree was recommended when grown on the land cleared from forest and 25gN+4gP+3g K/ tree on land previously cropped. Forth and six – year- old plantation 11-23g P/ tree is recommended. When land grown with cocoa is cleared from forest, 50-100g N+12g P +25gK/tree is recommended. Cocoa pod husk has showed to improve soil fertility due to it high content of potassium (K). Result has it that NPK fertilizer applications had a positive impact on the growth and development of cocoa seedlings. Area for further research include development of fertilizer use in cocoa rehabilitation and efficiency of various cocoa varieties

Key words: *Cocoa, Soil characterization, fertilizer management, organic matter and shade management*

INTRODUCTION

Cocoa has become a vital export crop for many countries, particularly in West Africa, which produces over 65% of the world cocoa. It is also a major foreign exchange earner for some Central and South American countries and for South and South East Asia (Wood,1985). Over 80% of all cocoa is produced by smallholder farmers. Cocoa provides employment in many rural communities and pays school fees of farmers' children. Smallholder cocoa is grown mostly under shade trees and either inter-cropped or grown in a semi-natural agro-forestry setting and hence, is a particularly rich and stable habitat for many species (biodiversity).

Soil requirements and characterization for cocoa

Cocoa is a forest crop and so it is suited to forest soils. Hence, it is exceptionally demanding in its soil requirements. Most tropical forest soils consist of accumulated plant nutrients in the top few centimetres. When forests are cleared, the nutrients are rapidly released, giving the soil a high fertility for a few years. Cacao requires a deep well drained soil with a high nutrient content, while the top soil should be rich in organic matter. Hardy (1958), reported that the depth of root-penetrable soil should be at least five feet, but deeper soils are required where annual rainfall is low, especially if the soils tend to be rather sandy (Charter, 1953). In Nigeria the cacao soils should also have a clayey texture, preferably with sandy clay loam within 4 inches of the soil surface and a sandy clay below 10 to 15 inches to ensure that the trees have an adequate moisture supply during the dry months (Smyth and Montgomery 1962). It is important to select an appropriate site before establishing a cocoa farm. The process of selecting a suitable site, the following could be useful hints such as presence of earthworms cast in the site since this gives an indication for humus soils and type of trees growing in the area among other things. The following soil characterizations are standards for cocoa cultivation, these include adequate internal drainage, the proportion of coarse elements in the soil and good soil texture (sandy-clayey mixture).

Soil texture and depth

The soil texture influences the soils ability to store water and nutrients. Clayey soils generally contain more organic matter and nutrients than sandy soils (Feller and Beare 1997), which increases the vigour of the trees (Wessel 1971). Sandy soils are more susceptible to leaching (Aranguren *et al*., 1982). Clayey soils have a large moisture holding capacity, while sandy soils have good drainage. The water stored in clayey soils may not be easily available to the plants and the release of water to the plants is slower and more even than in sandy soils (Wessel

ISSN: 2814-0508

1971; Wood 1985). Cocoa trees usually form a thick tap root up to a depth of 1.5m or more and hence require deep soils (Wessel 1971; Wood 1985). Even deeper soils are required when annual rainfall is low, especially when the water holding capacity is poor i.e. on sandy soils (Wessel 1971). Cocoa roots tend to root deeper in soils with a sandy topsoil than with a clayey topsoil, as sandy soils dry out to a greater depth during dry months. When the development of the tap root is restricted, the trees lack physical support and may fall over (Wood, 1985).

Soil moisture

Cocoa is sensitive to both drought and water logged soil (Carr andLockwood 2011; Gattward *et al.* 2012; Wood and Lass, 2001). Water logging, which may occur during the wet season in some regions, leads to inadequate soil aeration (Evans and Murray 1953). Water logging may prevent the initial growth and establishment of cocoa, and will reduce pod production in mature cocoa (Almeida and Valle 2007). Both water logging and drought may lead to nitrogen deficiency symptoms in cocoa (Evans and Murray 1953).

Soil nutrient requirements for cocoa production

Wessel (1971) reported that to achieve high productivity, Cocoa requires a soil abundant in nutrients. The importance of other soil characteristics, such as pH, is largely due to their influence on the availability of nutrients. In many cocoa growing regions, soil nutrient content without fertilizer application is poor, especially if the soil has been under cultivation for a long time (Hartemink and Donald, 2005; Baligar *et al.,* 2006). Although nutrients have different functions in the development of the tree (e.g. canopy formation, flowering, pod production), all nutrient deficiencies will ultimately lead to decreased yields. Annual nutrient requirements to replace nutrients exported from the system can be calculated using nutrient balance. Nutrient balance analysis in establishing fertilizer recommendations is based on the principle of replacement: the nutrients added in fertilizers should replace the nutrients leaving the system. To calculate fertilizer requirements using this method, only information about yields is required. Due to its simplicity, this is an attractive approach. Fertilizer recommendations for cocoa of some authors are largely based on the nutrient balance method, as their recommendations depend solely on the harvest obtained (Hardy in De Geus, 1973; von Uexküll and Cohen, 1980). However, the use of nutrient deficiency in soil is another method, where the critical level is considered for computation of fertilizer specific to the site under consideration.

pH

The availability of some plant nutrients is greatly affected by soil pH. The ideal soil pH is close to neutral, and neutral soils are considered to fall within a range from a slightly acidic pH of 6.5 to slightly alkaline pH of 7.5. It has been determined that most plant nutrients are optimally available to plants within this 6.5 to 7.5 pH range (Jensen and Thomas, 2010). Many nutrients become less available with increasing acidity while others become more available, which can lead to toxicity of these nutrients (Wood 1985; Baligar *et al.* 2006). The optimum range for growing cocoa is said to be pH 6.0-7.5 (Wood, 1985). Although according to Shamshuddin *et al.* (2004), cocoa is very sensitive to acidity, Wood (1985) argues that cocoa is tolerant to acid conditions as long as the soil provides adequate nutrients. High rainfall can lead to nutrient leaching and acidity of soils (Snoeck *et al.,* 2010). In the Nigerian cocoa belt, the annual precipitation of 1,150-1,650 mm can be considered to be less than ideal for cocoa production. However, this low rainfall is also the main reason why the Nigerian soils have not lost all their bases by leaching (Wessel, 1971). Generally, cocoa production will cause acidification (a lowering of pH) of the soil. Examples are decreases from pH 6.8 under forest to 5.5 after 10-15 years of cocoa cultivation in Nigeria (Hartemink and Donald, 2005).

Organic matter

Large amounts of nutrients, and in particular N, are present in the soil in organic form. Organic matter improves the structure of the soil, facilitates aeration and determines the capacity of the soil to hold water and exchange nutrients (Wood, 1985). Thus, soil organic matter plays crucial role in maintaining soil fertility (Van Noordwijk *et al.* 1997). Most of the soil organic matter is found in the topsoil. Wessel (1971) found that under cocoa the soil content of total N, organic P, CEC, and the sum of exchangeable bases (within certain pH limits) are all strongly positively correlated with the organic matter content of the soil.

The soil organic matter initially declines rapidly as a result of erosion, decreased litter supply and increased mineralisation in the exposed soils. Ahenkorah *et al.* (1974) found significant

ISSN: 2814-0508

reductions of C in the range of 40-60% (from 4 to 2% in the 0-5 cm layer and from 2 to 1% in the 5-10 layer) within 15 years of cocoa production.

Soil fertility and Fertilizer management in cocoa production

Soil nutrition in cocoa plantation often reduce as a result of continuous cultivation of cocoa. Wessel (1971) reported steady decline in almost all the nutrients with length of cultivation. Omotoso (1975) showed that a crop of 1000kg dry cocoa beans removed about 20KgN, 4KgP and 10KgK and where the method of harvesting (as in Nigeria) involves the removal of pod husks from the field, the amount of K (potassium) removed is increased more than five folds. According to Olson (1970), fertilizer could increase food production by at least 50%. In a recent work conducted by Opeyemi *et al*. (2005) an effective use of fertilizer on cocoa would help not only to improve yield but also has the advantages of profitability, product quality and environmental protection. Fertilizer practices were recommended by Cocoa Research Institute of Nigeria, (CRIN, 1986). In the year of planting, 4g P/tree was recommended when grown on land cleared from forest and 10kgN+4kgP+4kgK/tree when grown on land previously cropped with cocoa or other arable crops. In the second and third year after planting 10g P/tree was recommended when grown on land cleared from forest and 25gN+4gP +3gK/tree on land previously cropped. Fourth and six-year old plantation 11-23g P/tree was recommended. Where land grown with cocoa was cleared from forest, while 50-100g N+12g P+ 25gK/tree was recommended on land previously cropped. Rehabilitation of old cocoa farm requires a lot of fertilizer input especially when the soil is marginal for cocoa production. In Nigeria, there is still no standard approach to this. Recent work on the use of organic fertilizer from animal and plant sources indicated that cocoa seedling was positively enhanced by the application of cow dung compared with cocoa pod husk (Ibiremo *et al*. 2004). Ogunlade *et al.* (2006) also indicated that organic sources of nutrient and organic -based N (Neem) fortified pacesetter fertilizer were more efficient than inorganic NPK fertilizer in increasing N, P and K uptake and growth of cocoa seedling.

Use of compost: Composting involves using waste materials from the household such as cocoa pod husks, cassava, yam, sweet potato peelings). Compost can be applied to the planting hole when planting cocoa or to mature farms if one can produce enough compost. One can make compost with a mixture of many materials including cocoa pod husks, empty oil palm fruit bunches, wood ash, charcoal dust, rice straw, poultry dropping, cattle manure, sheep manure, corn stubble or any other waste available in large quantities. Cocoa pod husks contain a lot of potassium which the cocoa trees remove from the soil (Ogunlade, *et.al* 2006).

Agronomic practices for growing sustainable cocoa

There are no 'silver bullets' or simple solutions to these diverse and complex problems that currently affect the cocoa industry. Practices that will bring about sustainable cocoa production are: Pruning and shade management. This practice determines the shape of the tree, it maximizes the nutrient distribution towards pods and helps in preventing some pest problems.

Gaps in knowledge

Considering the vast experimental work done on cocoa nutrition and fertilizer management, a number of research effort should be made to determine the critical values or what nutrient is present in the cocoa leaf and soil nutrient composition otherwise called site specific fertilizer recommendation.

Recommended research

Research can be carried out on development of fertilizer use in cocoa rehabilitation and fertilizer use efficiency of the various cocoa varieties.

CONCLUSION

Selection of suitable site is key to successful cocoa establishment which involves presence of high organic matter (humus), adequate depth of 1m and above is texturally suitable for proper root development.

QUANTIFICATION OF KOLA POD HUSK BEING GENERATED IN KOLA PLANTATIONS IN NIGERIA

*Taiwo, N., Adebowale, L.A. and Ogunlade, M.O.

Cocoa Research Institute of Nigeria, Ibadan

Corresponding author's e-mail: nneorah@yahoo.com

ABSTRACT

A study was conducted at Cocoa Research institute of Nigeria, Ibadan, to determine the quantity of Kola pod husk being generated in kola plantations in Nigeria on wet and dry basis. Kola pods were collected from various kola plantations across major kola producing communities in Southwest Nigeria. The harvested pods were broken to remove the Kola nuts. The fresh and dry weights of kola pod husks and kola nuts were recorded individually in order to determine the percentage contribution of the fresh and dry kola pod weights to the Kola pod. Results indicated that kola pod husk contributed between 30-40% and 20-30% to kola pod on wet and dry weight basis respectively. Therefore, fresh kola nuts constitute 60 to 70% of kola pod. This suggests that though farmers neither take nor record quantity of kola pod husk generated on their farms, the record of fresh kola nuts yield can be used to estimate the quantity of kola pod husk generated on farmers' farm.

Key words: Kola pod husk, Kola producing states, wet and dry weight, kola nuts.

INTRODUCTION

Kolanut is a major cash crop for many farmers in parts of Western Nigeria as observed by Agboola 1979. Nigeria is the world's largest producer of kola nut. Kola-pod husk (KPH) is a by-product during Kola nut production. The pod husk, has been a farm waste to date. In Nigeria, kola pods are harvested, and collected at a central point within the farm where pods are broken, kolanuts removed and husks are discarded as waste. It is either left on the farm to rot or burnt. Instead of allowing these agricultural waste to be a source of menace to humanity, harnessing this by- product and utilizing them under adequate conversion techniques can make the to become useful. Kola pod husk can be used in the formulation and compounding of livestock (especially fish) feed and for the production of soap (Yahaya et al, 2001, Hamzat et al 2001). Kolanut pod husk can also be used as an organic fertilizer (Ipinmoroti 2007, Makinde, 2013). kolanut husk meal has high potential for consideration as possible substitute for conventional feed stuff such as maize in the nutrition of broilers Olubamiwa et al, 2011. Some other products obtained from KPH include biogas and substrates for microbial enzyme production and medicines Considering the diverse uses of KPH, it is necessary to know the quantity being produced for planning purpose. The knowledge of the quantity available will also guide the entrepreneur who might want to use Kola pod husk as raw material for the production of some of the derivatives earlier mentioned.

Most farmers in Nigeria do not keep records of kola pod husks being produced on their farms. Most farmers have information on the weight of kola nuts produced on their farms. The relationship between the kolanut weight and kola pod husk can be used to determine the percentage contribution of husk to kola pod. Therefore, the aim of this study is to determine the quantity of kola pods being produced by the farmers on the farm using the relationship between the dry and wet weight of kola nuts and kola pods.

MATERIALS AND METHODS

Ripe and ready to harvest kola pods were harvested from randomly selected kola plantations in kola growing communities covering five cola producing States in southwestern Nigeria: Ondo, Oyo, Osun, Ogun and Ekiti States. Eight locations were visited altogether with ten pods harvested per location. The fresh pods were weighed using a battery operated sensitive digital scale. Thereafter the cola pods were cracked to open up the pods and the nuts were removed and weighed. The percentage weight of the wet KPHs that were generated by the wet cola pods was then determined using the equation below.

$$\% \text{ Weight KPH (wet basis)} = \frac{W_h}{W_p} \times 100$$

Where Wh = weight of KPH on wet basis

Wp = Total weight of the fresh kola pod

Kolanuts from each pod were placed in a plate and dried at room temperature. Pod husks were also dried until constant weight was obtained, after about 14 days. Dried KPH and kola nuts from each of the pods were weighed separately using a battery operated sensitive digital scale. The percentage of dry pod husk was determined using the equation below:

$$\%\ \text{Dry KPH} = \frac{W_{dh}}{W_{dp}} \times 100$$

Where W_{dh} = weight of KPH on dry basis

W_{dp} = Total weight of the kola pod on dry basis

This was done for each of the 80 pods collected from 8 Kola plantations, the frequency distributions, means and standard deviations were determined as well.

RESULTS AND DISCUSSION

Most of the kola pods evaluated had between 20.1-40% fresh kola pod husk (Table 1). This implies kola pod husk contributed between 20-40% on wet basis to kola pods. The percentage mean of fresh KPH ranged from 28.78 to 41.16. The % fresh KPH of between 30.1 to 40% occurred most frequently with a mean value of 62.5%. (Table 2)

Table 1: Quantity of Fresh Pod Husk in Kola Pods

Locations	0-20%	20-40%	>40%	Total	mean	Std dev	minimum	maximum
1		10		10	31.48	2.96	28.85	36.04
2	3	7		10	28.78	10.60	14.26	38.5
3		6	4	10	41.16	8.33	32.98	53.36
4		7	3	10	39.20	3.85	35.91	45.98
5		10		10	31.44	5.82	22.17	33.22
6		10		10	32.24	10.93	24.51	39.97
7		10		10	30.04	4.35	25.03	32.76
8		10		10	31.41	2.25	29.23	34.31
Total	3	70	7	80				

Table 2: Percentage mean of fresh KPH

% fresh kph	Frequency	Percentage
0-20	3	3.75%
20.1-30	18	22.50%
30.1-40	50	62.50%
40.1-50	7	8.75%
>50	2	2.50%
Total	80	
Mean		33.80%
Standard Deviation		7.06%
Range		14.26-53.36%

CONCLUSION

Kola pod husk contributed 33.80% and 23.20% to kola pod on wet and dry weight basis respectively. Hence, fresh kolanuts constitutes approximately 66.20%of kola pod. Therefore, a farmer can determine the quantity of kola pod husk generated annually from the annual record of fresh kola nut yield.

ABSTRACT

A field trial was carried out for three years (2015, 2016 and 2017) during the rainy seasons at the research and demonstration farm of Federal College of Horticulture, Dadin Kowa, Yamaltu Deba local government area, Gombe State. The aim of the study was to investigate the effect of variety and intra row spacing on the performance of sesame. The experiment consisted of two varieties (E8 and NCRIBen04E) and three intra-row spacings (5cm, 10cm and 15cm). The two varieties and three row spacing were factorially combined and laid in a complete randomized block design with three replications. During the study period, growth characters such as plant height, number of leaves, leaf area, and number of branches were measured. Similarly, yield characters such as number of flowers and capsules, 1000 grain weight and grain yield were also recorded. All the characters studied significantly correlated with grain yield, except number of leaves, number of capsules and 1000 grain weight. Plant height, number of secondary branches and number of flowers correlated positively with grain yield while number of primary branches correlated negatively with grain yield. Therefore. from the results of the trial it could be concluded that, some characters like plant height, primary branches, and number of flowers had contributed to the grain yield of sesame and it revealed that the higher the flower the higher the grain yield in sesame.

Key words: Correlation, Sesame, Variety, Spacing.

INTRODUCTION

Sesame (*Sesamum indicum* L.) it is one of the oldest cultivated oilseed crops in the world it belongs to the family *Pedaliaceae*. Its known as beniseed in West Africa has been recognized as crop with high economic potential, especially in Nigeria where it is both used as a source of raw material for the industry and a reliable foreign exchange earner. In Nigeria, the crop is locally called *Ridi*, *Ekuku* and *Isasa* by the Hausas, Yorubas and the Igbos, respectively. Majority of sesame growers in the study area use local varieties which are low yielding when compared to the improved varieties made available by modern Agriculture. There are also discrepancies among farmers on the suitable row spacing, as different genetic variability of the crop in terms of growth habit exists. It is only of recent that its commercial cultivation captured the attention of farmers especially in North-eastern parts of Nigeria. Because of the relatively low documented scientific information on the production of sesame in the study area, the present study will attempt to fill the knowledge gap especially relating to acceptable varieties, the proper plant spacing and best methods of weed control.

The present investigation was carried with the following objectives. study simple correlation between growth and yield characters with grain yield of sesame

MATERIALS AND METHODS

Field experiment was carried out for three years during the rainy seasons of 2015, 2016 and 2017 at the research and demonstration farm of Federal College of Horticulture, Dadin Kowa Gombe State Nigeria. Dadin-Kowa is located at latitude 10^0 15'N and longitude 11^0 15'E in the northern Guinea savannah zone of Nigeria (GPS 2015). The climates in the region consist of two distinct seasons, rainy season (May to October) and dry season (November to April). Average annual rainfall in the study area is 1021.80mm, mostly distributed between the months of May and October, while the mean daily temperature ranges from 22^0 C to 35^{0}C (UBRBDA, 2008).

The experimental material used in this research consist of two varieties (E8 and NCRIBEN 004E) which were sourced from National Cereals Research Institute Badeggi, Bidda, (NCRIB) Niger State. The experiment consisted of two factors: variety (E8 and NCRIBen004E), Intra row spacing (5, 10 and 15cm). The two factors and their levels gave 6 treatment combinations which were laid in a randomized complete block design with three replications.

At the beginning of each trial during the three years, the land was cleared and harrowed twice to obtain a fine tilth. During layout of the experiment, pegs and ropes were used to demarcate plot boundaries, lay out plots and block boundaries. Each plot measured 3 x 3m (9m^2) in size with a distance of 0.5m between the plots and 1m between replicates. Six plots were obtained in a replicate, given a total of 18 plots.

Before sowing the crop in each year, soil samples were taken in a "Z" shape within the experimental area following the procedure of IFDC (2003) at a depth of 0-30cm using a tubular auger. The samples obtained were first air-dried, thoroughly mixed, ground and then sieved for analysis of physical and chemical properties in the laboratory as described by Page *et al.,* (1983). During the analysis, the following properties were determined: Size distribution (soil class), soil pH, organic carbon, total nitrogen, available phosphorous, potassium, cat-ion exchange capacity (CEC) and exchangeable bases to determine the fitness of the soil for sesame production (Appendix I).

In each plot, plants in the two outer rows from each side of the plot were taken as border rows. Ten plants randomly selected from the three central rows in each plot were then tagged using masking tape and from these sample stands all the data were collected and measured. Growth characters like plant height, number of leaves, leaf area etc were recorded at an interval of two weeks commencing from 4WAS, until harvest, yield characters like number of capsules, seed weight etc. were only taken once at harvest.

Analysis of variance (ANOVA) was used to analyze all the data collected as described by Gomez and Gomez (1984) and to test for the significant effect of all the treatments. Where there were significant differences among the means of the different treatments, they were separated using Duncan's Multiple Range Test (DMRT) following the procedure of Duncan (1955).

RESULTS AND DISCUSSION

Simple correlation between growth and yield characters of sesame taken in 2015, 2016 and 2017 rainy seasons is presented in Table 1. Characters taken were plant height, number of leaves, number of pods, primary branches, plant height, secondary branches, number of flowers, 1000 grain weight and grain yield. All the characters studied significantly correlated with grain yield, except number of leaves, number of capsules and 1000 grain weight. Plant height, number of secondary branches and number of flowers correlated positively with grain yield while number of primary branches correlated significantly negatively with grain yield.

Table 1: Simple Correlation among growth and yield characters with yield of Sesame grown in 2015, 2016 and 2017 rainy seasons

Characters	Correlations
Grain yield	
Plant height	0.2735**
Number of Leaves	0.0924ns
Primary Branches	-0.1996*
Secondary Branches	0.1630*
Number of flowers	0.4271**
Number of capsules	0.0660ns
Number of capsules	0.0660ns
1000 grain weight	0.0943ns

* = Significant at 0.05 probability. ** = Significant at 0.01 probability. NS=Not Significant

Plant height, primary branches, and number of flowers had contributed to the grain yield of sesame, hence these among other factors should be considered in the selection for high yield capacity in sesame production as described by Olowe (2004). In a related study, the relationship between seed yield of sesame crop and various growth and yield parameters were reported by several researchers. Engin *et al.*, (2010) in a study conducted in Australia involving 345 sesame genotypes originating from 29 different sesame producing countries worldwide, he reported that, plant height, number of branches and 1000 seed weight had a positive significant correlation with seed yield. In another correlation studies conducted in Nigeria by Muhamman *et al*., (2009) it was revealed that, number of branches, plant height and leaf area had a positive correlation with seed yield of sesame crop, while 1000 seed weight showed a non-significant relationship with seed yield. Subramanian and Subramanian (1994), reported that, seed yield had a positive significant correlation with number of capsule, number of primary branches, number of seed per capsule and 1000 seed weight. It was also reported by Adeyemo *et al.,* (1992) that seed yield had a significant correlation with number of capsule, seed yield per plant, number of seed per capsule, number of primary branches and 1000 grain weight.

CONCLUSION

A field trial was carried out for three years during the rainy seasons of 2015, 2016 and 2017 at the research and demonstration farm of Federal College of Horticulture, Dadin Kowa, Yamaltu Deba local government area, Gombe State. The aim of the research was to study the effect of variety, and intra row spacing on performance of sesame. The two varieties were E8 and NCRIBen04E while the three intra-row spacing were 5, 10 and 15cm During the investigation, growth characters such as plant height, number of leaves, leaf area, number of branches and leaf area index were measured. Yield characters such as number of flowers, number of pods, 1000 grain weight and grain yield were also recorded. Therefore, from result of this study it could be concluded that, some characters like plant height, primary branches, and number of flowers had contributed to the grain yield of sesame. Moreover, it was revealed that, the higher the flower, the higher the grain yield in sesame.

ABSTRACT

Climate change has been observed as one of the most serious environmental threats facing mankind worldwide with the likelihood of reducing agricultural production in the tropics. It brings with it changes in weather patterns that can have serious repercussions on humanity, upsetting seasonal cycles and harming ecosystems and water supply, thereby affecting agriculture and food production in a number of ways. Extreme weather events such as thunderstorms, heavy winds, and floods devastate farmlands and can lead to crop failure. As weather becomes fiercer and storms increase in frequency and intensity, it poses a significant impact on global and regional food production of both stable food and cash crops performance in tropical sub-humid climatic zone. However, the extent and nature of this impact still remain uncertain. In this study, records of ginger yield and rainfall in Kachia Local Government Area of the southern Kaduna area of Kaduna State, for a period ten years (2001-2010) were evaluated. Onest and cessation equation was adopted to derive the onset and cessation dates as well as the length of rainy season. Trend lines and linear trend equations were fitted to show the magnitude and direction of rainfall effectiveness indices and ginger yield. Correlation analysis showed that there is a relationship between the rainfall effectiveness indices and ginger yield. The results of the study showed that the trend in onset dates ($y=1.5939x +42462$), cessation dates ($y= 0.384x + 41916$), length of rainy season ($y=2.8424x +79.267$), annual amount of rainfall ($y=18.429x + 1635$) and ginger yield ($y=0.2721x + 7.8733$), were at increase. The correlation coefficient (r) between onset date and ginger yield ($r=0.34$) showed a strong positive relationship, cessation dates and ginger yield ($r= -0.20$) showed a negative relationship, length of rainy season and ginger yield ($r=0.38$) showed a positive relationship and the annual amount of rain and ginger yield ($r=0.19$) showed a weak positive relationship. Based on these results, the study suggests that ginger yield in the study area is high at early onsets and longer rainy seasons.

Key words: Ginger yield; Rainfall variability; Onset and cessation dates; Length of season

INTRODUCTION

Agriculture is one of the most weather sensitive human socio-economic activities substantially affected by climate variability and change globally (Adamgbe and Ujoh, 2013; Lalego *et al*., 2019). Climate change and climate variability are projected to contribute to increased drought episodes, food insecurity, irreversible decline in herd sizes, and deepening poverty (Ayanlade *et al*., 2009). In the Sub-Sahara African region, where 63% of the population continues to depend on rain fed agriculture, climate variability and change remain the major challenges hampering agricultural productivity, with direct influence on the quantity and quality of production (Sani and Chalchisa, 2016; Fadina and Barjolle, 2018). Africa is one of the most vulnerable continents to the current climate variability with strong economic impacts (Mustapha *et al*., 2012). This vulnerability is accentuated by developmental challenges such as endemic poverty, ecosystem degradation and limited access to capital, markets, infrastructure and technology (Juana *et al*., 2013; Fadina and Barjolle, 2018). Also, the events of climate change and variability lead to substantial losses of both crop and livestock causing agricultural activities to be at high risk, unattractive and unbeneficial to the majority of small-holder farmers (Assoumana *et al*., 2016; Gebreeyesus, 2017). Hence, Climate determines whether or not rain fed agriculture will be feasible and the type of crops that can be successfully cultivated in a given area (Omonijo, 2014).

Rainfall variability has been defined as the variations in the mean state and standard variation of the occurrences of extremes of rainfall on all spatial and temporal scales beyond that of individual precipitation events (Odjugo, 2010;

ISSN: 2814-0508

Atiyong, 2018). Theoretically, there are three different forms of rainfall variability namely spatial, inter-annual and intra-annual variability (Ayanlade *et al*., 2009). Spatial variability is the differences in total rainfall received between places structurally located within a given region, Inter-annual rainfall variability is the annual deviation from long-term averages or the differences in rainfall between years, while intra-annual rainfall variability refers to the distribution of rainfall within a year. Since Nigeria's agriculture is predominantly rain-fed, agricultural production is therefore heavily dependent on the seasonal characteristics of rainfall which has been shown to diminish in amount and duration as one move from the south to the northern part of the country (Sanni *et al*.,2012; Atiyong, 2018). Intraseasonal and interannual variability methods have been employed to monitor rainfall patterns in rainy seasons in the subhumid areas of Africa and to assess the potential threat of rainfall variability to food security (Kyei-Mensah *et al*., 2019).

Nigeria is a tropical country characterized by alternating dry and rainy seasons; with the annual rainfall less than the amount of the water that a crop would require to transpire during the growing season (Hamzat *et al*., 2017). Rainfall variability from season to season therefore adversely affects the sustainability of a variety of agricultural crops grown in Nigeria, particularly in the northern part of the country, which results in low productivity (Yunusa *et al*., 2017). Notably among such water loving crops is ginger. Ginger (Zingiber officinale Roscoe) is a herbaceous perennial crop, grown as an annual crop for its spicy underground rhizomes, which contain volatile oil, fixed oil, pungent compounds, resins, starch, protein, and minerals (Fumen, 2003; Onu and Simonya, 2017). Grown mostly in southern Kaduna Sate, the traditional home of ginger in Nigeria (Ayodele and Sambo, 2014), ginger requires an annual rainfall of 1500mm or more and a rainfall duration well distributed between 2 and 4 months for sustainable and higher yield (Atiyong, 2018).

Studies have been conducted on the changing rainfall patterns by many researchers notably, Abaje *et al*. (2010), Abaje *et al*. (2015), Leonard *et al.* (2015), Mkonda and He (2017), Yunusa *et al.* (2017), Murtala and Abaje (2018), Kyei-Mensah *et al*. (2019), among others. Results of these studies show that there is an annual change in the occurrences of wet and dry season regimes in Sub-Saharan Africa, annual decadal and inter decadal variations in rainfall and a general decline in rainfall amount in the West-African sub-region, particularly Nigeria. The variability in rainfall which may result in either a decrease or increase in the rainfall trend in different regions of the world have resulted in reduction of water levels or total dry up of some perennials and seasonal rivers and lakes (Atiyong, 2018). Nigeria's agriculture has been observed to largely depend on climate to function and that precipitation, solar radiation, wind, temperature, relative humidity and other climatic parameters affect and solely determine the global distribution of crops, livestock as well as the productivity and sustainability of agricultural lands (Aderibigbe, 2016).

Although, it may seem as if there is little or nothing could be done to minimize variability in rainfall since most of its causes are natural, there is need for in-depth study and understanding of spatio-temporal rainfall variability as well as its significant impacts on crop yield. It should also be noted here that, in spite of great advancement in the understanding and dealing with the problem of rainfall variability impact on crop yield at the international level, awareness and concern for the problem at national and local levels remain poor or in some cases non-existent (Ayanlade *et al*., 2009). This research work, therefore, attempts to look at the rainfall variability impact on ginger yield with particular reference to Kachia Local Government Area of Kaduna state, for a period of ten years (2001-2010)

MATERIALS AND METHODS

Data Collection

Data and information for this study were obtained between the months of June and August, 2016 from verbal questions to farmers and use of secondary sources. The secondary data on average rainfall and ginger yield for the study area (Kachia LGA) were obtained from two sources; climatic data on rainfall for a period of 10 years (2001-2010) and ginger yield for the same period, from the Department of Hydrology Hydrology (Meteorological Unit), Kaduna State Water Board and Kaduna State Agricultural Development Project (KADP) respectively.

Data Analysis

Data Analysis Linear regression was used to determine the linear trends of rainfall and ginger yield in order to compare people's perception of climate change and the observed change (Atiyong,

ISSN: 2814-0508

2018). The formula for the linear regression is given as:

$$y = a + bx \quad (1)$$

Where, a is the intercept of the regression line on the y-axis and b is the slope of the regression line. The values of a and b were determined.

To further examine the nature of the rainfall trends, the Standardized Anomaly Index (SAI) was used. It provided an area-average index of relative rainfall yield based on the standardization of rainfall totals. Similarly, the relationship between rainfall and ginger yield in the study area was tested using Pearson's product moment correlation coefficient.

Both data were transformed to a common base [log 10]. The rainfall data was segregated into specific rainfall effectiveness indices such as Onset, Cessation and Duration of Rainy season and were derived as adopted by Walter (1967). To examine the trends, Onset and Cessation dates, annual rainfall, length of rainy season and ginger yield, were subjected to trend lines and fitted linear trend line equations. Each of the parameters was plotted graphically to show the direction and magnitude of impact of change on the parameters in the area. Correlation analysis was used to show the relationship between the rainfall effectiveness indices and ginger yield, using the statistical package for social scientist (SPSS) software.

RESULTS AND DISCUSSION

Table 1 shows the precipitation parameters (Annual rainfall, Onset Date, Cessation Date and Length of rainy season) and ginger yield

Table 1: Rainfall and ginger yield data analysis

Year	Annual Rainfall (mm)	Onset Dates	Cessation Date	Length of rainy Season Days	Ginger yield (Tons/ha)
2001	983.47	11th April	24th September	83	8.20
2002	1474.92	10thApril	12th November	61	8.50
2003	1814.76	26th March	29thOctober	117	8.50
2004	1684.09	17th April	25th October	99	8.50
2005	3279.11	16th March	22nd October	89	9.20
2006	1745.23	22nd April	18th October	94	10.00
2007	1620.23	16th April	16th October	93	10.00
2008	1675.5	23rd April	15th October	88	10.10
2009	1568.1	15th April	24th October	112	10.70
2010	1517.95	17th April	22nd October	113	10.00

Annual Rainfall Amount

The analysis in Table 1 shows that the highest observed annual trend of rainfall amount within the study period was 3279.11 mm in 2005, while the lowest amount was 983.47mm in 2001. This result conforms to the report of NEPC (1999) which maintained that ginger produces well at rainfall of 1000-1500mm distributed evenly over 6-8 months.

Onset Dates

The result shows that the rainy season started as early as 16th march in 2005 and the latest onset date was 23rd April 2008 with an average onset date of 11th April.

Cessation Dates

The termination of the rainy season as shown in table 1 shows that the end of the wet season was earliest in 2001, on the 24th of September while the 12th of November, 2002 marked the latest termination date with average cessation date of 20th October.

Length of Rainy Season

The result also shows that the length of the rainy season generally falls between 80- 120 days with the average of 95 days each year. The longest wet season recorded during the study period was 117 days in 2003 and the shortest duration was 61 days in 2002.

Ginger Yield

Ginger yield as presented in the analysis shows that the largest ginger harvest was recorded in

2008 a production of with 10.10ton/ha while the least harvest was 8.20ton/ha in 2001.

The result in Figure 1 indicates a late onset. The linear trend line equation (y=1.5939x +42462) shows that the onset dates are on the increase thus, implying delay in the commencement of ginger cultivation therefore risking effective production/

Trends of Precipitation Effectiveness Indices and Ginger Yield

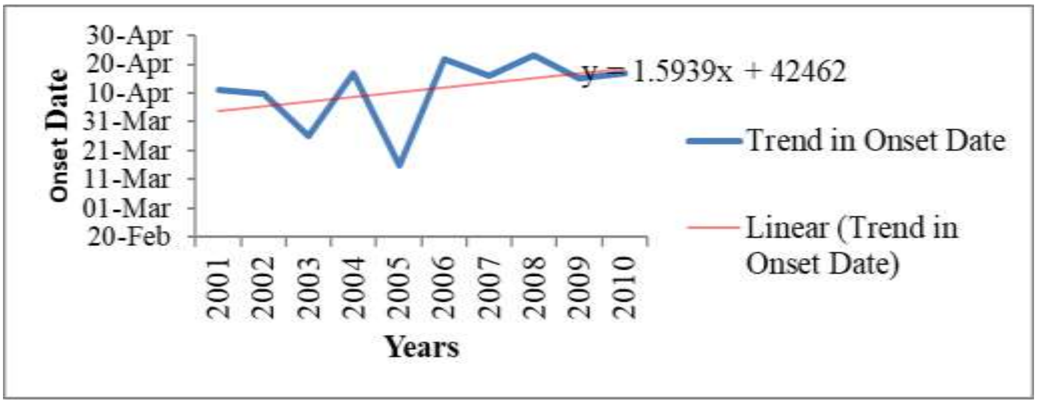

Figure 1: Trend in onset date

Trends in Cessation Dates

The cessation dates of the rainy season in the study area as presented in Figure 2 shows that there was an early termination in September, 2001 a very late termination in November, 2002. The linear trend line equation (y= 0.384x + 41916) shows increasing trends of cessation dates. This trend suggests a leverage for optimum ginger yield as the late cessation of rain may compensate for the late onset.

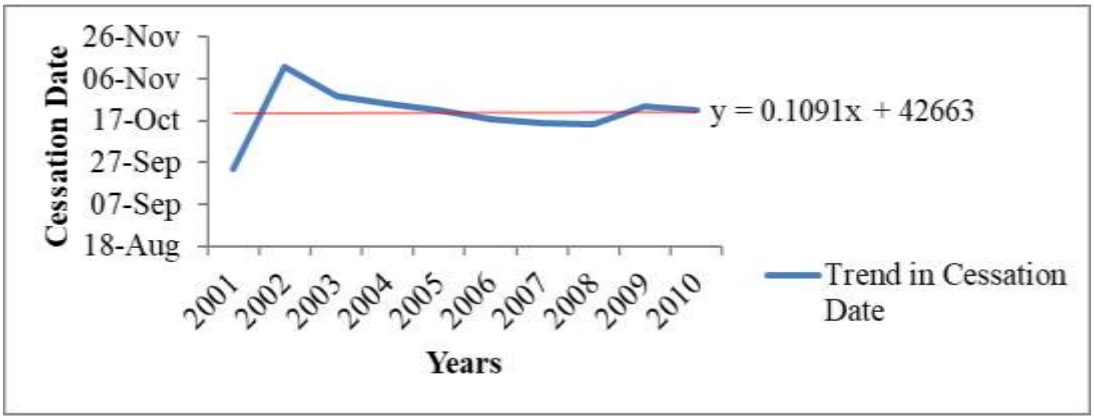

Figure 2: Trend in cessation date

The analysis in Figure 3 shows that there was a very short period of rainy season in 2001 and 2002, while the longest wet season was experienced in 2003. The linear trend line equation (y=2.8424x +79.267) show increase in length of wet season especially from 2008-2010. This trend implies a great chance for higher yield in ginger production as the requirements tend to be met through a longer rainy season.

Trend in Annual Rainfall

The result in Figure 4 shows that the lowest amount of rainfall received within the study period was in 2001, it increased until the highest amount was recorded in 2005. The amount fell in 2006 through 2010. Conversely the linear trend line equation (y=18.429x + 1635) indicates an increase in rainfall amount. This trend shows a consistency in the increase of rainfall amount, thereby ensuring security in water requirements of ginger.

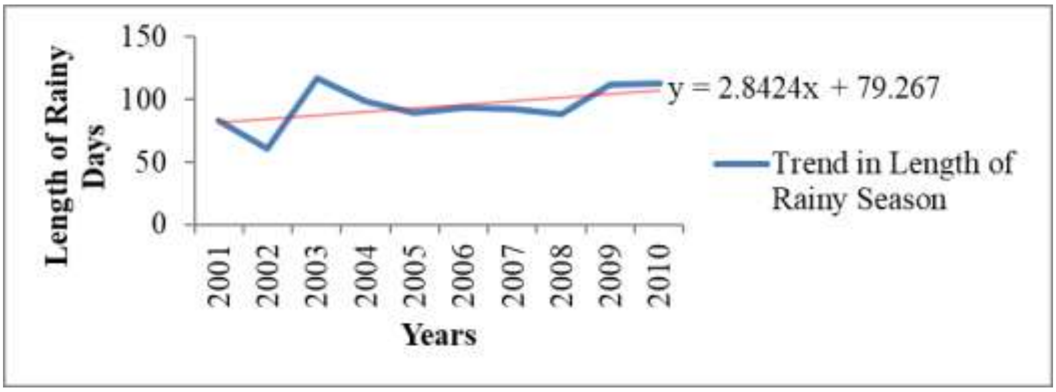

Figure 3: Length of rainy season

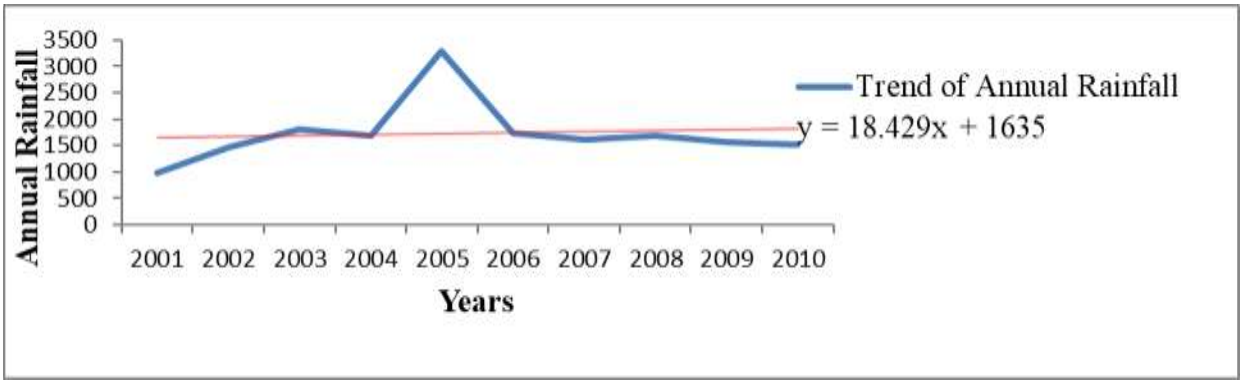

Figure 4: Trend in annual rainfall

Trend in Annual Ginger Yield

The result presented in Figure 5 clearly indicates an increase in the annual yield of ginger within the study period. While the least yield was recorded in 2001, there was increase in yield through to 2010. The linear trend line equation (y=0.2721x + 7.8733) confirms the obvious fact of an increase pattern.

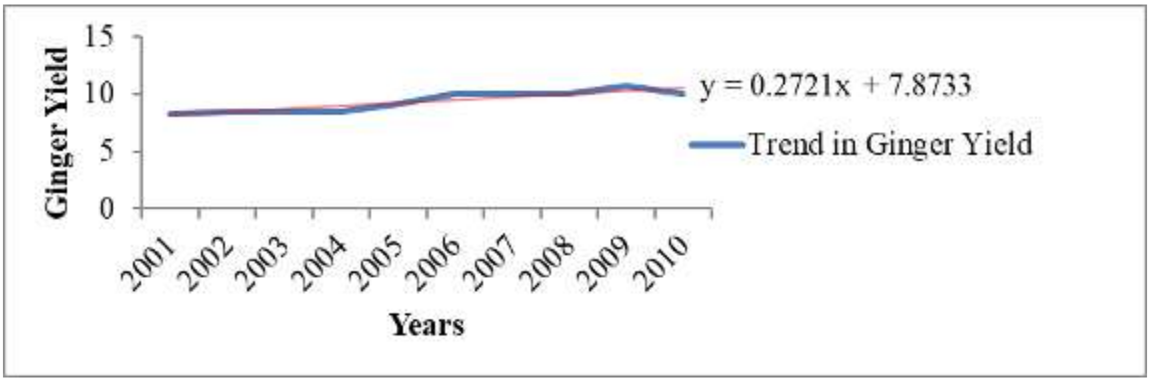

Figure 5: Showing trend in annual ginger yield

The Relationship between Ginger Yield and Rainfall Effectiveness Indices

The correlation values in Table 2 shows that there is a weak positive relationship between ginger yield and the annual amount of rainfall (r = 0.19) in the area. The onset date shows a strong positive relationship (r = 0.34) with the yield of ginger implying, the earlier the onset, the better chances of higher yield. The cessation date shows a negative relationship (r = -0.20) with the yield of ginger implying that if the rains terminated at earlier dates it will hamper optimum yield of ginger. The length of the rainy season on the other hand shows strong relationship (r = 0.38) with ginger yield. This means that, increase in the yield of ginger is encouraged by increase in the length in raining season.

Table 2: Correlation matrix of ginger yield and rainfall indices

Parameters	R-value
Annual rainfall	0.190
Onset date	0.335
Cessation date	- 0.198
Length of rainy season	0.383

CONCLUSION AND RECOMMENDATIONS

The study has shown that there is wide variability in onset and cessation of growing seasonal rainfall with a negative trend with upward rising of temperature in the study area, which has huge implications in soil moisture, potential evapotranspiration, and heat stress on crops. Consequently, the variations in rainfall pattern have had enormous impacts on ginger yields. Although cessation, duration and amount of annual rainfall influenced the yield of ginger, the major determinant of the yield variability was found to be the onset date of the rainy season. This is partly due to the fact that farmers are less informed and are only motivated by the commencement of the rains which cause them to begin planting late. This affects the growing period of the crops, as the wet season often comes to the end while the crops are still growing thereby resulting in lower yields. To minimize the effect of rainfall variability and enhance ginger yields in the study area and Kaduna state, at large, below are some suggestions:

i. The National Meteorological Agency (NMA) should provide forecasts of onset and cessation of growing season in all the 23 local government areas of the state. At present, the weather forecast in Nigeria is lacking. The forecast has not been able to give precise rainfall onset, cessation, and its impact on crop yields. Such information could guide farmers, agriculture extension officers, and crop breeders on the type of adaptation strategies to initiate and to enhance crop yields and food security in the country.

ii. The national and county governments should sensitize farmers on climate/weather variability and monitoring of crop-climate relationship in the area in other to achieve improved crop yield.

iii. Irrigation to supplement crop water requirements should be promoted.

iv. In view of high correlation and maximum temperature, crops that are tolerant to heat stress should be bred for farmers in the study area.

ABSTRACT

Coffee was introduced to Nigeria around 1859 and is mostly cultivated in the lowland areas for Robusta (Coffea canephora) and Highland areas for Arabica (Coffea arabica). Apart from its health benefits, coffee has contributed to Nigeria economic growth as one of the major export crops. However, this contribution has diminished over the years due to poor quality of planting materials, soil quality, land acquisition, bean quality, unstable and unfavourable government policies which result in poor marketing. These had adversely affected the livelihood of coffee farmers and eventually led to abandonment of the crop. However, CRIN research efforts have produced high yielding compatible coffee clones from 3 Robusta varieties {Niaoulli (M10), Java (T1049) and Quillou (C90, C36 and C111)} which have resulted in increase in coffee yield from 500-1360kgha^{-1}. Efforts on multiplication of improved planting materials, sensitization of farmers' interest to establish new plantations, development of improved rehabilitation techniques are recent ways of increasing production. Nigeria has over 1.5million ha that is suitable for coffee production and 13 of the existing 36 States in Nigeria are commercially suitable for coffee cultivation. Though majority of farms are old, moribund and unproductive, markets are also unorganized. The current policy of the government to diversify the economy is a strong opportunity to arouse farmers' interest, while influence of climate change is a factor that deserves urgent attention. In view of the strengths and opportunities that abound in coffee production, the current administration should give coffee the pride of place in her diversification policy.

Key words: Climate change, coffee yield, foreign earnings, rehabilitation, sustainable production

HISTORY

Coffee is a member of the large Rubiaceae family, within which it constituted the C*offea* genus with different species. Notably among the species in Nigeria are *Coffea Arabica* and *Coffea canephora* (Robusta). Coffee was introduced to Nigeria in the colonial times around the same time as cocoa in 1859. Coffee is one of the most important export crops for Africa and Latin America countries. It is the 2nd traded commodity in the world after oil and the 2nd consumed liquid after water as eight million tons is consumed each year globally.

In Nigeria, Coffee occupies a significant area of land covering about 270,000 hectares of land with an average production of 174000 metric tons yearly. It is commercially grown in 13 States namely; Taraba, Kogi, Ondo, Oyo, Ogun, Osun, Edo, Kwara, Ekiti, Adamawa, Plateau, Abia and Cross River as shown in Figure 1. However, Coffea Arabica is grown only on Mambilla Plateau and Obudu hills while Robusta is grown in low altitude.

The earlier production was reflected in the export figure of 1896 as 5.5 metric tons, 25.5 mt in 1901(Williams, (1989). It was reported by World Coffee Press 2015, that the Nigeria coffee industry has been on a steady downward slide since mid-1960s, from a production of 100,000 bags in 1964 to almost zero 2014.

IMPORTANCE

Coffee as a beverage is the second most consumed liquid after water in the world and the second important crop commodity after cocoa traded in the world market. Once upon a time, the trade in Coffee created numerous millionaires. It is on record that Kabba Coffee was noted in the world market in the 60s and released markets, middlemen and Coffee merchants in many parts of the country. The Coffee trade was source of livelihood to the farmers before the liberalization of the marketing board. Many Coffee traders built numerous houses and they were able to send their children to places such as the United Kingdom to study. The markets popularity grew in leaps and bounds. With respect to international trade, Coffee products are exported to Congo Brazzaville, Gambia, United States of America (USA), Saudi Arabia, Germany, United Kingdom, Pakistan, Turkey, France, The Netherlands, Cote d'Ivoire, Chad and Senegal.

Similarly, the contribution of coffee to export trade in Nigeria has declined over the years due to low levels of output and export. It is recognized that poor marketing and inadequate technical know-how of the management practices are the major factors responsible for the poor performance of the coffee sector in Nigeria. However, there is a growing demand for coffee globally and low stocks, supply constraints and new price floors are also prevalent. There are great opportunities for Africa and especially Nigeria by tapping from the success story in Vietnam and Brazil.

The health importance of coffee cannot be overemphasized. The biggest source of antioxidants in the western diet, it helps in burning fat, it guards against gout, it improves energy level and make you smarter and alert, improves physical performance, may lower the risk of type II diabetes, can protect you from Alzheimer's disease and dementia, may lower the risk of Parkinson's, has protective effect on liver, lowers the risk of some types of cancer, does not cause heart disease and may lower the risk of stroke, a cup of coffee contains essential nutrients: Riboflavin (Vitamin B2) 11% of the RDA, Pantothenic acid (Vitamin B12) 6% of the RDA and Manganese and Potassium 3% of the RDA.

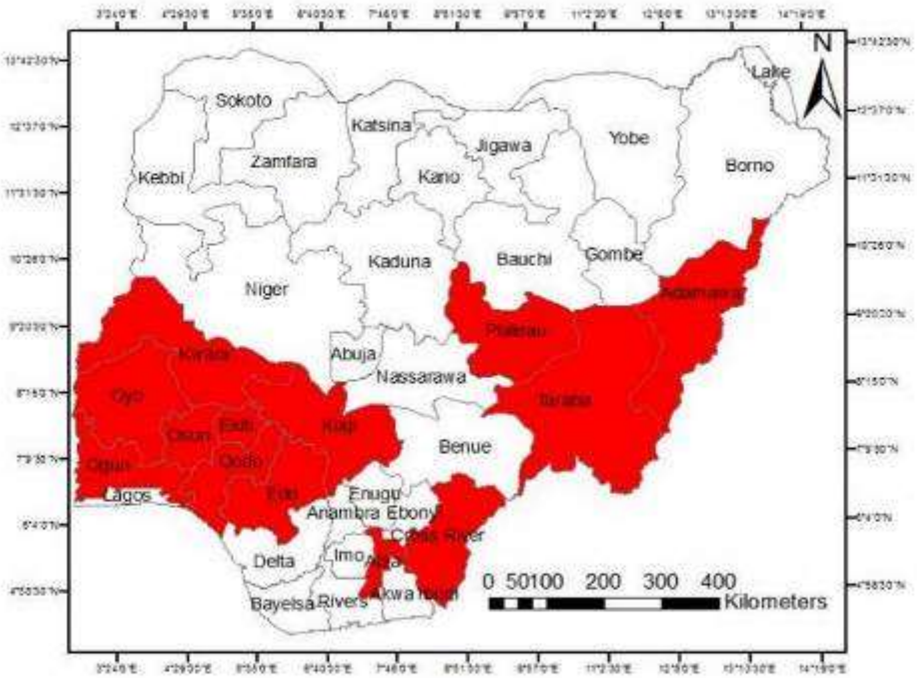

Figure 1: Showing Coffee growing area (CRIN, 2014)

PROBLEMS

The problem of coffee production in Nigeria started in the 60s, when the crude oil was discovered and by 70s when the oil boom started, the Federal Government started shifting their attension from Agriculture. This resultantly resulted into farm abandonement, by youth who have the strength for farming, leaving aged farmers on the farm. In the 70s, Commodity board was also proscribed leading to the liberalisation of the price; a free for all marketer to bargain. However, as if these are not enough; the enterprise was faced with poor planting material, emmerging pest infestation, soil depletion that resulted in low yield. Coffee production undertake value addition to attrack good market, hence a good processing method is required to market a quality berry. Farmers are faced with problem of good processing method, while the influence of climate change is not in favour of farmers.

POTENTIALS OF COFFEE IN NIGERIA

Nigeria coffee was noted in the world market for its quality as this crop grows easily without or less use of chemical. Coffee is produced predominantly by the small scale farmers in the highland of Mambilla Plateau in Taraba state (Williams, 1998). In the world trade, Arabica coffee is of the greatest economic importance and account for 4% of export in Nigeria. According to The United States Department of Agriculture (USDA), Nigeria produced 35,000 bags of coffee in 2014,

ISSN: 2814-0508

representing an increase of 16.67% over the 30,000 bags produced in 2013. Coffee production in Nigeria peaked at 95,000 bags in 1964 and has been dropping steadily since 2000, remaining below 60,000 bags on annual basis. The stakeholders within the system have attributed the poor development to apathy which has caused Nigeria its membership position in International Coffee Council.

Amongst 95% of Nigerian coffee farmers, incompatibility problem has been observed to be a major factor limiting yield to 600-800/g/ha. This makes investment in coffee production less profitable (Omolaja, 1999). Omolaja (1999) observed that to mitigate this development, coffee berries selection from appropriate compatible clones is essential for establishment of polyclonal plantation that could yield about 2-3 tons per hectare.

World coffee exports amounted to 8.79 million bags in January 2015, compared with 8.77 million bags in January 2014 of which Brazil is leading in coffee export followed by Vietnam and Colombia (ICO, 2015). On a global scale, Nigeria is very much a minority player in terms of global export, this is however, mainly due to the fact that majority of the small scale farmers has lost interest in the cultivation of coffee. This stems from some production constrains in coffee such as poor market for Nigeria coffee, fire outbreak, poor policy, drought, poor processing, poor access to farm credits, low income from coffee among others.

Considering the climatic advantage, the country is blessed with and coupled with the ever increasing demand for coffee at the world market of which coffee ranks second after oil, coffee production in Nigeria can be increased tremendously to improve on the livelihood of farmers and increase the foreign earnings of the country.

Soil as a major factor of declining coffee production in Nigeria

The role of Cocoa Research Institute of Nigeria among other mandates includes research into all aspect of coffee production in the following area, Agronomy, Breeding, Entomology, Soil and Plant Nutrition, Pathology, processing /utilization, marketing and above all helping farmers to solve production problems (Carlos et al., 2015; Adejumo et al., 2005; USDA, 2015). Most crucial factors considered in crop production are the suitability of the soil (Ipinmoroti et al., 2013). Over the years, various findings have shown that, soil supporting coffee production in Nigeria Alfisol and oxisol for coffee canephora often referred to as lowland coffee mainly produced in the low laying areas of Nigeria underlined by acid crystalline rocks of basement complex with basaltic rocks of varied thickness (Daniel, 2009). While Ultisol is for coffee arabica (high land coffee), the soils are mostly underlined by granite gneiss (Obatolu, 2001), with soil and foliar critical nutrient established (Carlos, 2015). In respect of Coffee species, almost 99.9% of the farms are privately owned mostly planted in the fifties (Obatolu, 1999) presently overgrown, unproductive and uncared for as a result of dearth of market for their produce resulting in low yield farmer's pest and disease infestation cutting down them down to replace with arable and Tea in case of Arabica. The poor earnings, absence of infrastructures, old and low financial base has all to improper processing method - dry processing with none of the farmers attempting to wet process their products despite the fact that, it is the best method that produces high grade coffee. Over the years, research effort on rehabilitation of old farms have been carried out and recommended i.e. 30cm coppicing with paint coating of the coppiced surface. Currently, efforts are geared towards sensitizing and training of farmers on the rehabilitation methods, use of organic fertilizers in rejuvenation of old farms as well as fabricating of wet processing machines aimed at improving the quality of coffee produced in Nigeria.

INTERVENTIONS

Cocoa Research Institute of Nigeria has the mandate to improve coffee production through development of new cultivars, value addition and further dissemination to end-users. Sensitisation and campaign programs are going on in the growing areas to increase farmers' knowledge and farm practices through capacity building.

The intervention programme being proposed is to improve the livelihood and income of the Coffee farmers. This will come through the adoption of new improved varieties, training on Good Agricultural Practices (GAP) as well as increased value addition to Coffee export. The action plan will provide support to researchers, input suppliers, Coffee farmers, marketers, processors, pharmaceutical companies and many other users of Coffee either in its raw or pocessed form.

ISSN: 2814-0508

1. Provision of planting materials with respect to the species of interest. Arabica coffee (seeds and seedlings) and Robusta coffee (Cuttings and grafting).
2. Seed garden has been designed to increase the yield output of coffee production thereby increases the premium attached to the commodities. Seed garden is established on the compatibility evaluation of available varietes of Robusta coffee (*Coffea canephora*) in Nigeria, which will increase the yield output from the current 600kg/Ha to 1,360kg/Ha.
3. Selection and introduction of self compatible varieties of *Coffea arabica* which are rust resistance are currently established in the institute germplasm at Mambilla plateau, Taraba state. The seedlings are raised for collection from the farmers.
4. Hybridistion and mutation breedings to produce a hybrid and mutant variety are ongoing. This is to produce varieties that could withstand the imminent change in climatic condition.

RECOMMENDATIONS

1. Inter cropping of compatible clones has a resisted in yield of up to 1.3 metric tons per ha compared with yield range in Africa at 250-347 kg/ha (ACRN, 2001). Combined clone includes C111, C36, T1049 and M10 in an augmented design.
2. Rehabilitation of old/unproductive coffee farms by coppicing at 30 cm has led to improved growth and bean yield
3. Rehabilitation through improved chupon regeneration by grafting is presently encouraging (Famaye et al, 2015)
4. Alley cropping of coffee with some fast growing leguminous shrubs like leucaedea, cajanus, Albizia are also encouraging. The result is a pointer to cultivation of coffee on marginal soils thereby discouraging encroachment to the available forest lands in producing states

ABSTRACT

The standard plant spacing recommendation for cocoa over the years has been either 3.1m by 3.1m (1,040 stands/ha) and 3m by 3m (1,111 stands/ha). The existing spacing have not put into consideration morphological variations that might exist in the latest hybrids released by the Cocoa Research Institute of Nigeria (CRIN) relative to older hybrids. To project the likely field spacing for these hybrids, an experiment was initiated in December, 2020 with the cacao hybrids of TC1(A); TC2(B); TC3(C); TC4(D); TC5(E); TC6(F); TC7(G); TC8(I) and F3 Amazon (H) as control laid out in a Completely Randomized Design (CRD) in 3 replicates with a total treatment unit of 27. Polythene bags of 25cm by 12.5cm filled with sieved forest topsoil. 2 seeds were sown per bag and reduced to one after germination. Germination percentage was taken fortnightly for 4 weeks after sowing. Subsequently, morphological variables of height, stem diameter, number of leaves and leaf area were measured fortnightly as well. Morphology variation in terms of height, stem diameter and leaf area were noticed-there was stability in growth by 4-6 months in the nursery, an indication that the seedlings were physiologically mature for transplanting to the field. Destructive sampling done at 6-month period revealed no significant difference in shoot and taproot length while root wet weight and lateral root length were different($P \leq 0.05$). The lateral root length is in the order of 13.41cm (F3) >12.13cm (TC6) >10.33cm (TC1) > 10.31cm (TC4) >10.25 (TC8) > 9.55cm (TC3) > 8.9cm (TC7)>7.31cm (TC5) > 5.5 cm (TC2) revealing variation among the hybrids. This indicates the likelihood of different plant spacing (population densities per hectare) in the following order: 1,445, 2,710, 1,563, 1,447, 2,041, 1,230, 1,667 and 1,456 for TC1 to TC8 respectively compared with 1,040 or 1,111 stands/ha in F3 Amazon. These results have indicated higher densities for the TC series relative to what is obtainable in F3 Amazon. A field trial to validate these results is suggested.

Key words: Cacao, morphology, lateral root, hybrids, F3 Amazon, nursery, spacing.

INTRODUCTION

Cacao (*Theobroma cacao L.*) is a crop of global significance economically and nutritionally. It was believed to have been introduced to Nigeria by a native Chief Squiss Banego in 1874(Howes, 2010). The crop is a small to medium-sized tree of 8-10 m high belonging to the family Malvaceae (Naturland, 2000). It was reported to be of significance in food, beverage and pharmaceutical industries (Kumar *et al*, 2004). For a country like Nigeria it contributes the most in agricultural sector than any other commodity crops. Research interest is growing in compliance to good agronomic practices (GAP) as cultivation is expanding. Among the aspect of cacao cultivation that deserves research attention is optimization of plant population per unit area of land which is a function of spacing adopted for such crop. The ideal spacing in crops gives the best remunerative per unit area of land (Ayegboyin *et al*, 2020). Introducing new hybrids is lso an important consideration for yield optimization. However, getting the optimal spacing for the hybrids is critical to realising the genetical potential as access to sunlight, moisture and nutrients is critical (Khunba *et al*, 2021). Existing spacing for cocoa in Nigeria are 3.1m x 3.1m (1040stands/ha) and 3.0m x 3.0m (1111stands/ha). The eight new cacao hybrids released for farmers by CRIN since 2011 have not been evaluated for spacing differential (CRIN, 2011). These hybrids are genetically early maturing, high yielding, pests resistant, highly adaptable and of high bean quality(CRIN,2011). There is therefore the need to establish hybrid specific spacing for these new breeds to actualise their potentials. Since these hybrids varies in their morphological attributes viz: plant height, stem diameter, leaf area, taproot length and lateral root length. The latter especially may contribute significantly to likely spacing on the field. This study therefore intends to simulate the spacing for these hybrids based on their morphological performances especially the lateral root length in the nursery.

MATERIALS AND METHODS

This experiment was conducted from December, 2020 to June 2021 at the Central Nursery of the Cocoa Research Institute of Nigeria (CRIN). The experiment was a completely randomized design(CRD) consisting of eight cacao hybrids as treatments namely: TC1(A); TC2(B); TC3(C); TC4(D); TC5(E); TC6(F); TC7(G); TC8(I) and F3 Amazon (H) as the control treatment which were replicated three times giving treatment units of 27. Black polythene bags of 25cm by 12.5cm were filled with forest top soil and arranged on the nursery beds, watered and 2 seeds sown per bag and reduced to one at germination. The seedlings were watered every other day; Germination percentages were determined at fortnight interval for 4 weeks after sowing. Morphological data of plant height, stem diameter, number of leaves, leaf area were taken fortnightly. At the end of a 6-month period, destructive sampling was done with shoot and root wet weight taken, taproot and lateral root length measured. To estimate cacao spacing from the lateral root length of the genotypes, mathematical law of simple proportion was applied where lateral root length of the F3 Amazon was related to the recommended spacing of 3m x 3m(1111stands/ha). Result from this was used to generate spacing for the TC series. Data collected were subjected to Analysis of Variance (ANOVA) using SAS 2010 Statistical page and means separated using Duncan Multiple Range Test (DMRT) at P≤0.05.

RESULTS AND DISCUSSION

Table 1 reveals the percentage seed germination within four weeks after sowing (WAS), at 2WAS, TC 7 had attained 100% germination while germination of >60% was attained in the order TC1 (86.67%)>F3(80%)>TC4, TC1, TC8 (73.33%)>TC3(60%).The least as at 2WAS was in TC5 (20%) and TC2 (26.67%). By the fourth week after sowing 100% germination was obtained for TC1, TC3, TC7 and F3 Amazon(Control); 93.33% in TC4, TC6 and TC8 while the least was in TC2(80%) and TC5(73.33%). Tables 2 - Table 6 revealed morphology variation in terms of height, stem diameter and leaf area- there was stability in growth, an indication that the seedlings were physiologically mature for transplanting to the field by 4-6 months in the nursery (Naturland, 2021). The variation in leaf area confirmed the work of Lotode and Muller (1983) inherent genetic variation in cacao seedlings. At the end of a 6-month nursery period, destructive sampling was done with shoot and root wet weight taken as well as taproot and lateral root length measured. Also there was no significant difference (P≤0.05) in the plant shoots wet weight and taproot length while there were significant differences in the root wet weight and lateral root length. The lateral root length was in the order of 13.41cm (F3) >12.13cm (TC6) >10.33cm (TC1) > 10.31cm (TC4) >10.25 (TC8) > 9.55cm (TC3) > 8.9cm (TC7)>7.31cm (TC5) > 5.5 cm (TC2) revealing variation among the hybrids. Table 6 indicates the likelihood of different plant spacing (population densities per hectare) in the following order: 1,445, 2,710, 1,563, 1,447, 2,041, 1,230, 1,667 and 1,456 for TC1 to TC8 respectively compared with 1,111 stands/ha in F3 Amazon. Spacing in crops determines whether it is low or high density, 3m x 3m practiced in Nigeria is described as low density (Kamaldeo *et al*, 2003). These results have indicated higher densities for the TC series relative to what is obtainable in F3 Amazon. Our suggesting higher density planting is more genotype specific as against the recommendations of Ayegboyin *et al* (2020); Lin *et al* (1986) who suggested higher density planting for TC series in Nigeria and cocoa hybrid in Malaysia when they are not fully matured. TC2 as indicated in Table 6 can be planted at a projected spacing of 1.92^2 (2,710 stands/ha) based on its compactness in the nursery, ditto TC5 (2,041stands/ha and TC7 (1,667stands/ha). There was no significant difference in taproot length among the treatments though TC6 (23.15 cm) and TC5 (16.43 cm) had the highest and lowest taproot length respectively, this is an indication that the TC series can survive were F3 Amazon survives however TC 6 and TC 5 may survive dry spell better than others especially when there is irrigation in the dry season. Lotode and Muller (1983) had reported those plantations established through seeds/seedlings are inherently divergent in terms of growth habit, vegetative behaviour fruit characteristics and potential yield.

CONCLUSION

Root weight and lateral root length play a significant role in plant spacing and plant density per unit area of land. The lateral root length in this experiment is in the order of 13.41cm (F3) >12.13cm (TC6) >10.33cm (TC1) > 10.31cm (TC4) >10.25 (TC8) > 9.55cm (TC3) > 8.9cm (TC7)>7.31cm (TC5) > 5.5 cm (TC2) revealing variation among the hybrids. The following plant spacing (population densities per hectare) are recommended: 1,445, 2,710, 1,563, 1,447, 2,041, 1,230, 1,667 and 1,456 for TC1 to TC8 respectively compared with 1,111 stands/ha in F3 Amazon. Since plant spacing in cacao determines whether it is low or high density. These results have indicated higher densities for the TC series relative to what is obtainable in F3 Amazon especially TC2 (2,710 plant/ha) and TC 5(2,041 plants/ha). Field evaluation and validation of these results is however very important as a follow up study.

REMOTE SENSING AND GIS FOR FIRE BEHAVIOUR ON COCOA (*THEOBROMA CACAO*) PLANTS AT THE COCOA PLANTATION AT THE COCOA RESEARCH INSTITUTE OF NIGERIA, IBADAN, OYO STATE

Asunbo, O. I.
Cocoa Research Institute of Nigeria, Idi-Ayunre, Ibadan. Nigeria

ABSTRACT

Fire is regarded as an ecological disturbance which is mostly anthropogenic. Cocoa plantation is being razed yearly with fire, thus leading to enormous reduction in its production and biodiversity losses. Globally in the tropics, about 98 million ha of forest are affected by fire, and damage caused to cocoa plantation is very devastating and control is difficult. Therefore, the use of remote sensing and also GIS for fire behavior at the Cocoa research institute of Nigeria, Ibadan (CRIN) were assessed. This study was carried out at CFC cocoa plantation section at CRIN, 2021. The digital 20m contour interval [also known as Digital Terrain Model (DTM)] was used to obtain the elevation, slope and aspect using ArcGIS for basic calculations. Aspect map shows direction (i.e. how slope direction influences fire behavior) and also, degree of steepness of the slope, and each category is symbolized using different colours (red, orange, yellow, gray, green), degree of slope is mapped with saturation of colors (steeper slopes are brighter). ArcGIS 10 was used to identify separately time of each fire from 2010 to 2021 to estimate the fire frequency in a space of twelve years and time of last fire (from the Landsat images) was determined. From the maps obtained using the ArcGIS, contours on the elevation shows layers which was depicted by different colours to shows the levels (flat or steep), indicating also that the areas of fire burns, irrespective of their elevation. The lowest elevation was depicted in green colour, and ranged between 131-133 meters above sea level (MSL) and highest in white colour from 148-150 MSL respectively, and no obvious ridges and valley seen. The degree of slope was represented from 0-90º. The lower the values the flatter the terrain is (in green) and the higher values, indicates the high degree of steepness in the area (in red) which likely to experience intense fire burns. The aspect map indicated the direction of the slope in a clockwise direction from the north (0-360º) and back to north and areas with no slope and are flat was assigned a -1. However, the imagery generated indicated eleven (11) fire outbreaks had occurred from the year 2010 to 2021 on the study site. This study attempts to integrate the use of remote sensing and GIS to monitor fire behavior on cocoa plantation. Movement of the slope in the northern direction indicates that the area gets more sun, thereby making the soils and litters very dry and predisposed to high fire intensity than the southern or eastern slopes. These findings will be a baseline for further research, also helps to identify high risk areas for better prevention and management to reduce losses to fire outbreaks.

Key words: Forest fire, Ecological disturbance, Remote sensing, ArcGIS 10, Elevation, Slope

INTRODUCTION

Fire is an ecological disturbance that affects the ecosystem functions (i.e. irregular destruction of the ecosystem), composition and structure thereby causing alterations in the ecosystem. However, fire has an ecological role in the ecosystem, it influences the development of the plant community, nutrient availability and biological diversity. Hence, fire is considered necessary for vegetation succession. Uncontrolled fire can cause serious adverse effects to the ecosystem at large. Most fire is caused by accidental introduction through anthropogenic sources which have a sweeping effects on the vegetation, plant arrangement, and likely to reduce plant bulk in subsequent years. Fire has been known to change landscape structure (species composition) thus affecting diversity of plants and animals (micro and macro) in the ecosystem (Bowman *et al*., 2016).

The introduction of remote sensing and GIS techniques in fire management in cocoa production is a new concept for proper planning to help reduce the risks of fire occurrences in cocoa plantations, and also for monitoring the process of restoration. GIS is used to capture and analyse information of the burnt area and its environs and it also displays geographic facts visually. ArcGIS presents the data in maps for quick evaluation (which involves the cause of the fire, how or factors responsible for the spread) and state of the vegetation after the fire. Globally in the tropics, about 98 million ha of forest were affected by fire in 2015 and Africa and South America having about two third of the burnt area (about 65 million ha burnt). In Nigeria, reports of International Forest Fire News (IFFN, 2006) reported that Cocoa, and other cash crops were seriously destroyed by wildfire. Although, the information on statistics of fire records are scare. Geomatics (2000) also reported high fire outbreaks in the dry season in Nigeria which is characterized by high temperature, low humidity, high combustibles and wind. In the Savannah, dry season is between October-April, and November-March in the rainforest (Balogun *et al*., 2004). However, the peak for the two ecological zones is January to February. Rainfall and relative humidity are very important factor to determine the intensity of fire burns. A change in this pattern due to climate change could result to wildfire outbreak in Agricultural forests. Fire is without any doubt a major challenging global concern. A change in the climatic factors plays an important role in burning (both in direct and indirect ways), hence it determines when and how fire burns.

It is no new news that fire is a big threat to cocoa production, effective prevention of fire from gaining access to the cocoa plants is of paramount importance both on the long or short term basis. Hence this informs the objective of this study to generate elevation, slope and aspect maps of the burnt areas to monitor fire behaviour in the areas, also using remote sensing and GIS to monitor fire behavior on cocoa plantation at the CRIN.

STUDY SITE

The study was conducted at the Cocoa Research Institute of Nigeria headquarters, Ibadan (CRIN), on CFC cocoa plantation section. CRIN is in the rainforest zone, located on latitude 7º 30'N and longitude 3º 54'E at an altitude of 200 m above sea level (Mokwunye *et al*., 2011; Azeeze, 2016). Annual mean temperature is about 25º, rainfall 1200mm and relative humidity 76% (Ajewole *et al*., 2010). On the 18th February, 2021, the CFC cocoa plantation plot at CRIN was razed by fire, fire got about 60% (4.22 ha) of the plot which is about 7 ha area of land. However, the remaining 40% was just under fallow, the fire virtually got all the cocoa plantation in that area.

MATERIALS AND METHODS

A spatial analyst was engaged to generate elevation, slope and aspect maps of the study area, using the digital 20m contour interval [also known as Digital Terrain Model (DTM)] and ArcGIS 10 for basic calculations and the detailed information gathered as follows:

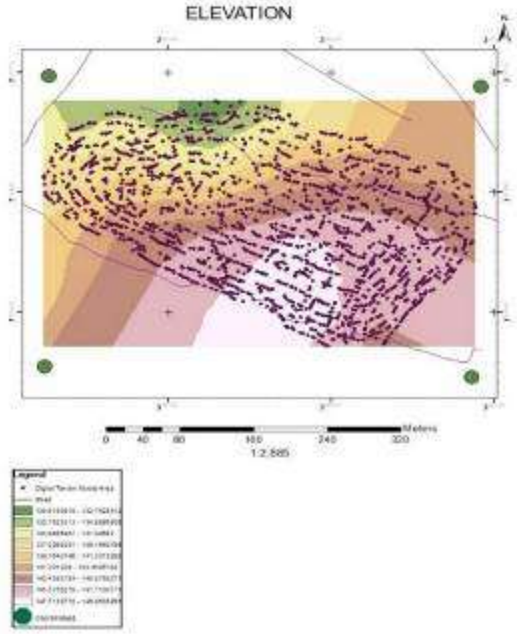
From existing data sets, the Arc GIS 3D was used to generate new surfaces. Surfaces which was viewed as normal grids or as TINs (Triangulated Irregular Networks). After the surface data has been created, it can be utilized for future analysis, such as enhanced visualization, such as creating a shaded relief, or more complex analysis. The contour, slope, and aspect maps are all useful data that was generated using the Arc GIS 3D. These enable us to efficiently relate our data to real-world elevation and examine how these various surfaces may affect the ecosystem.

RESULTS AND DISCUSSION

Elevation

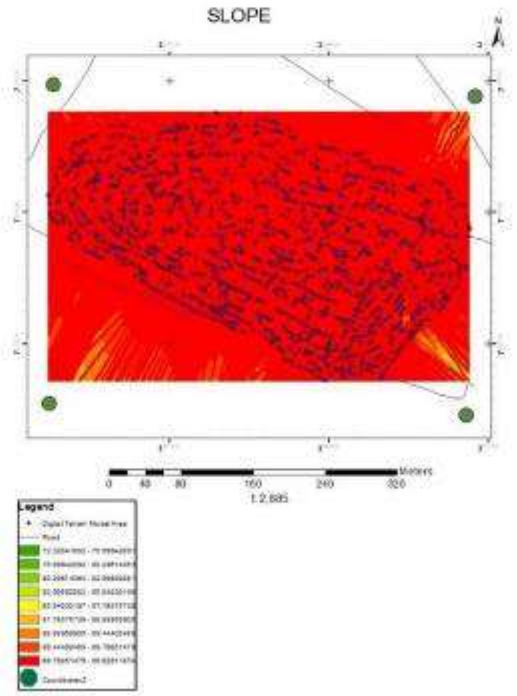
The polylines on the elevation map represents locations with same magnitude of data sets. The contours show locations of same values (as shown below). This shows the steepness of an area which also infers the rate of spread of fire in the plantation. At the CFC, ranged between 131-133 meters above sea level (MSL) and highest in white colour from 148-150 MSL respectively. However, the elevation of a given area is associated with temperature, moisture in form of rainfall and wind which in turn influences the vegetation. In observing fire behaviour, areas with high altitude have less severity of fire intensity.

ISSN: 2814-0508



Slope

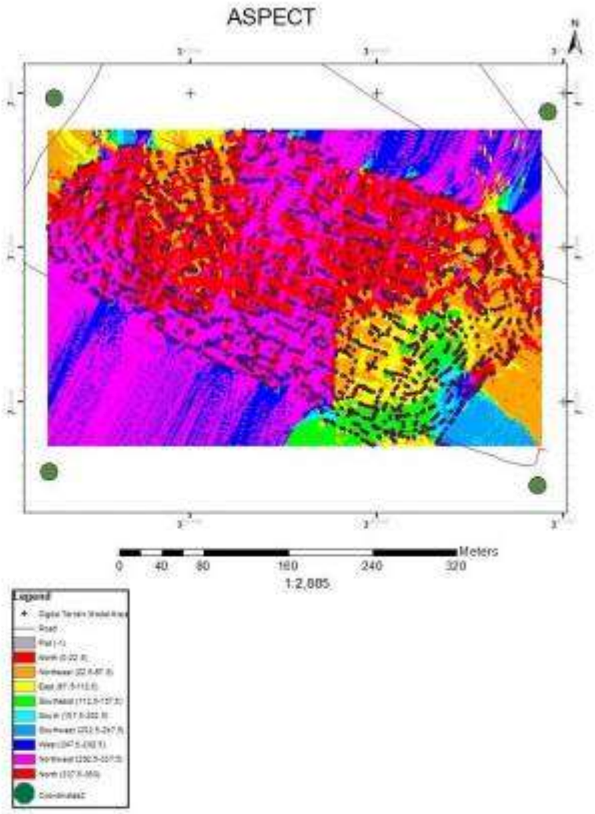
The slope is calculated in degrees of percentages. It identifies the maximum rate of change in a given area. Generating a slope map after a fire outbreak helps to suggest the areas that will be susceptible to runoffs which could result to erosion (as indicated below). However, the degree of a slope is between 0-90º, and a lower value indicates a flatter topography and higher values indicates degree of steepness. These two parameters influence how fire is spread out during an outbreak. Fire tends to move faster up the slope and slower down the slope. Also, rate of fire is likely to increase in areas with high slope values which is associated with strong wind effects.



ISSN: 2814-0508

Aspect

Aspect indicates the direction of slope which correlates with the amount of sun that reaches it. It is expressed in degrees from 0-360 measuring clock wisely from the north (shown below). Areas of no slope has a -1 value, i.e. there is no data available. Areas facing the South experiences more sun, high temperature, low rain and high wind at a direct angle than the North facing. Hence, vegetation in the south facing slopes are drier. However, the north facing slopes gets sunlight at a lesser angle such that a little sun is spread out at a large expense of area. These factors influence the high fire outbreaks in such areas.



Fire Frequencies (2010-2021)

Fire is a major concern and a big challenge to plantation management globally. The outbreaks of fire recorded at the CFC cocoa plantation from the year 2010 to 2021 sums up to twelve (12) with the February 2021 fire having the most devastating effect (60% burnt). This virtually implies that fire occurs every year since 2010. Fire outbreaks is favoured subsequently by increased temperatures, relative humidity and wind thus leading to global warming a serious global challenge. Also, this has also determined the loss of species diversity in the area (loss of plant species) and introduction of some invasive weed species (vegetation mapping results in subsequent paper) and risk of soil erosion.

CONCLUSIONS AND RECOMMENDATION

This research work was initiated immediately after the fire incidence in February 2021 at CRIN. Remote sensing used provided the vegetation data, while GIS processing made it possible to create fire maps to monitor fire behaviour. This work will serve as a baseline to further research on how best to manage and reduce fire outbreaks in the cocoa plantation.

ABSTRACT

This study assessed the level of involvement and economic valuation of tomato value chain with distinct reference to gender characteristics in Akinyele Local Government Area, Oyo State Nigeria. The study used a structured questionnaire for data collection from a survey of 160 tomato households in Akinyele LGA of which 96 were women and 64 were men. Descriptive and gross margin analyses were carried out to analyze the study. According to the findings, women played a leading role in marketing, processing, packaging and publicity/promotion while men played a leading role in production and distribution value chain activities, as this development favours respective tomato households' economic welfare accordingly. The study therefore recommended among other things that there should be robust public-private collaboration with relevant tomato value chain stakeholders so as to improve processing, packaging and promotion of tomato.

Key words: tomato, gender, value chain, economic, valuation

INTRODUCTION

The role of women in agricultural production especially in sub-Sahara Africa cannot be over emphasized giving credence to their mode of managing their own farms as well as providing their labour to their husband's fields. Irrespective of the prevalence of a gender bias regarding their access to resource, women involvement remains an indelible factor to be reckoned with as far as agricultural development is concerned. All over the world, gender issues in the development of agriculture and women's role and contribution to agriculture have taken a central stage among scholars, professionals and policy makers. Despite the wide range of literature available, the importance of agriculture to the economic development in Africa and the critical role that rural women play within this sector still constitute an attractive research agenda (Ndoye, 2010).

In Sub-Saharan African countries, where agriculture provides food for the majority of the population, a strong growth in agriculture is needed to drive their process of economic development. Therefore, agriculture must be the leading sector for overall growth, poverty alleviation, and the reduction of income disparities. Given this background, promoting agricultural production across board is essential. Above all, considering the far-reaching fluctuations in the world food situation that is ravaging Africa more than any other region, a deserved attention should be given to the agricultural supply chain, both for food crops and market-oriented crops. In fact, cash crops, with high added value products like horticultural products, offer opportunities to boost the agricultural growth in developing countries like Nigeria, where horticulture is a key element of the agricultural sector.

However, the key role of women in the agricultural sector, calls for more gender-sensitive approaches and policies particularly with respect to horticultural crops along its value chain in Nigeria. Value chain encompasses full range of activities from the production, distribution, processing, transporting and value addition, finally to the end consumer. Tomato is one of the most important popular vegetable crops in Nigeria. The major problems confronting the tomato value chain were found to be low prices, high perishable nature, lack of access to credit, poor quality of tomatoes, inadequate storage and processing facilities, inadequate transportation facilities, dispersed nature of supply and high interest rate (Emam, 2011). In sum, the aforesaid reasons usually justify the relevance of this study, which aims at analyzing tomato value chain along gender perspective.

Gender is assessed on the basis of men and women who engage in tomato with a view to draw a comparison analysis between the two gender categories among households (comprising producers, processors, distributors, marketers, promoters and consumers) in tomato value chain. Therefore, given credence to the severe nationwide food crisis and the marketing challenges, emerge three main research questions addressed in this study, related to (i) the socio-economic characteristics of households in tomato value chain in Akinyele Local Government Area

(LGA) (ii) the level of involvement in tomato value chain between men and women and (iii) economic valuation of tomato value chain with distinct reference to gender dominance.

MATERIALS AND METHODS

The study used a structured questionnaire for data collection from a survey of 160 tomato households in Akinyele LGA of which 96 were women and 64 were men. The respondents were tomato households that engaged in a variety of tomato crops value chain activities. The sample frame covers the producer (who takes actual responsibility of producing tomato); the intermediate/middlemen (who gathers various quantities of produce from different producers and sells them to large-scale traders, processors, retailers and processors); the wholesaler (who purchases large amounts of products with better financial and information capacity); the retailer (who sells small quantities of tomato products either directly to individual, household or institutional consumers); and the consumer (who purchases the products for consumption). Descriptive and gross margin analyses were carried out to analyze the study.

In calculating the gross margin across each tomato value chain activities to compare their economic valuations, we subtracted the total cost (cost of direct materials used, direct labour, equipment costs, utilities cost, distribution cost involved in all the value chain activities from total revenue (i.e. total income generated per month) and divided that number by total revenue. The result was expressed in percentage. In addition, this financial analysis was built on naira per kg of fresh tomato while the processed tomato (tin and or sachet) were measured based on their equivalent naira per kg of the fresh tomato. For instance, if a 10kg of fresh tomato is sold at N5, 000, the quantity of processed tin or sachet tomato that would be sold at that same N5, 000 were taken as their equivalent kg within a particular period.

RESULTS AND DISCUSSION

Table 1: Socio-economic characteristics of tomato households

Item	Frequency	Percentage
Household's head sex		
Male	71	44.4
Female	89	55.6
Household's head age		
≤ 20 21 - 40 41 – 60 61 – 80	10 88 40 22	6.3 55.0 25.0 13.7
Household's head year of education		
No Formal Education Primary Secondary Tertiary	3 36 90 31	1.9 22.5 56.3 19.4

Field Survey 2021

Table 2: Level of involvement in tomato value chain activities

Value chain activities	Male	Female	Means	Standard deviation
Production	66	40	4.2	0.04
Processing	44	31	1.2	0.01
Packaging	45	30	1.2	0.01
Marketing	112	30	4.1	0.03
Distribution	56	47	3.3	0.02
Publicity/Promotion	23	44	1.1	0.01

Field Survey 2021

Data on the level of involvement in tomato value chain activities using 5 point Likert scale were reflected in Table 2. The overall results show averages of 4.2, 4.1, 3.3 and 2.8 for production, marketing, distribution, processing/packaging and publicity/promotion respectively with their low standard deviations. This indicates that production and marketing were the main value chain activities that were predominant among tomato households in the study area. This result therefore suggests that other value addition activities like processing, packaging, publicity/ promotion were not maximally explored. This is however logical since the bulk of these tomato households were mainly rural entrepreneurs who operate an informal market system with little educational background and technical knowhow. So, processing/packaging and activities that involve washing, sorting, crushing, preheating system, packing rebranding etc were carried out by few that may have tomato dryer fabricated machines or those that are working mainly in tomato processing industries. In the same vein, based on gender-specific representations, a great gender gap and disparity were identified in particular with regard to production and marketing as most men participated in production of tomato than in marketing and vice-versa. Though, there were some households who combined various value chain activities together across the gender line.

Table 3: Economic valuation of tomato value chain

Value chain activities	Male (%)	Female (%)	Financial analysis of tomato per naira/kg (N)		
			Average total revenue	Average total cost	Gross margin
Production	69.4	30.6	71,670	491260	32%
Processing	39.4	60.6	41,350	35110	15%
Packaging	39.4	60.6	26,550	20,230	23%
Marketing	33.5	72.5	70,670	40,260	43%
Distribution	54.4	45.6	37,477	24,465	34%
Publicity/Promotion	46.3	53.7	14,123	10,543	25%

Field Survey 2021

This study goes a step further by focusing particularly on economic valuation of each value chain in tomato business per month putting the percentage of gender participation into consideration. Though, some of the value chain activities that relate to processed tomato as far as this study is concerned include processing, packaging and publicity/promotion. Further, due to the sharp fluctuation of tomato prices, and its seasonal characteristics, average values of both total revenue and total cost per month were used for the computation of its gross margin analysis. The study delimits the rate of demand and supply of tomato but focuses on value chain activities with higher gross margin value in relation to gender participation in the study area.

In terms of economic valuation, the higher the gross profit margin the better. Therefore, tomato households who engaged in marketing activity has higher gross margin than the others indicating that they did well in managing their cost of sales. It also shows that these households have more to cover for operating, financing, and other costs. Considering the gender dichotomy, the tomato households that concentrated in marketing activity were dominated by women (72.5%) meaning that tomato marketing favours women folk than men in term of economic valuation.

Further, using this economic valuation trajectory in relation to gender participation statistics, publicity/promotion, packaging and processing in that order also favour women folk than men while, distribution and production activities in that sequence favour male folk than women in the study area. These outcomes therefore suggest that women are more favoured and predominant in tomato value chain activities than men. On the other hand, men are more involved in some of the rigorous value chain activities as this may be due to their nature and tendency to undertake risk than women.

CONCLUSION AND RECOMMENDATIONS

Based on the findings, the study therefore concluded that production and marketing were the main value chain activities while processing, packaging, publicity/promotion activities leave much to be desired among tomato households in the study area. Also, women played a leading role in marketing, processing, packaging and publicity/promotion while men played a leading role in production and distribution value chain activities, as this development favours respective households' economic welfare accordingly. The study therefore puts forward to decision makers a number of recommendations for a better participation and economic valuation of tomato households. Firstly, there should be robust public-private collaboration with relevant tomato value chain stakeholders so as to improve processing, packaging and promotion of tomato. Likewise, more men should be encouraged in production activities through provision of necessary inputs and technology to enhance their production capacity as there should be a friendly off-taker mechanism network for women to boost their marketing potentials.

ABSTRACT

The study examined gender differential in sweet potato production in Oyo state, Nigeria. Data were collected with the aid of questionnaire and interview guide from 120 respondents comprising of 60 males and 60 female sweet potato farmers using multistage sampling techniques and analysed using descriptive statistics, multiple regression analysis and Z-test. Results revealed that 37.5% of male and 61.6% of the farmers had no formal education with mean age of 45 and 41 years respectively. A total of 85% of males and 76.7% of females were married, with an average household size of 8 and 6 persons, mean farming experience of 26 years for males and 21 years for females, and cultivated an average farm size of 1.39ha (male) and 0.77ha (female) while the mean income realised per season for the male and female sweet potato farmers were ₦325,285.12 and ₦226, 882.66 respectively. Factors influencing output of male farmers were household size, farm size, off-farm activities and extension services while that of female farmers were age, access to loan, other occupation and land ownership. It was therefore recommended that efforts should be intensified at implementing policies aimed at improving female farmers' access to land and other production inputs in the study area. Training of more female extension agents who can work freely with the female farmers in the area of timely dissemination of improved production technologies in sweet potato production should be undertaken by both the local and state governments in the study area.

Key words: Gender differentials; sweet potato; multiple regression, Oyo

INTRODUCTION

Gender is synonymously used with sex to denote the condition of being male and female (Ogunniyi *et al.,* 2013). Gender participation is a term that describes the roles and activities of men and women according to traditions and beliefs of a particular culture (Olagunju *et al.,* 2013). Issues on gender were of utmost concerns in the early seventies with the introduction of programs such as Women in Development (WID), Women and Development (WAD), Gender and Development (GAD) to address the problem of gender inequality, provide resources and create activities for women (United Nations Development Programme (UNDP), 2014). Subsequently, efforts were made to place both men and women on equal grounds in all project activities (Yisa *et al.,* 2020).

Sweet potato (*Ipomoea batatas (L) Lam*) is an important food and feed crop in sub-Sahara Africa (SSA) and ranks fourth after maize, bananas, and cassava (Food and Agricultural Organization (FAO), 2015). Nigeria ranks second among the world's largest producers of sweet potato with 3.4 million metric tons annually (World atlas, 2019). It requires low inputs of land, labour, capital and less management in its production activities; it performs well on marginal soils and irregular rainfall, more productive than most other crops (Baruwa, 2016). Sweet potato production is a gender activity involving both men and women in its production activities. However, the roles played are task specific, with the women carrying out menial activities such as planting, weeding, harvesting, processing, storage and marketing of crops while the men are more involved in strenuous tasks such as bush clearing, land preparation, tree felling, stumping among others (Oyugi *et al.,* 2015;) Studies (Obisesn, 2014; Albertson, 2016) have shown that men and women adopt new technologies at different rates, considering their diverse needs, socio-cultural context, access to available resources, unequal workloads and decision making power. The allocation and distribution of farm incentives are done with gender bias, Agarwal (2017) reported a great disparity between women and men in the size of land holdings as well as their involvement in agricultural production. Olagunju *et al.,* (2013) submitted that agricultural production will increase substantially if the contribution of men and women are taken into account equitably when allocating productive resources. Hence, this study was undertaken to examine gender differential in sweet potato production in the study area. It specifically described the socio-economic characteristics and determined factors influencing income from sweet potation production by gender in the study area. The hypothesis which states that, there is no significant difference in the involvement of male and female farmers in sweet potato production activities in the study area was also tested.

MATERIALS AND METHODS

Study Area: The study was conducted in Oyo State, Nigeria. Oyo State is an inland state in South-western Nigeria, with its capital at Ibadan. It is bounded in the north by Kwara State, in the east by Osun State, in the south by Ogun State and in the west partly by Ogun State and Republic of Benin. Oyo State is located on longitude 7.8500N and latitude 3.9330E, and covers approximately an area of 28,454 square kilometers and a population of 5,580,894 people at 2006 census. Agriculture is the main occupation of the people of Oyo State. The climate in the state favours the cultivation of crops like maize, yam, cassava, cocoyam, sweet potato, millet, rice, plantains, cocoa, palm produce, cashew and so on.

Sampling Procedure and Data Collection: A multistage sampling procedure was used for this study. The first stage involved the purposive selection of Oyo West and Atiba Local Government Areas of Oyo State due to the prominence of sweet potato production in the LGAs. The second stage involved the random selection of three villages each from the selected LGAs making a total of 6 villages. At the third stage, simple random sampling technique was used to select 20 sweet potato farmers (10 males and 10 females) from each of the selected villages making a total of 120 (60 males and 60 females) respondents for the study. Data were collected with the aid of questionnaire and interview schedule in the study area.

Analytical Techniques: Descriptive statistics such as mean scores was used to describe the socio-economic characteristics of the respondents, Z-test analysis was used to ascertain gender differential in sweet potato production activities in the study area while multiple regression analysis was used to determine the factors influencing output from sweet potato production in the study area. The model is specified as:

$$Y = \beta 0 + \beta 1X1 + \beta 2X2 + \beta 3X3 + \beta 4X4 + \beta 5X5 + \ldots\ldots\ldots + \beta 12X12 + \mu$$

Where: Y = Income (₦); X1 = Age of farmers (years), X2 = Educational level (years), X3= Household size (No of people), X4 = Farming experience (years), X5 = Farm size, (hectares) , X6 = Other occupation (1 if farming only, 0 otherwise), X7 = Type of labour used (1 if hired, 0 otherwise), X8 = land ownership (1 if yes, 0 otherwise), X9 = Membership of cooperative society (1 if yes, 0 otherwise), X10 = Extension contact (1 if yes, 0 otherwise), μ = Random sampling error term.

RESULTS AND DISCUSSION

Socio-economic characteristics of the respondents

The result in Table 1 reveals a mean age 45 and 41 years respectively for the male and female farmers in the study area. This implies that the farmers were still in the productive age. This is in consonance with the findings of Michael (2014); Nwaobiala *et al.,* (2019) that farmers were young, active and capable of undertaking activities involved in cassava farming which is also a tuber crop. The result also indicates that the farmers had one form of education or the other, while majority (62.5%) of the male were educated, 61.6% of the female farmers had no former education which implies that male farmers were more educated than their female counterparts in the study area. This result agrees with the findings of Oyewo *et al.,* (2018) that male farmers had higher literacy level experience which may help in improving the adoption of new technologies by the farmer, while the female level of education may affect their production level negatively. Majority of the farmers were married with mean household size of 8 and 6 persons for the male and female farmers respectively. Majority (96.7%) of the male farmers owns their farmland while only 39.2% of the female farmers own farmlands. This could have effect on the area of land cultivated to sweet potato and possible expansion of the enterprise as well as income in the study area.

Table 1: Selected socio economic characteristics of the respondents

Variable	Male	Female
Age	45	41
Education	62.5	38.4
Marital status (married)	85	76.7
Household size	8	6
Farm size	1.39	0.77
Farming experience	28.5	20.7
Farming only	75.2	35.1
Hired labour	41.7	62.8
Access to loan	26.9	11.6
Cooperative membership	21.7	44.3
Extension contact	26.4	18.7
Land ownership	96.7	39.2
Income	325, 285.12	226,882.66

Source: Field Survey Data, 2021

Factors influencing output from tuber crop production in the study area

Table 2 shows the regression estimates of the determinants of income from sweet potato production for the male and female farmers in the study area. The semi-log functional form was chosen as the lead because the model had the highest value of coefficient of determination R^2, highest number of significant variables conforming with the a priori expectation and significant F-value. The R^2 values of 0.794 (male) and 0.747 (female) imply that about 79% (male) and 75% (female) of the variations in the income from sweet potato production were jointly explained by the variables included in the model. The F value of 6.271(male) and 5.711 (female) were significant at 1% level of probability indicating goodness of fit of the regression line.

Result in Table 2 reveals that education of the male farms had a positive significant relationship with income at 5% alpha levels. This implies that income of the male farmers increases with their educational level in the study area. Educated farmers are more likely to adopt new technology and innovations leading to increased income in the study area. The coefficients of farm size for the male and female farmers were positive and significant at 1% alpha levels respectively. This implies that income from sweet potato production increases with increase in the size of farmland cultivated. This result corroborates the findings of Olagunju *et al.,* (2013) that increase in the availability of farm land for sweet potatoes leads to increase in the farm output for female and male farmers in Osun State. Likewise, the coefficient of other occupation and ownership of farmland were positive and significant at 5% level of probability for the male farmers. This implies that income increases with ownership of farmland and the male farmer engaging in farming as the sole occupation in the study area. The coefficient of other occupations engaged in by the male farmers was positive and significant at 5% alpha levels. This is because the male farmers were able to concentrate fully on their farming activities as its their only source of income. However, the coefficient of age of the female farmers had a negative significant relationship with income in the study area. This implies that income from sweet potato production decreases with age of the female farmers. This agrees with Mbah (2011) that output declines with advancement in age. In the same vein, the coefficient of land ownership ($p<0.05$) had an indirect relationship with income. This implies that income of the female farmers decreases with land ownership, this is so because majority of the female farmers did not own a farmland in the study area. Also, extension visit had a negative significant relationship with income of the female farmers at 5% level of probability implying that income decreases with insufficient visits from extension officers in the study area.

Table 2: Determinants of factors influencing output from sweet potato production

	Male		Female

Gender differential in sweet potato production activities

The result in Table 3 shows that there was significant difference in the level of involvement of male and female farmers in sweet potato production activities (Z=-6.23, P< 0.01). It can therefore be inferred that the level of involvement in sweet potato production in Oyo State varies by sex. The mean level of involvement of 24.510 and 17.231 for the male and female farmers implies that male farmers were more involved in sweet potato production activities than female in the study area. This finding contradicts the null hypothesis which states that there is no significant difference in the level of involvement of male and female farmers in sweet potato production activities. The alternative hypothesis is therefore accepted. This result confirms the findings of Audu (2009) that women trailed behind men in their participations in farming activities and production of food and cash crops. Yisa *et al.,* (2020) reported that male farmers were more technically efficient than their female counterpart and thus, had higher gross income per hectare in cassava production in Abia State, Nigeria

Table 3: Gender difference in level of involvement in sweet potato production activities

Level of involvement	Mean	Standard deviation	Z-test
Male	24.510		-6.23
Female	17.231		

Source: Field survey data, 2021

CONCLUSION

This study has established that there is gender differential in sweet potato production activities in the study area. It was revealed that male farmers were more involved in sweet potato production activities than their female counterparts. Education, farm size, other occupation and ownership of farmland influenced male farmers' income from sweet potato production while age, farm size, ownership of farmland and extension visits were the major influencing income of female farmers. Therefore, efforts should be intensified at implementing policies aimed at improving female farmers' access to land and other production inputs in the study area. Training of more female extension agents who can work freely with the female farmers in the area of timely dissemination of improved production technologies in sweet potato production should be undertaken by both the local and state governments in the study area.

ABSTRACT

The study assessed the socioeconomic variables of cocoa farmers in Akamkpa Local Government Area (LGA) of Cross River State, Nigeria. The study employed a multistage random sampling technique to select cocoa farmers. The first stage was a purposive selection of the LGA. A total of eighty-seven (87) cocoa farmers were randomly selected in the LGA. Well-structured questionnaires were used to elicit information from the farmers. Data were collected on age of the farm, age of the farmers, marital status of farmers, household size, farming experience, educational level, membership of farmers' association, farm distance and tenure type. The level of education (2±1.0 years), mean age of farmers (48±8.7 years), membership of farmers in an association as well as the low mean age of farms (18±5.6 years) in the study area pointed to a potential increase in the level of productivity. It is recommended that more women be encouraged to partake in cocoa production in Akamkpa LGA as their involvement may bring about more efficiency in cocoa farming or cultivation. In addition, membership of farmers' association is encouraged as this will make them present a common front in making and having their demands met by the government and thus improve cocoa production specifically in Akamkpa LGA and generally in Cross River State.

Key words: Cocoa farmers, Socio-economic variables, Cross River State, Nigeria

INTRODUCTION

Cocoa (*Theobroma cacao)* hails from the Amazon basin. It has enjoyed world wide spread and popularity especially in the tropical zones due to its economic value in the world market (Ojo and Sadiq, 2010). Cocoa came into Nigeria in the year 1887 and has since been one of the major cash crops cultivated in the country. Nigeria is the fourth largest cocoa producing country in the world after Cote d'Ivoire, Ghana and Indonesia (Afolayan, 2020). According to Olatuyi (2020), that cocoa is produced in fourteen out of the thirty-six states in Nigeria with Ondo, Cross River, Osun and Oyo states being four of the top producing states. In addition, about 96 percent of the total cocoa produced in the Nigeria is exported to the international market while about 10 percent is processed in Nigeria (Olatuyi, 2020). Cross River state is the second largest producer of cocoa in Nigeria. The state is made up of eighteen (18) Local Government Areas (LGAs). Cocoa production is concentrated in fourteen (14) of the LGAs. This implies that the state is to be reckoned with when it comes to cocoa production in the country (http://www.crossriverhub.com/about-akamkpa-local-government/, accessed on 07.01.2021). Notably, most poor people from less developed countries (LDCs) reside in rural areas and make their living from agriculture. The role of the agrarian sector and institutional settings in general, and the rural poor, in terms of socioeconomic and demographic factors in particular, are of central importance in economic development. Traditionally, the agriculture sector and rural economy especially in LDCs, have been characterized by the predominance of a small landowning class, tenants, sharecroppers, and landless labourers who are at the core of the poverty problem (Imran *et al.,* 2009). Meanwhile, Krishna *et al* (2016) considered gender, age, income and education as the main attributes of socioeconomic variables. Similarly, socioeconomic status has been operationalised in a variety of ways, most commonly as education, social class, or income (Alexander *et al.,* 2017). Therefore, the study assessed the socio-economic variables of cocoa farmers in Cross River State.

MATERIALS AND METHODS

The study was carried out in Akamkpa Local Government Area (LGA) of Cross River State, Nigeria in 2016. Akamkpa LGA is one of the fourteen (14) cocoa producing LGAs in Cross River State. It is located between Latitudes: 5°001[1] and 5°481[1] North of the equator; and Longitudes 08°001[1] East of the equator. The LGA has a landmass of 4,943.04 sq km and a population of over 150, 000 persons according to the last population census (Aboh and Effiong, 2019). The LGA is characterised by a couple of rural areas with

ISSN: 2814-0508

about 260 villages and about 30 different clans (http://www.crossriverhub.com/about-akamkpa-local-government/, accessed on 07.01.2021). Furthermore, the study employed a multistage random sampling technique to select cocoa farmers in the study areas. The first stage of the sampling technique was a purposive selection of the LGA. This is because of the volume of cocoa production in the LGA. The second stage was a random selection of three villages (Osomba, Ojork and New Ndebiji) within the LGA. The third stage was a random selection of eighty-seven (87) cocoa farmers in the LGA. Primary and secondary data were used for the study. Well-structured questionnaires were administered to the cocoa farmers for the primary data. Data were collected on age of the farm, age of the farmers, marital status of farmers, household size, farming experience, educational level, membership of farmers' association, farm distance and tenure type of farmers in the study area. Data was analyzed using simple descriptive statistics (means, frequencies, percentages and standard deviation).

RESULTS AND DISCUSSION

Table 1 shows the socio-economic characteristics of cocoa farmers in Akamkpa Local Government Area (LGA) of Cross River State. The table reveals that majority of the farmers (84%) were men. This result is in conformity with Girei *et al* (2013) who reported that in Africa, men are more in a crop that is perceived to have commercial value. The implication of this is that cocoa farming in the study area is largely dominated by the male gender. Moreover, the mean age of the farmers is 48 years, which implies that cocoa farmers in the LGA are still in their productive years and thus cocoa production in the study area is expected to be on the increase. However, this finding is not in consonance with those of Adeogun *et al* (2010) and Adebiyi and Okunlola (2013) who reported that cocoa farmers in some selected states of Nigeria were advanced in age; a good example being cocoa farmers in Oyo State of Nigeria who had passed their productive ages. Similarly, the table reveals that about 75 percent of cocoa farmers in Akamkpa LGA had formal education, though at the primary school level. The implication of this is that the farmers may not have adequate information on good agricultural practices with regard to cocoa production. However, it was revealed that majority of the respondents (89.70%) belonged to one farmers' group or the other, implying that they are likely to access information on improved production methods and procedures from their professional associations. This result is in tandem with Akinpelu (2019) who reported that about 76.50% of cassava farmers also belonged to one professional association or another. Membership of farmers' groups would afford farmers the opportunity of sharing information on modern production techniques, methods of purchase items in bulk and modes of exchanging labour (Onubuogu *et al.,* 2013). It would also help them to share information easily and be able to make demand on matters of a collective common welfare (Esiobu *et al*., 2014). Moreover, the expectation is that membership of farmers' organizations would influence farmers' adoption of improved technologies. Contrarily, Ahmed and Anang (2019) reported that membership of farmers group brought about a lower adoption of improved maize varieties. Furthermore, the table reveals an average household size of six persons, implying that farmers may sometimes utilize members of their households as labour for some operations relating to cocoa production or farm rehabilitation. This may reduce the production costs that would have been incurred in hiring for farm work. Mean age of cocoa farms in the study area was about 18 years. What this means is that the cocoa farms are in their productive years. This is contrary to findings by Adeogun *et al* (2010) who reported that cocoa farmers in selected states of Nigeria had aged trees that are older than thirty (30) years, thus implying diminishing returns on production over time. Finally, it was revealed that about 55.17% of the farmers have their farms located far from home. This is expected because cocoa is unlike any arable crop that can be cultivated close to the house. Similarly, fertile lands for cocoa production are typically in the forests as land close to the village areas are usually dedicated to building residential houses.

CONCLUSION AND RECOMMENDATION

The study assessed the socioeconomic variables of cocoa farmers in Akamkpa Local Government Area of Cross River State. The level of education, mean age of farmers, membership of farmers in an association as well as the low mean age of farms all pointed to a potential increase in the level of productivity. Cocoa farmers in Akamkpa LGA have a productive low mean age, which means that they have age on their side and can afford to improve their level of productivity. It is recommended that more women be encouraged to partake in cocoa production in Akamkpa LGA as their involvement may bring about more efficiency in cocoa farming or cultivation. In addition, it is recommended that those yet to join farmers' association be encouraged as this will make them present a common front in making and having their demands met by the government. The associations could also serve as an avenue for government to reach or extend any form of assistance to smallholder farmers in the study area. These recommendations could help improve cocoa production specifically in Akamkpa LGA and generally in Cross River State.

ABSTRACT

The study was carried out in Kwara State. Primary data was collected through a well-structured questionnaire. A multi-stage random sampling technique was used. A convenience sampling techniques was used in administering a total of 200 questionnaires to rice farmers and agro-processors within the selected communities. Findings from the study showed that 75.8% of the respondents were males while 24.2% were females. Majority of the respondents (77.8%) have farming as their main occupation, while others engaged in other occupations apart from farming. 22.2% of the respondents had 1 – 8 years of rice processing experience, while 3.0% of the respondents had between 9 – 11years of experience and majority of the farmers 74.7% had above 12 years of rice processing experience. The study further revealed that the cost of using manual thresher was about 63% higher than NCAM thresher. While the average total revenue of rice threshed was #103,079.00 and #138,125.00 respectively. This gives a profit of #82,869.00 manually and #125,295.00 NCAM thresher. The findings in this study clearly showed that using NCAM mechanical rice thresher is more profitable and economic efficient in the study area.

Key words: Rice Farmers, Agro- Processors, Mechanical Rice Thresher, NCAM, Economic Analysis

INTRODUCTION

Rice is both a food and a cash crop for farmers, contributing to smallholders' revenues in the major producing areas of Nigeria. Rice is grown approximately on 3.7 million hectares of land in Nigeria, covering 10.6 percent of the 35 million hectares of land under cultivation, out of a total arable land area of 70 million hectares; 77 percent of the farmed area of rice is rain-fed, of which 47 percent is lowland, while 30 percent upland (World Bank, 2014). Although rice production in Nigeria has boomed over the years, there has been a considerable lag between production and demand level with imports making up for the shortfall (World Bank, 2014). Recently, Central Bank of Nigeria (CBN) banned importers from accessing foreign exchange markets in 55 categories of items, including rice. Any attempt at addressing the issues of rice production in Nigeria, must of necessity concentrate on efforts to stimulate adoption of rice processing technologies among our rice farmers. However, the most important step in the application of the new technology is the awareness of the economic incentives accruable from it such as its profitability, convenience, adaptability, durability, etc. Most rice farmers (90 percent of total) in Nigeria are smallholders, applying a low input strategy to agriculture, with minimum input requirements and low output (Adeniyi, 2015). The Federal Government of Nigeria through several measures in trying to improve rice production from subsistence to commercial production has laid emphasis on increasing the use of modern rice farming technologies such as power tillers, tractors, improved seeds, SAWAH technology, rice processing machines, etc. In line with this, the National Centre for Agricultural Mechanization (NCAM) Ilorin has made remarkable efforts in the establishment of rice processing Centers across the six geo-political zones in Nigeria, equipped with rice threshers and other rice processing machines for value addition. Hence, this study is being carried out to assess the economic analysis of NCAM mechanical thresher in the rice processing system using the established NCAM rice processing centers as a case study.

MATERIALS AND METHODS

The study was carried out in Kwara State. Primary data was collected through a well-structured questionnaire. A multi-stage random sampling technique was used. A total of 5 communities were sampled; namely Pategi, Lade, Godiwa, Edogi and Sapefu. These communities were selected purposely based on their high rice production and processing activities as well as the fact that these communities are where NCAM rice processing centers are located. A convenience sampling techniques was used in administering a total of 200 questionnaires to rice farmers and agro-processors within the selected communities.

ISSN: 2814-0508

The data were analyzed using descriptive statistics and budgetary analysis. The gross margin model was employed. The gross margin (GM) is the difference between the total revenue (TR) and the total variable cost (TVC). The gross margin model is expressed mathematically as:

GM = TR – TVC--eqn 1

Where, GM = Gross Margin (N/ha)

TR = Total Revenue

TR= PQ (P= price per unit output and Q=total quantity of output)

TVC = Total Variable Costs (N/ha)

While the profit/ net income model states;

π = Gross margin – TFC--eqn 2

Where, π **=** Profit or Net Income (N)

TFC = Total Fixed Cost (N/ha).

Profitability ratio was further used to examine the costs and return of the farmers. This is because gross margin though necessary but is not a sufficient tool to determine the profitability level of an enterprise.

Hence the model is presented thus:

$$\text{Gross Profit Ratio} = \frac{\text{Gross Margin}}{\text{Total Revenue}} \times 100 \text{ --eqn 3}$$

RESULTS AND DISCUSSION

The socio-economic characteristics of rice farmers directly or indirectly affect their farming operations. Results from Table 1 indicate that about 75.8% of the respondents were males while 24.2% were females which are in line with the findings of Matanmi et al, 2011 that rice production in Pategi is dominated by men. This implies that the sex distributions of the rice farmers in that area are predominantly towards male respondents. Result from table 1 also revealed that majority (71.2%) of the respondents are within their productive age (31-50 years). This is an advantage since they are still in the age at which they are supposed to be energetic, more mentally alert in learning new technology than the older farmers and hence can be actively involved in processing activities. This result is in line with studies of Adam, 2018, Ben-Chendo, 2017, Igboji, 2015 and Agwu, 2004 that age is an important determinant of social-economic status, people wane in energy as they advance in age. Majority of the respondents (80.8%) were married while 6.1% were single, 8.1%, 3.0% and 2.0% were widowed, divorced and separated. This implies that the respondents are responsible according to the societal standard and therefore are likely to have some experience of life. The result further revealed that majority (65.6%) had family size ranging from 4 to 10 implying that they have enough family labour for processing activities. This agrees with the studies of Adam and Bidoli (2017); Giroh *et al*., (2011) which established that household size is not significantly related to adoption but reported that socio-economic status of farmers is positively and strongly related to adoption. The data on educational status revealed that about 92.1% are literates. Positive correlation has been found between education and adoption of new technology as elucidated by Junge *et al.,* (2009) and Olaolu *et al*., (2011). Also, Agbamu, (2006) asserted that there is an inverse relationship between formal education and adoption of technologies.

The result from the study also shows that majority of the respondents (77.8%) have farming as their main occupation, while others engaged in other occupations apart from farming. The implication of this is that, instead of the respondents to plough back the money or income realized from rice processing into investment in agriculture, they invest the extra income in other business which will serve as sources of income to sustain them during the off season period. Table 1 also shows that 22.2% of the respondents had 1 – 8 years of rice processing experience, while 3.0% of the respondents had between 9 – 11years of experience and majority of the farmers 74.7% had above 12 years of rice processing experience. Generally, this implies that farmers in the selected communities had long period of experience which is in line with the research study carried out by Igboji, (2015).

Table 1: Socio-Economic Characteristics of the Respondents

Variables	Frequency	Percentage (N=198)
Gender		
Male	150	75.8

Source: Field Survey, 2020

This could increase their knowledge, experience and subsequent adoption of NCAM rice threshing technology. The findings from the study further shows that majority (78.8%) of the respondents belonged to one farmers' group (farmer cooperative, thrift cooperative services) or the other and majority have spent about 5 years being member of the cooperative society while 21.2% of the respondents were not members of any farmers' group/cooperative. The implications of non-membership are that the potential of social-network through farmers group as source of agricultural related information has not been fully utilized. This observation is in line with the studies conducted by Agwu (2004), Odoemenem, (2007) and Salasya *et al*., (2007). The result indicated that majority 66.2% of the respondents did not have access to credit while the remaining 33.8% had access to credit facilities. Negash, (2007) confirmed that access to credit is statistically significant to the adoption of improved technologies.

The result from Table 2 revealed that almost all of the respondents (96%) reported that there were differences in their output as a result of adopting NCAM rice thresher. This could be due to the fact that NCAM rice thresher is efficient, faster, reliable and eliminate the drudgery associated with manual threshing which all the respondents reported is most stressful.

Table 2: Output from Adoption of NCAM Rice Thresher

		Frequency	Percent	Valid Percent	Cumulative Percent
Valid	Yes	190	96.0	96.0	96.0
	No	8	4.0	4.0	100.0
	Total	198	100.0	100.0	

Profitability of Analysis of Rice Thresher

The profitability ratio was used to examine the cost and returns of rice threshing in the study area. The analysis enabled us to determine whether rice threshing is profitable in the study area or not. It equally helps to elucidate the advantage of using NCAM rice thresher over the manual threshing. The cost components include the costs of labour, transportation, bag, drum, fuel and tarpaulin. Labour accounted for 39.6% manually and 23.4% while usingNCAM rice thresher. Also 22.8% and 35.9% of the cost of rice threshing is spent on transportation. Bags are used by farmers to pack the rice before and after threshing. This constitutes 7.7% manually and 14% NCAM rice thresher of the total cost incurred in rice threshing. NCAM rice thresher was higher because wastages of rice were minimal. The rent of the threshing drum and tarpaulin accounted for 18% manually, while 16.4% was incurred on fuel. Other minor expenses are purchase of bowl, brooms, thread and needles (Table 3).

The average total cost of rice threshed was N20,210.00 manually and N12,830.00 NCAM thresher. The cost of using manual thresher was about 63% higher than NCAM thresher. While the average total revenue of rice threshed was N103,079.00 and N138,125.00 respectively. This gives a profit of N82,869.00 manually and N125,295.00 using NCAM thresher.

The gross profit margin of NCAM mechanical thresher is 0.907 (90.7%). A high gross profit ratio is an indication that the farmers are selling their produce at high profit level. Hence, the farmer are expected to have sufficient funds to pay for operating expenses such as wages, utilities and rent while having high turnover in the study area.

CONCLUSION

The overall purpose of this study was aimed at determine the comparative economic analysis of NCAM Mechanical rice thresher and manual thresher amongst rice farmers and processors in Kwara state. The findings in this study clearly showed that using NCAM mechanical rice thresher is more profitable and economically efficient in the study area. It is therefore recommended that rice farmers and agro-processors should be encouraged to use NCAM Mechanical Rice Thresher.

COMPETITIVENESS OF COFFEE PRODUCTION IN KOGI STATE OF NIGERIA

Oluyole, K.A., Akinpelu, A.O. and Odedele S.O.
Cocoa Research Institute of Nigeria, PMB 5244, Idi Ayunre, Ibadan

ABSTRACT

The study investigated the competitiveness of coffee production in the study area. The project was carried out among coffee farmers in Kogi State of Nigeria. Simple random sampling technique was used to collect data from the farmers. Data were collected from the respondents with the aid of structured questionnaire and the data obtained from the questionnaire were analysed using Descriptive analysis, Private Profitability and Private Cost Ratio. Majority (92.59%) of the respondents were above 50 years while majority (70.37%) of the farmers were having formal education. However, 81.48% of the farmers are having farm size 5 hectares and below. The result of Private Profitability was positive in all the three management systems while the Private Cost Ratio (PCR) was less than one in all the management systems considered. The study concluded that coffee production is highly competitive in the study area.

Key words: Coffee, Production, Competitiveness, Policy Analysis Matrix

INTRODUCTION

Coffee as a crop is a member of the family Rubiaceae, a large family of over 5500 species widely distributed in the tropics. There are three species of coffee grown for commerce, these are *Coffee arabica*, which is highland coffee and it grows very well at altitude of 600m and above, it has a mild taste and is more fragile; *Coffee canephora* (popularly known as *Coffee robusta*), this is more resistant and is lowland coffee thriving best at the altitude range of 0 to 750m above sea level and the third species is Coffee liberica which is a mild-altitude coffee thriving best at an altitude of 400m to 600m (Opeke, 2005). However, *Coffee arabica* produces the best quality of coffee and still supplies the bulk of the world coffee, but it grows well only at cooler air temperature (Akinbode, 1980). According to Milford (2004), the coffee tree can be grown only in warm areas without frost or sudden temperature shifts, and it also needs plenty of rain. This explains why it is a common export commodity for countries in tropical areas, and an unsuitable one for the rest of the world.

The vast majority of coffee production has its roots in colonialism, during which missionaries or colonialists usually imported the plant. Coffee then became a "cash crop, planted and harvested by serfs or wage laborers on large plantations, then exported to imperial countries" (James, 2000). Consequently, governments, ethnic relations and general ways of life were changed in these countries because of the shift to the new reliance on coffee production. However, with the growth of the United States economy, the market for exporting coffee also expanded. Therefore, coffee became a major source of income for many countries in Central and South America, Africa, and South Asia where colonialism was present and the environment was ideal for coffee trees (Cleland, 2010). Meanwhile, the coffee plant originated in Ethiopia. However, coffee-drinking habits had spread to Europe by the 17th century.

However, the producers of these coffee beans are often small-scale farmers who are reliant on faceless consumers, large corporations and an ebbing market for their income and resources. Meanwhile, empirical studies have shown that smallholders in developing countries face numerous constraints due to the pervasive imperfections of markets. Increasing evidence shows that through collective action, smallholders can reduce transaction costs of accessing input and output markets, adopt efficiency-increasing and value-adding technologies, and tap into high-value markets associated with certification and labeling (Kersting and Wollni, 2012; Wollni and Zeller, 2007;). In the early 2000s, a historic world market price slump hit millions of coffee farmers hard, especially smallholder producers in Africa and Latin America (Ponte, 2002). The volatility of coffee markets in combination with poor production infrastructure and services have sunk the majority of coffee producers in developing countries in low-input-low-output cycles and structural poverty. Similarly, coffee is a traditionally worldwide traded cash crop with new emerging markets; many coffee-producing developing countries such as Nigeria are struggling with production and marketing of the crop. In addition, smallholder coffee growers face high transaction cost, lack of market information, poor infrastructure, and weak capital markets. Moreover, imperfect competition in which farmers are getting paid less for their produce than they would in a competitive situation occurs among the smallholder coffee growers in Nigeria. When this effect is added to the other aforementioned factors that are characteristic of the coffee industry, we can perhaps understand why, to many of these farmers, this situation must seem unfair. The objective of the study was therefore to determine how competitive coffee production is in the study area.

MATERIALS AND METHODS

The project was carried out among coffee farmers in Kogi State. Ijumu Local Government Area (LGA) was purposively selected from the State and from the LGA, Iyamoye community was also purposively selected because coffee farmers are mostly concentrated in the community. Simple random sampling technique was used to collect data from a total of 81 farmers randomly selected from the community. Data were collected from the respondents with the aid of structured questionnaire and the data obtained from the questionnaire were analysed using Descriptive analysis as well as Policy Analysis Matrix (PAM). The constituents of PAM that were used in this study are Private Profitability and Private Cost Ratio.

Descriptive Statistics was used to describe the socio-economic characteristics of the farmers while Private Profitability and Private Cost Ratio were used to determine the competitiveness of coffee production in the study area. However, for ease of comparism of these indices, two coffee production management systems were considered, these are Self owned and Inheritance production systems.

PAM is a product of two accounting identities, profit, defined as the difference between revenue and cost while the other measure the effect of the divergences (distorting policies and market failures) as the difference between observed parameters and parameters that would exist if the divergence were removed (Monke and Pearson, 1989).

Private Profitability (PP) – This demonstrates the competitiveness of the agricultural system given current technologies, prices of input and output and policy

$$\prod = \sum Y_i^{\,p} P_i^{\,p} - (\sum a_{ij} P_j^{\,P} + \sum a_{ij} P_k^{\,P})$$

..................(1)

Where:

$\prod$ = Private Profit;

$Y_i^p P_i^p$ = Value of output produced at private prices;

$\Sigma a_{ij} P_j^p$ = Cost of tradable inputs used at private prices;

$\Sigma a_{ij} P_k^p$ = Cost of domestic factors used at private prices.

If Private Profit < 0, which is negative private profit, this shows that the product is not competitive given current technologies, prices of inputs and outputs, and policy and that operators are earning subnormal rate of return when private profit = 0, operators are earning normal profit while when private profit > 0, that is positive private profit. The positive private profit implies that the product is competitive given current technologies, prices of inputs and outputs, and policy and the producers are earning positive returns and this should lead to expansion of the system.

4.5.1.2. Private Cost Ratio (PCR) - This shows the private efficiency of the farmers or the marketers and is an indication of how much one can afford to pay domestic factors (including a normal returns to capital) and still remain competitive.

$$PCR = \frac{\sum a_{ij} P_k^{\,p}}{Y_i^{\,p} P_i^{\,p} - \sum a_{ij} P_j^{\,p}}$$

....(2)

Where:

$\Sigma a_{ij} P_k^p$ = Cost of domestic factors at private prices;

$Y_i^p P_i^p$ = Revenue at private prices;

$\Sigma a_{ij} P_j^p$ = Cost of tradable inputs at private prices.

PCR < 1 indicates that the product is highly competitive given current technologies, inputs and output prices and policy and that entrepreneurs are earning excess profits. It shows that the entrepreneur can pay for all the domestic factors including bank loan and its interest with the operation still remaining competitive. The PCR > 1 implies entrepreneurs are making losses, that is after paying for the domestic factors, the operation is no more competitive PCR = 1 indicates the breakeven point.

RESULTS AND DISCUSSION

The result of the socio-economic characteristics of the farmers is shown in Table 1. The table shows that only 7.41% of the total respondents are of age 50 years and below indicating that the proportion of youths among the respondents is low. Meanwhile, 77.77% of the total respondents were above 60 years of age. Hence, 77.77% of the farmers were above the productive age of 60 years. The lowness in the proportion of the youths is a bad pointer to coffee production efficiency as younger farmers are more active on farm work than the aged ones. Table 1 also shows that 100% of the respondents were males. This is quite obvious in that farm work is a tedious work and is only men that could cope effectively with it. Apart from this, most of the farms were inherited and some traditional cultures permit only the male children to inherit farms. As regards the educational level of the respondents, the result of the analysis shows that 70.37% of the respondents were having formal education. This would improve the efficiency of the farmers in as much that literate farmers would find it easier to adopt new technologies on coffee than the illiterate ones. The analysis on farm size shows that 81.48% of the respondents had farm size of 5 hectares which shows that most of the farmers are small scale farmers. Table 1 also shows that 66% of the farmers had the age of their farms greater than 30 years showing that most of the farms are old and hence the farm's productivity would reduce, therefore such farms needs to be rehabilitated. As regards farming experience, 96.7% of the farmers were having more than ninety years of experience on coffee farming. This is a good pointer to an increased productivity. Table 1 also revealed that majority (85.19%) of the farmers had inherited farms while just 14.81% established their farms themselves.

The result of the competitiveness analysis as shown on table 2 showed that coffee production is highly competitive in the two coffee farm ownership types considered. This is because the Private Profitability (PP) and the Private Cost Ratio (PCR) result is positive and is less than one respectively in all the farm ownership types. Considering the values of PP, coffee production in the two ownership types is highly competitive since the values are very high in the two ownership types. However, coffee production is more competitive in self owned type of ownership because the value of Private Profitability is the higher between the two ownership types (N241,192.86). This is followed by inheritance type of ownership with PP value of N104,850.00. The values of Private Cost Ratio showed that coffee production in the two ownership types is highly competitive, meanwhile, the lower the PCR the higher the competitiveness. Therefore, coffee production in self ownership is more competitive since it is having the lower PCR (0.089). This is followed by inheritance type of ownership with PCR of 0.166. Looking at the values of both the PP and PCR together, it clearly showed that coffee production is more competitive in self ownership than inheritance type of ownership given current technologies, prices of inputs and outputs, and the prevalent government policies.

CONCLUSION

Majority of the respondents are formally educated and this is a good pointer towards high productivity and thus increases the competitiveness in coffee production. Also, most coffee farmers in the study area were small scale producers, this is because majority of the farmers were having farm size of five hectares and below. Coffee production in the study area is highly competitive. However, coffee production in self ownership management system is the most competitive of the two types of farm ownership. In as much that coffee production in the study area is highly competitive, it is hereby recommended that government should give farmers incentives to expand their coffee farms as majority of the farmers are small scale farmers (having less than 5 hectares of land). The incentives may include provision of soft loans as well as subsidized inputs.

ABSTRACT

The studies examine the effect farm Efficiency on the profitability of coffee production in Kogi, Nigeria. There have been a lot of studies on efficiency of annual crops with little attention given to perennial crops such as coffee Multi stage sampling technique using purposive and simple random sampling proportionate to size was used to select four hundred respondents for the study. Data collected included those of socio- economic characteristics of farmers and their production. The data collected were analyzed using descriptive statistics and Net Revenue (NR) Results revealed that majority (77.8%) are male. Only eight percent of them had farming experience of less than 10 years in coffee production. The coefficient of farm income is statistically significant and positive in determining the profitability of coffee production in the study area. The coefficient of male gender is statistically significant and positive in determining the profitability of coffee production in the study area. Fire incidence and climate impact were the major constraints to production of coffee. The study recommended that government should support expanded production of coffee to other potential areas, government and other lending agencies should also do more in assisting the farmers with soft loans in order to reduce the problem of inadequate capital among the farmers and adoption of climate change and adaptation strategies should be used by farmers in order to reduce the incidence of fire outbreak climate impacts.

Key words: Coffee, Farm Efficiency, Profitability

INTRODUCTION

Agriculture is the mainstay of the Nigerian economy from the standpoint of its various contributions to the economy. Coffee is a member of the Rubiaceae family.It has two major species in Nigeria, *Coffea arabica and Coffea canephora (robusta).* Coffee plant is native of Africa. The origin of Coffee arabica has been traced to Ethiopia in the 9th century while *Coffee robusta* is believed to have come from Central Africa. Coffee was introduced to Nigeria around 1859 and is mostly cultivated in the lowland areas (*Coffea canephora*) and Highland areas (*Coffea arabica*). Coffee growing and drinking started in Ethiopia. Today, it is an important commodity and a popular beverage in the world. Coffee is one of the most important export crops in Africa and Latin America countries (Opeke, 2005). It was introduced to Nigeria around the same time as cocoa. It is commercially grown in 13 States namely; Taraba, Kogi, Ondo, Oyo, Ogun, Osun, Edo, Kwara, Ekiti, Adamawa, Plateau, Abia and Cross River (CRIN, 2014). According to the United States Department of Agriculture (USDA) among 95% of Nigerian coffee farmers, compatibility problem has been observed to be a major factor limiting yield to 600-800 kg /ha. This makes investment in coffee production less profitable (Omolaja, 1999). The empirical results become useful tools for policy makers in agricultural planning and this will lead to better production performance and overall productivity. A study of this nature is however, very pertinent because it gives the actual picture of the effects of farm efficiency on the profitability of coffee production which will help address coffee value chain issues. The findings from this study suggest solutions to the constraints encountered by the coffee farming households in Nigeria.

Objectives of the study

The overall aim of the study is to examine the effect of farm efficiency on the profitability of coffee production in Kogi, Nigeria

The specific objectives of the study are to:

(a) examine the socio-economic characteristics of coffee farmers in the study area;

(b) estimate the effect of farm efficiency on the profitability of coffee production.

MATERIALS AND METHODS

The study was carried out in Kogi State, Nigeria, It's capital is Lokoja, located in north central of Nigeria, Kogi State occupies a total land area of 29,833 square kilometres. The wet season ranges from the month of April to October while the dry season is between November and March. The annual rainfall is between 1000mm and 1500mm, the annual temperature varies between 27°C and 37°C with

ISSN: 2814-0508

relative humidity between 30 and 40% in January and rising between 70 and 80% in July to August. The soil in the study area is predominantly sandy loam in texture. The study made use of primary and secondary data. A multi-stage sampling technique was used for the study. In the final stage of sampling, simple random sampling proportionate to size was again used to select the respondents that were administered structured questionnaire and the final sample size for the study is 400 (Ijumu,116, Kabba –Bunu,139 and Yagba East,145) The data collected were analyzed using descriptive statistics and Net Revenue (NR)

To Estimate the Effect of Farm Efficiency on the Profitability of Coffee Production.

The Tobit model: If a continuous random variable X has pdf f(x) and a is a constant, thenS

$$f(x/x>a)=\frac{f(x)}{\Pr ob(x>a)}$$

If x has a normal distribution with mean μ and standard deviation σ, then

$$\Pr ob(x>a)=1-\Phi\left(\frac{a-\mu}{\sigma}\right)=1-\Phi(\alpha)$$

Where α = (a-μ)/σ and φ(.) is the stardard normal cdf. The density of the truncated normal distribution is then

$$f(x/x>a)=\frac{f(x)}{1-\Phi(\alpha)}=\frac{(2\pi\sigma^2)^{-1/2}e^{-(x-\mu)2/(2\sigma^2)}}{1-\Phi(\alpha)}=\frac{\frac{1}{\sigma}\phi\left(\frac{x-\mu}{\sigma}\right)}{1-\Phi(\alpha)}$$

Where φ(.) is the standard normal pdf. The truncated standard normal distribution, with μ = 0 and σ= 1. Likewise, the discrete random variable is the truncated at Zero Poisson distribution,

$$\Pr ob|Y=y/y>0|=\frac{(e^{-\lambda}\lambda^y)/y!}{\Pr ob[Y>0]}=\frac{(e^{-\lambda}\lambda^y)/y!}{1-\Pr ob[Y=0]}=\frac{(e^{-\lambda}\lambda^y)/y!}{1-e^{-\lambda}},\lambda>0,y=1,\ldots$$

Implicit form;

$Y^*_{ij}= \beta'X + \varepsilon_i$ $\quad\quad$ $\varepsilon i \sim N(0,\sigma^2)$

$Y_{ij} = Y^*_{ij}$ $\quad\quad$ for $Y^*_{ij} > Y_i$

$Y_{ij}= Y_i$ $\quad\quad$ for $Y^*_{ij} \leq Y_j$

Where

Y = The profitability index ($\frac{NI}{TR}$) as a proxy of farm profit (ratio in figure).

X_1= Farm income (naira)

X_2 = No of products for sale per farm (coffee)

X_3 = Total value of all the products sold in the last session (naira)

X_4 = Total amount of money spend on production in last session (naira)

X_5 = Age of the farmer (number)

X_6 = Educational level of the farmer (number of year spent in school)

X_7 = Sex of the farmer (male = 1; 0 if otherwise).

X_8 = Household size (number)

X_9 = Size of the farm $\quad$ X_{10} = Amount of loan accessed in last production year (naira)

X_{11} = Experience in coffee farming (year) X_{12} = Presence of other occupation (yes = 1; 0 if otherwise

RESULTS AND DISCUSSION

Table 1 showed that majority of the respondents, (77.8%) were male while 22.2% were females. This tends to show that any likely increase in farm efficiency of Coffee production would be as a result of the predominant involvement of male farmers who are most likely to be more agile than their female counterparts. This implies that coffee farming activities in the study area is gender sensitive.

Table 1: Distribution of Respondents by Sex

Sex	Frequency	Percentage
Male	311	77.8
Female	89	22.2
Total	**400**	**100.0**

Source: Field Survey, 2019

Only eight percent of them had farming experience of less than 10 years in coffee production. Thus suggesting that with the relatively long exposure, it is expected that most farmers must have mastered the skills required for success in their coffee production business (Table 2).

ISSN: 2814-0508

Table 2: Distribution of Farmers According to Years of Experience

Farming Experience	Frequency	Percentage
<10 years	32	8.0
11-20 years	121	30.3
21-30 years	122	30.5
31-40 years	77	19.3
41-50 years	39	9.8
>50 years	9	2.3
Total	**400**	**100.0**

Source: Field Survey, 2019

Out of the 12 variables modeled, only farm income and male gender were statistically significant in determining the profitability of coffee production in the study area. The coefficient of farm income is statistically significant and positive in determining the profitability of coffee production in the study area. This showed a direct relationship between farm income and the profitability of coffee production in the study area. This implies increase in the farm income will lead to increase in the profitability of coffee production in the study area (Table 3).

Table 3: Effect of Farm Efficiency on the Profitability of Coffee Production.

Variables	Co-efficient	t value	Marginal effect
Constant	0.208	0.491	0.208
Farm income	0.113**	2.026	0.113
Number of products for sale per farm	0.019	0.051	0.019
Total value of all the products sold in the last session	0.014	0.338	0.014
Total amount of money spend on production	-0.017	-0.722	-0.017
Age of the farmer	0.227	0.866	0.227
Educational level of the farmer	0.091	0.816	0.091
Sex of the farmer	0.847*	1.687	0.847
Household size	-0.000	-0.455	-0.000
Size of the farm	-0.048	-0.845	-0.048
Amount of loan accessed in last production year	0.000	0.242	0.000
Experience in coffee farming	0.000	0.105	0.000
Presence of other occupation	-0.036	-0.051	-0.036

Sources: Field Survey, 2019. * = Significant at 10%. ** = Significant at 5%. *** = Significant at 1%

The coefficient of male gender is statistically significant and positive in determining the profitability of coffee production in the study area. This showed a direct relationship between male gender and the profitability of coffee production in the study area. This implies that coffee production in the study area tends to increase with more involvement of male gender in the study area.

ABSTRACT

The study determined the costs and returns of garden egg production in Ringim Local Government Area (LGA) of Jigawa State, five (5) villages/wards out of the ten (10) wards in Ringim LGA were purposely selected where sixty-four (64) garden egg farmers were randomly selected. Findings revealed that, the ages of the farmers within the range of 19-26 years was the highest (34.3%). Majority of them (62.5%), were married where 32.8% attained primary school and only 12.5% attained tertiary school. About 92% of the farmers cultivate less than 1 hectare revealing that most of the farmers were small scale producers. However, g*arden egg production was found to be profitable with Gross margin of N93,775 per hectare. Return per naira invested was found to be N1.95. Constraints such as lack of government support, inadequate capital, lack of improved varieties, high cost of inputs, pests and disease incidences, lack of market and storage facilities were identified to be hindering the possible growth of the crop in the area. Conclusively, garden egg production, if well harnessed, could serve as an engine room for sustainable promotion and upliftment of the rural livelihood in the area. It is recommended that government should provide the garden egg farmers with modern irrigation facilities and farm inputs to boost its production and increase income generation.*

Key words: Cost and Return, Garden egg Production, Jigawa State

INTRODUCTION

The name ― Garden eggplant was derived from the shape of the fruits of some varieties which are white and shaped like chicken eggs, (Chen et al., 2001) The plant, (Solanum spp) is a vegetable with increasing popularity in the world (Pessarakli and Dris, 2003). Production of Garden egg is highly concentrated with 90% of output coming from five countries. China is the top producer (58% of world's output), India is the second (25%) other countries are Iran, Egypt, and Turkey. More than 4,000,000 acres (i.e. 1,600,000 ha) are devoted to its cultivation in the world. Garden egg is one of the greatest foods, in terms of health benefits as it is packed with vitamins, minerals and other nutrients. Some of the major problem facing farm production in Nigeria include lack of classified data and information on the suitability, adaptability and performance of commercially available agricultural products against this background, viability of a sustainable rural livelihood promotion could benefit immensely with empirical evidence of the cost and returns in garden egg production as incurred by its farmers living in the rural area.

Objectives of the Study

The main objective of the study is to examine the cost and returns of garden egg production in the Ringim LGA of Jigawa State. The specific objectives are to:

i. Describe the socio–economic characteristics of garden egg producers.
ii. Determine the costs and returns of garden egg production.
iii. Examine the problems associated with garden egg production.

MATERIALS AND METHODS

Study Area

Ringim Local Government Area of Jigawa State, Nigeria, is located in the North-western part of the State. It is about 6,494 km^2. Ringim is semi-arid, characterized by wet season from May to September. The annual rainfall ranges from 600mm to 759mm. The region falls within the Sudan savanna vegetation zone. Hausa and Fulani constitute the major ethnic groups. The area has a fertile land for both wet and dry season farming activities and the people in the area also engaged in marketing as well.

Methods of Data Collection

Primary data were collected using questionnaires. Information obtained include socio economic characteristics, costs and returns, input-output relationship and constraints affecting garden egg production.

Sampling Techniques and Sampling Sizes

A multistage sampling procedure was used for the study. The first stage involved a purposive selection of five (5) wards out of ten (10) in the Local Government Area these are; Dabi, Karwai, Gabarin, Zangon Kanya, and Yanduste, the selection was based on the intensity of garden egg production in the area. At the last stage a simple random selection was done to select 50% of the total population of 126 farmers. Therefore, a total of sixty-four (64) garden egg farmers were randomly selected to represent the sample size as shown in Table 1.

Table 1: Sampling Frame and Sampling Size

Village/Ward	Number of registered farmers	Sampling Size (50%)
Dabi	20	10
Karwai	25	13
Gabarin	26	13
Yandutse	20	10
Zangon Kanya	35	18
Total	126	60

Sources Field Survey: 2019

Data Analysis
Descriptive Statistics

These are concerned with scientific methods for summarizing, presenting and analysing data as well as drawing valid conclusions and making reasonable decisions on the basis of such analysis. This is done using mean, percentage and frequency distribution.

Mean; this is the sum values in the data group divided by the number of values, thus,

$$\overline{X} = \frac{\Sigma fx}{\Sigma f} \quad \text{...} (1)$$

Farm Budgeting Techniques

Gross margin and Return per naira invested were used to determine the costs and returns associated with garden egg production. Mathematical representation of the above tools is as follows:

Gross margin:

$$GM = TR - TVC \quad \text{..............................} (2)$$

Where,

GM = gross margin

TR= total revenue

TVC = total variable cost

While,

Return per naira invested:

$$RI = \frac{GM}{TVC} \quad \text{...}(3)$$

Where,

RI = Return per naira invested

GM = Gross margin

TVC = Total variable cost

RESULTS AND DISCUSSION

Socio–economic Characteristics of Garden Egg Producers

The socio economic variables being analysed here were: Age, Farm size, Household size, Experience, Marital status, Labour, Ownership, Sources of finance and level of education. Socio–economic characteristics data of the garden egg producers like their age, sex marital status household size, occupation, level of education, farm size, and farming experience were described in Table 2.

Table 2: Socio–economic Characteristics of Garden Egg Producers

Variable	Frequency	Percentage (%)
Age		
19 – 26	22	34.37
27 - 34	16	25
35 – 42	17	26.52
43 – 50	5	7.81

Sources Field Survey: 2019

Discussion of Socio-economic characteristic of Garden Egg Producers

The result shows that majority of the farmers (60.89%) fall within the age range (19-42years) that is termed economically active by FAO (1992), while the remaining (13.3%) of the farmers are beyond the economically active stage. At this stage in life, Anyawu et al. (2001) recognized that people are more likely to be energetic and have the capacity to use innovation. The result in Table 2 shows that most of the garden egg producers (62.5%) were married and the remaining percentage (18.7%) are single. The marital status of the farmers shows that majority of the farmers are having a sense of responsibility and it also shows that garden egg production is a means of livelihood for most farmers in the area. The result shows that a substantial number of garden egg producer (32.8%) in the area have primary education while 25% have secondary education and 29.6% have attended Qur'an school. By implication, reasonable number of farmers in the area should be able to understand the use of improved technologies and apply it to achieve increased production. Through education, the quality of labour is improved and with it the propensity to adopt new techniques (Tijani et al., 2006; Hyuha, 2006). The result in Table 2 shows that majority (54.6%) of the farmers' household sizes falls within the range of 1-5, and 25% of the farmers' household sizes falls within the range of 6-10. The result shows that majority of the farmers were having extended families. It also shows that certain percentage of the farmers will utilize their family size as their source of labour. However, Oladeepo and Oluwaranti (2012) reported that 7-12 size of household of cassava farmers is found in the southern part of Nigeria. Table 2 also showed that most (76.5%) of the producers had farming as the source of income and 23.4% were involved in other business after farming such as welding, black smiting and teaching.

Costs and Returns

Costs and returns refer to the expenses incurred and revenues generated by a farm firm. Costs and returns analysis is used to determine the ability of a farm to earn profit. A profit is what is left of the revenue which a farm generates after it pays all expenses directly related to the generation of the revenue. Table 3 gives the results of the costs and returns analysis per hectare of garden egg production.

Table 3: Average Cost and Returns of Garden Egg Production per Hectare

Variable cost	Unit price(N)	Quantity	Total cost/ha	Percentage total cost
Seed(Kg)	300	2	600	1.04
Fertilizer(Kg)	8000	100	16000	28.7
Pesticide(ltr)	4000	2	8000	6.26
Labor(Man-day)	500	30	15000	26.0
Sack	40	100	4000	6.95
Fuel(ltr)	145	225	32625	56.76
				100
Total Variable Cost			**76,225**	
Returns				
Output(bag)	1000	170	170,000	
Total revenue			**170,000**	
Gross margin			**93775**	
ROI			**1.95**	
Gross farm ratio			**0.33**	

Source: Field survey, 2019

The results in Table 3 show that total cost of producing garden egg per hectare was N76,225, the total revenue was found to be N170,000 and the gross margin was N93,775. That means the profit was N93,775, signifying that garden egg production in the area is profitable. Return on investment, ROI of 1.95 indicated that for every N1 invested in garden egg production, a return of N1.95 is expected.

Constraints Affecting Garden Egg Production

The field of agriculture is bound to be constrained by many factors ranging from natural to manmade factors. Garden Egg production in Ringim LGA is no exception to these factors; hence Table 4 presents the factors that are militating against garden egg production in the area

Table 4: Constraints Affecting garden egg Production in Ringim LGA

Variable	Frequency	%
Poor Government support	60	100
Inadequate capital	53	88.3
Lack of improved varieties	50	83.3
Poor market	30	50

Source: Field survey, 2019 * Multiple responses

The farmers were found to be constrained by the following factors: Inadequate Government support (100%), inadequate capital (88.3%), Lack of improved varieties (83.3%), and poor market. These are the major constraints that are militating against the production of garden egg in the area. Combating these constraints will pave way to higher production of the nutritious vegetable and ultimately increase income for the rural populace thereby promoting viable rural livelihood.

CONCLUSION

Findings of this study revealed that garden egg production is profitable. It is however, dominated by male who were at their active age. Most of them have attended one form of education with an average farming experience of up to seven years. Fuel and fertilizer constitutes the highest percentage of the farm inputs. Constraints identified to be hindering the growth of the crop were not unsurmountable and if solved can provide increase in returns and higher production. As such the following recommendations were given.

- Garden egg producers should be trained in proper farm record and management to better organise their production activities.
- Relevant Government and non-governmental agencies should assist garden egg producers in the supply and timely distribution of farm inputs such as fertilizer, improve seeds and pesticides.
- Government should provide the garden egg producers with modern irrigation facilities so as to overcome irrigation problem faced by the producers.

GROSS MARGIN ANALYSIS AND NUTRITIONAL BENEFITS OF COCOYAM: CASE STUDY OF IDO LOCAL GOVERNMENT AREA OF OYO STATE

Badmus, M.A. Aderibigbe, O.R, Azeez, S.O and Badmus, S.M

ABSTRACT

This study examined the Gross profit analysis and nutritional importance of cocoyam in the study area. A total of 70 respondents in Omi Adio markets in Oyo were interviewed using a structured questionnaire. Data were analyzed using descriptive, and inferential statistical tools. Gross margin analsis was used to estimate the profitability of the trade. The result showed that about 77% of the respondents were females with the mean age of 40 years. About 40% had secondary education while 33% had primary education. The mean of the farming experience of the correspondents is 15 years. Result also revealed that the benefit cost ratio of the cocoa yam business is 1.85. This shows that for every #1 the farmer spent on the cocoa yam business, he or she will be able to generate 1.85 return with gross margin of 0.85. It nutritional components can be concluded from this study that cocoyam is a good remedy for diabetis. It is also used in the control of blood pressure and boosting of immune system amongst others.

Key words: Cocoyam, Nutritional content Gross Margin Analysis.

INTRODUCTION

Cocoyam (Colocasia spp) is a taproot of edible aroid famiy(Araceae). This crop is an important food crop across many countries in SSA, particularly in Nigreria, Ghana and Cameroon. Cocoyam is one of the most accepted and cultivated root and tuber crops, almost everywhere throughout the tropics and in over 65 countries of the world (Pollock et al., 2000). It is ranked third in importance, after cassava and yam in many West and Central African countries (Adisa et al., 2011).

Nigeria and Ghana are the world's leading countries in cocoyam production (Oke and Bolarinwa, 2012) where it is mostly grown amongst smallholder farmers and contributes immensely to address the problem of food insecurity. After yam and cassava, cocoyam is the third important staple crop and a cheaper substitute for yam, especially during lean periods. when there is food scarcity. Cocoyam, in addition to cassava and yam, is one of the staple foods in Nigeria It is widely cultivated in the country because its production is favored by the country's soil and climate. Cocoyam is a common food plant that has a long history of cultivation cultivars of two species *colocasia (Taro)* and *xanthosoma.* They are widely grown for food and consumed particularly during periods preceding harvest which underscores its importance as a possible substitute for the crop (Sefa- Dedeh *et al.,* 2004). Cocoyam is often intercropped with perennial cash crops like cocxoa, banana, oil palms becaus it can tolerate shade, especially at the early stage of these plantations. Cocoyam tubers are uesd in same ways like other root and tuber like yam, potato and cassava. It is eaten in cooked form and can also be converted into other product and can be used industially such as industrial starches (Lawal,2004), good substiture for maize as binding agent in the manufacture of tablets (Subhadhirasakul et al; 2001) production of baby foods amongst others. They are widely grown for food and consumed particularly during periods preceding harvest which underscores its importance as a possible substitute for the crop (Sefa- Dedeh *et al.,* 2004).

Cocoyam is an important staple crop especially among the low-income earners in the tropical regions of the world (Adeboyejo *et al.,* 2020). This crop is essentially cultivated by women who are mostly resource poor with minimal access to agricultural inputs. A gender efficiency analysis of smallholder cocoyam farmers in Eastern state of Nigeria revealed a ratio of 3:1 for female against male farmers (Dimelu et al; 2008). However, as cocoyam attracts more economic value, the ratio of men to women is increasing. Cocoyam also has a lot of nutritional benefits. This study whilst xtraying some of the nutritional benefits, also examines the profitability of cocoyam marketing, especially among the women.

Nutritional profile of cocoyam

When compared with other major root and tuber staples, cocoyam is postulated to have superior nutritional value especially in terms of their protein digestibility and mineral composition (Calcium, Phosphorous and Magnesium) (Lim, 2016). According to Opara (2003), Xanthosoma sagittifolium can generally be regarded as an appreciable (middle range) source of dietary energy, proteins, and vitamins. It is said to be high in potassium, zinc, and nicotinic acid as well as a low inhibitor of trypsin compared to other edible aroids. Cocoyam offers vitamins and soluble fibers which is a perfect complementary element for all type of meals (Talwana *et al.,* 2009).

The nutritional potential of cocoyam could be adequately tapped by diversifying its utilization through the development of new food products for different food industries and market needs. Two such industries which could be targeted are the snack and complementary (baby) foods sector. Both are currently thriving markets and utilizing cocoyam would go a long way to produce culturally acceptable and nutritious food products to enhance the variation of products for sustained food and nutrition security. The leaves of cocoyam, especially, are a food resource with potential health benefits that could be applied in the pharmaceutical industry. Similarly, the cormels, flours, and starches could be explored in the snack and complementary food industries utilizing their peculiar processing properties, ease of crop production, and storability, as well as their nutritional value.

Cocoyam is rich in starch which makes it an excellent source of carbohydrate. It contains dietary fiber and higher protein content than the most of the other tropical root crops. Cocoyam is nutrient dense which is why it is recommended for consumption because it is vital for maintaining a healthy immune system which helps our body utilize the nutrient ingested. Dietary fiber helps bowel movement and aids digestion. Cocoyam also have appreciable amount of protein, thiamine, copper, calcium, niacin, manganese, vitamin B6, vitamin C, A and E as well as riboflavin, magnesium, phosphorus, iron, zinc and potassium. (James *et al.,* 2019).

Table1. Nutritional facts of cocoyam per 100g (Nigeria Food composition table 2017)

	Nutrient Value	Percentage
Energy	130kcal	
Carbohydrate	11.9g	48%
Protein	8.5g	35%
Fat	1.9g	17%
Water	66.3g	
Dietary fiber	6.7g	
Sodium	136mg	
Potassium	259mg	
Vitamin B1	3.6mg	
Vitamin B2	0.3mg	
Vitamin B6	2.5mg	
Vitamin C	35.1mg	
Calcium	154mg	
Iron	6.5mg	
Zinc	2.2mg	
Phosphorus	132mg	
Magnesium	215mg	

MATERIALS AND METHODS

The study was conducted in Omi Adio Market, Ido Local Government Area. Cocoyam marketers were purposively selected and interviwed using snowball' method. Structured questionnaire was administered to 100 selected traders. Descriptive statistics such as frequency and mean were used to analyse the data. Gross margin analysis was used to determine cost and return as well as the profitability of cocoyam marketing.

RESULTS AND DISCUSSION

The demographic characteristics of cocoyam marketers is as summarized in table 2. The characteristics of respondents considered include sex, age, marital status, household size as well as educational status.

Table 2: Demographic Characteristics of cocoyam marketers

Gender	**Frequency**	**Percentage**
Male	21	30.0
Female	49	70.0
Total	**70**	**100**
Age		
Below 20	1	1.43
21-35	27	38.57
36-50	32	45.71
51-65	8	11.43
Above 65	2	2.86
Total	**70**	**100**
Marital status		
Single	9	12.86
Married	50	71.42
Widow	9	12.86
Divorced	2	2.86
Total	**70**	**100**
Household size		
1-5	45	64.29
6-10	18	25.71
11-15	7	10.00
Total	**70**	**100**
Years spent in school		
No formal education	12	17.14
1-6	21	30.00
7-12	27	38.57
12 and above	10	14.29
Total	**70**	**100**

Source: Field Survey Data (July, 2021).

The result revealed that majority of the cocoyam marketers (70%) were females. This may be due to the fact that the sale of the crop enhances women income capacity even as cocoyam is already named as a 'female' crop. The distribution of the cocoyam marketers in the study area revealed that majority of them were within the age range of 36 to 50 years. This showed that were within the productive stage of their life. Also, most (71%) of the respondents them were married with household size comprising between one and five people. This implies that they have access to family labour in carrying out marketing functions.

Table 3 is the result of the gross margin and benefit cost analysis of cocoyam marketing.

Table 3: Benefit- Cost Analysis of Cocoyam Marketing

Scale of operation	**Average cost(#)**	**Average revenue (#)**	**Gross margin(#)**	**Benefit Cost Ratio**
Small scale	80,000	134,320	54,320	1.68
Medium scale	276,987	496,453	219,466	1.79
Large scale	735,211	1,406,459	671,248	1.91

Assumption: Average variable cost is the cost incurred in getting the cocoyam to the market and this includes the cost price of the cocoyam corms, cost of transportation and cost of loading and offloading. The revenue is the selling price of the cocoyam multiplied by quantity of the cocoyam sold.

The result revealed that the average gross margin of the small-scale marketers is **#**54,320 while the gross margin of the medium scale is **#**219,466 while that of the large scale marketers is **#**671,248. The return on cocoyam marketing however, can be better explained using financial ratio, especially benefit-cost ratio that relate the relationship between cost and revenue. Benefit cost ratio explain the revenue generated with every #1 cost incurred in the marketing of cocoyam.

The benefit cost ratio of the small, medium and large scale marketers of cocoa yam are 1.68, 1,79 and 1.91 respectively. This implies that small, medium and large scale cocoyam marketers will generate 168%, 179% and 191% of the total cost incurred as revenue. This implies that small, medium and large scale cocoyam marketers are able to generate 68%, 79% and 91% profit margin from the marketing of cocoyam after deducting cost.

CONCLUSION AND RECOMMENDATION

The gross margin of cocoyam marketing is a profitable business with high relatively good gross margin. Thus, trade in cocoyam is a profitable venture that should be promoted. There is need to also encourage the consumption of cocoyam because of the inherent health benefits. In addition to the associated nutritional and health advantages, even the potentials of cocoyam as an important staple for food and income security remains underexploited. There is need to change the narrative about cocoyam because of its importance to the livelihoods of millions of people are either under-estimated or under-reported and therefore unappreciated.

ABSTRACT

The study was carried out at the National Horticulture Research Institute (NIHORT) Bagauda Kano state. (Latitude 11^0 33in, Longitude 8^0 231E, with altitude of 481m) in the 2018 cropping season. This was to determine the economic potential of Five varieties of water melon in Sudan Savanna ecological zone Kano. 1kg seed of water melon were sown directly on 4m^2 plots with ridges of 0.75cm by 1m spacing in Randomized Complete Block Design (RCBD) replicated three times. All agronomic practices were carried out according standard practice. Result obtained showed that, Kaolack (2.6t/ha) with production cost of ₦35920 gave the return of ₦164,080. It is followed by Sugar baby (2.0t/ha) with a return of ₦42,280 and Oranaise variety (2.7t/ha) with a return of ₦23,280. Charleston Grey (2.4t/ha) and Grey bell (1.4tha) a return of ₦11,280 and ₦6,280, respectively. The net return showed that, Kaolock gave highest economical return and therefore its production is more profitable and economically viable in Sudan Savanna agro-ecological zone.

Key words: Water melon, Economical, Varieties, cropping.

INTRODUCTION

Water melon (*Citrullus lanatus*) (Thumb) is an important vegetable grown for its large fruit. It is a vine – like climber and trailer herb, which has origin in the hot, dry region around the Mediterranean. According to USA (2000), production in 1991 was estimated at 1.9 million tons with a monetary value of $26.8million, as the crop is cultivated both for its large fruit and vegetative parts which are highly nutrition (Schippers, 2000; Ben *et al*., 2006). In 2002, worldwide production dramatically increases to about 90million tons, with an average production of 25 tons' ha' (FAO, 2003). The production of water melon is increasing in Nigeria (Oguntola, 2006) and Kano state is one of the most important area of its production. It has been reported that melon production is usually more profitable when intensively managed (Clough, 1992; Robinson and Decker – Wilters 1997; Hochmuth *et al.,* 2001; Bolin and Brandenberger, 2001). Intensive crop management is characterized by a combination of cultural practices at different level of usage, cultural practices such as irrigation, cultivation and spacing, choice of variety and control of weeds, insect, pest and disease play important roles in determining yield in water melon (Taylor et al., 2003). The threshold plant population beyond which yield does not increase depending on environment factors, many varieties of watermelon exist with shapes, skin colour conotene content (Miles, 2004) and wide variety of water melon have been cultivated in topics. (Zohary & Hopf, 200). The variation in the performance of varieties in vine crop has been widely documented by scholars (Manyrong, 1997; Ajisefinani, 2004) which could be composition owing to their different genetics different varieties of water melon will respond differently to various growth factors and mixture. Tindall (1983) recommended several varieties to growers but only few have gained popularity in Nigeria. Those include sugar baby, Oranaise, Kaolack, Charlesten Grey, and Grey ball. Although studies confirmed production practice are common (Ben et al., 2006, Wieners, 1990).

Water melon widely grown display types of translucid flesh with very high water content, a sweet taste and red or sometimes yellow in colour, they are very refreshing when eaten in hot climates. They are relished by many people across the world as a fresh fruit. This is because water melon is known to be low in calories but highly nutrition and thirst quenching. It also contains vitamin C and A in form of the disease fighting beta carotene and works in conjunctions with other plant chemicals not found in vitamins and minerals supplements. Potassium is also available in it and is believe to help in the control of blood pressure and possibly prevent strokes (FAO 2007). The water melon requires a good spadesful manure or compose and hence the need to incorporate it in the soil before planting (Greensil, 1976). The soil must be fertile with good organic matter content sandy loam texture and well drained (Messian, 1992). The largest production of the crop comes from the northern part of Nigeria where the suitable agro ecology is found. Nevertheless, water melon could also thrive in other ecologies with intensive management and is still economically feasible (Adekunle *et al.,* 2004). It is widely grown in the northern part of the country perhaps due to the average rainfall there. The potential of water melon as a cash producing crop is enormous for farmers especially those residing near the urban areas (Abubakar, 2010). The aim of the studies to determines the economic potential for the water melon production in Sudan savannah.

MATERIALS AND METHODS

The study was carried out at the National Horticulture Research Institute (NIHORT) Bagauda Kano state. (Latitude 11^0 33in, Longitude 8^0 231E, with altitude of 481m) in the 2018 cropping season. This was to determine the economic potential of Five varieties of water melon in Sudan Savanna ecological zone Kano. 1kg seed of water melon were sown directly on $4m^2$ plots with ridges of 0.75cm by 1m spacing in Randomized Complete Block Design (RCBD) replicated three times. All agronomic practices were carried out according standard practice. Application of fertilizer NPK 20:10:10 and Urea 46:0:0 were applied at recommended rates. All the five varieties of water melon were evaluated to determine the benefits potentials of each variety using (N.P.V.).

$$\text{N.P.V.} \;= \left(\frac{B-C}{(i+r)t}\right)$$

Where B= Benefit, C= cost, i= Interest rate and t= Time.

Positive N.P.V. means viable venture

Negative N.P.V. means not viable return

RESULTS AND DISCUSSION

The result obtained showed that, the experimental field was characterized as sandy loam (Table 1). Table 2 showed the production input of the five varieties of water melon. A higher production cost was observed in Kaolack while the remaining varieties maintained a uniform production cost. The variation in the production cost of Kaolack could be due to the value of the variety being the most desired and production pressure due to demand attracting higher cost. The output (yield) and net profit per hectare is presented in table 3. All the varieties were profitable that of Kaolack was outstanding which agreed with Bolin and Brandenberger, (2001) who reported that water melon production is profitable. Kaolack performed the best among the varieties.

Table 3: Economics analysis of cost input – output estimate per Naira

Varieties	Input cost/ha (N)	Output t/ha(N)	Gross benefit (N)	Net benefit (N)
Kaolack	35,920	2.6	200,000	164,000
Oranaise	35,720	2.7	59,000	23,280
Grey bell	35,720	2.5	42,000	6,280
Sugar baby	35,720	2.0	78,000	42,280
Charlestone grey	35,720	1.4	47,000	11,280

CONCLUSION AND RECOMMENDATION

Kaolack (2.6t/ha) with production cost of N35920 and net return of N164,080, performed the best among the varieties in the study area which require minimum input and gives profitable output. Therefore, the variety is recommended to be cultivated for more profit in Sudan savanna agro-ecological zone.

GROWTH RESPONSE AND ECONOMIC BENEFITS OF FEEDING GRADED LEVELS OF ALKALI-TREATED COFFEE PULP TO WEANER RABBITS

Adebowale, B.A., Orimoloye, P. O. and Mustapha, K

Cocoa Research Institute of Nigeria, PMB, 5244, Ibadan, Nigeria.

ABSTRACT

Growth response and economic viability of dietary inclusion of alkali treated coffee pulp in growing rabbit diet was evaluated. Thirty-six (36) mixed breed weaner rabbits of mean live weight of 534.5g were randomly grouped into four treatments (1,2,3 and 4). Alkali treated coffee pulp were mixed into four experimental diets at 0%, 4%, 8% and 12% inclusion levels and fed to weaner rabbits for a period of twelve weeks. Treatment 1 rabbits were fed Diet 1, while Treatment 2, 3, and 4 were respectively fed diets 2,3, and 4diets 1(0 %), 2(4%), 3(8%), and 4(12%) inclusion levels. Each of the treatments was replicated thrice, with three rabbits per treatment. Feed and water were given ad libitum. At the end of the feeding period, growth performance and feeding economy were assessed. Mean daily weight gain of weaners fed diet 1 was the highest (22.22g), while least value was recorded for T4. Mean value for cost/kg wt. gain for T4 (N101.78k) was however the best. Although cost per kilogramme weight gain of the rabbit was best in T1 (control), cost per kg. feed was highest. Consequently, it is cheaper to produce a kilogramme meat of rabbit using diet 4. Livestock farmers (particularly rabbit farmers) can gain more as return on investment by substituting expensive basal ingredients like maize with alkali-treated coffee pulp.

Key words: Economic viability, Weaner rabbits, Cost per kg. feed, Alkali-treated coffee pulp

INTRODUCTION

Many tropical countries including Nigeria are marked by low per capita animal protein intake resulting from rapid human population growth and shortfall in livestock production (FAO, 2004). The large animals (cattle goat and sheep) production has not been able to meet the animal protein requirement of the increasing population growth because of their long production cycle (Opong Anene, 2010). It may however be met by engaging in farming of livestock with short production cycle like rabbits and other monogastric animals. Production and consumption of rabbits has been described as an authentic way of mitigating animal protein insufficiency in the tropics (Ajala *et al*., 2004). Rabbits have a short production cycle with high litter size. If rabbits are left to produce unrestrainedly, they can produce for about five to six times in a year with average of six to seven offspring per period. Their meat has low cholesterol, low fat, low energy and high protein value (Adeyemo *et al*., 2013). Despite these potential and good attributes, high price of conventional feed ingredients is a major factor limiting the production of rabbit in the tropics (Ani *et al*., 2011). The problem has been worsened due to the increasing competition among human, other livestock and industry for the conventional feed stuffs such as maize, soybean and groundnut. Increasing human population is undoubtedly aggravating the case of feedstuff shortage in the livestock sector of the country (Touleun *et al*., 2007). This problem has been the major stimulants for the continuous search for agricultural waste materials which one would have been thrown away without a second thought.

Coffee pulp is inherently rich in fibre, proteins, carbohydrates and minerals especially potassium but also contains appreciable amount of anti-nutritional factors such as caffeine, tannins and polyphenols (Roussos *et al*., 1998). Coffee pulp is a by-product of coffee crop which is obtained during the pulping operation of the coffee cherries to remove the beans. The pulp is always considered as valueless waste; they are often burnt and sometimes cause serious disposal problem (Negesse *et al*., 2009). Previous researches on feeding untreated coffee pulp to ruminant showed negative results in growth performance owing to the presence of anti-nutritional factors (Sauza *et al*., 2004). A challenge therefore for animal nutrition scientists is investigation into processing of coffee waste with the aim of reducing the anti-nutritional factors to the minimum safe level of the animals. It is based on this premise that this research was embarked upon to determine the economic benefits of weaner rabbits fed graded levels of alkali treated coffee pulp meal.

MATERIALS AND METHODS

About 25kg of coffee pulps were collected from the coffee pulping centre, Cocoa Research Institute of Nigeria, Ibadan. The pulps were sterilized in an autoclave at 121^0C for 15 minutes, allowed to cool. The solutions of high concentration of potash

(K_2CO_3) was made by soaking cocoa pod ash in water overnight at ash: water ratio 1:3. The potash was allowed to mixed, dissolved into the water and waited for the solids to sink to the bottom. The water was then poured off gently, and then sleeping 25kg of sterilized coffee pulps in it for a period of 12 hours. The pulps were then removed, washed, sun dried and stored in jute bags until it was used. Thirty-six (36) mixed breed weaner rabbits were purchased from Adeeko Farm, Ibadan, Oyo State. Before the commencement of the experiment, the rabbits were acclimatized for seven days. During this period, rabbits were all fed control diets and were also treated against endo and ecto-parasites using sodex (dewormer) and ivomectin respectively. The animals were randomly divided into four treatment groups. Each group comprised of nine rabbits. Each group was further sub-divided into three, such that replicate groups of three rabbits were obtained for each sub-group with three rabbits per replicate. The alkali treated coffee pulp (ATCP) was mixed into rabbits ration at 0, 4, 8 and 12% inclusion level designated T_1, T_2, T_3 and T_4(table 1). All diets were formulated to meet the nutritional requirements of weaner rabbits based on (NRC, 2007) recommendations and the experimental diets were offered to rabbits twice in a day at about 7:00 am and 4:30 pm. The animals were allowed *ad libitum* access to feed and water throughout the trial. The trial lasted for 84 days. Data collected from this study were subjected to statistical analysis (SAS, 2008 version 9.2) and significant means were separated using Duncan multiple range test (Duncan, 1955).

RESULTS AND DISCUSSION

Results of the growth performance of weaner rabbits fed alkali-treated (K_2CO_3) coffee pulp based diets is shown on Tables 1 and 2, while 3 show the economic benefits of the feeding trial. Highest value for feed intake was recorded on treatment 2. Reduced quantity of feed intake was noticed as the level of coffee pulp inclusion increases, although this was not significant. Similar observation was also reported by Ogana *et, al* (2020). From this result, treatment of coffee pulp in alkaline solution is suspected to have improved the nutrient content of the husk and hence better utilization. This is because rabbit fed diet 3 consumed more quantity of feed than the control. This is in agreement with Adeyina *et. al* (2005) which said that reduction of anti-nutritional (theobromine) content of feed ingredient, will undoubtedly increase the intake of such feed ingredient (Adeyina *et al*., 2010). At 12% inclusion level of alkali-treated pulp (Diet 4), average daily feed intake was however noticed to decrease correspondingly from T1 to T4. Several authors have reported same as the ash content of feed increases progressively with increased inclusion of fibrous feedstuff in animal diet. (Devender (1978); Day and Dilworth (1984). This was evidenced in the mean live weight gain of fed rabbits. Although the average daily feed intake of treatment 1 (control) was the lowest, average daily weight gain of weaners fed diet 1 was the highest. Ogana *et. al*. (2020) asserted this fact, when graded levels of treated cocoa husk meal were fed weaner rabbits. Although highest feed intake and best feed conversion ratio (6.92) was reported in the diet with no cocoa husk. The difference was however not significant at P< 0.05. Feed conversion efficiency of diet 1 was the best (5.35), but not significant across table. This shows that biologically, diets 1 – 3 were similarly utilized as the control.

From the economic point of view, cost of producing a kilogramme of the experimental feed was significantly lower on diets 3 and 4, which contained 8 and 12% alkali treated coffee pulp respectively. The cost of pre-treating coffee pulp was so small at this experimental level and the calculation of cost of producing a kilogramme was based on prevailing market prices of the ingredients. The cost was found to be lowest on diet 4. Cost /kg of diet 4 was significantly lower than all others in the study. Consequently, livestock farmers (particularly rabbit) can gain more as return on investment by substituting expensive basal ingredients like maize with alkali-treated coffee pulp. In this study, price per tonne of compounded feed decreased from the control (Diet 1) to Diet 4. Thus, the economic viability of the practice is justified by the use of cheaper feed to produce similar kilogramme weight of rabbit meat.

Table 1: Feed composition and calculated nutrient values of the experimental diets

Parameters	T_1	T_2	T_3	T_4

A META-ANALYSIS OF FARMERS' SOCIAL ECONOMIC STATUS (SES) AFFECTING COFFEE PRODUCTION, PROCESSING AND UTILIZATIION IN KOGI STATE, NIGERIA USING DATA MINING

Akinola, C.O., Jayeola, C.O., Olorundare, B. and Ogunsowo, A.O.

Department of Value-Addition Research, Cocoa Research Institute, Idi-Ayunre, Ibadan

Corresponding author's e-mail: christiana.akande1611@gmail.com

ABSTRACT

Coffee is a popular beverage choice among many people not only because of its distinctive aroma and flavor, but also for its numerous health benefits. However, while coffee utilization and consumption around the world continues to rise, it is at low ebb in Nigeria. One of the major factors limiting coffee uptake and consumption both for industrial and domestic use is the deplorable state of production of Nigeria-grown coffee. As a result, this paper examined how farmers' socio-economic statuses impact coffee production and processing, and subsequently, utilization and consumption in Kogi State through extensive meta-analysis and data mining. For this research, secondary data were generated from three original articles. The secondary data were analyzed using descriptive statistics. Results revealed that 70.12% of the farmers were over 50 years of age with moderate to no formal education exposure. By extension, only 92.5% had formal training on coffee production. In addition, many of the farmers (82.84%) depended on their personal savings for coffee production and exploration. Consequentially, only 55% of the farmers focused solely on farming activities for income source, out of which many grew coffee alongside other crops. Taken with other variables such as mode of land inheritance, access to available market, and financial facilities, the study discovered that the low socio-economic statuses of farmers greatly impede coffee production and processing in Nigeria. As a result, the threshold of production and the quality of coffee beans falls below the desired industrial specifications. It is therefore, expedient for stringent measures such as favorable policies, increased access to incentives, capital, and loan facilities, efficient extension programs and step-down of new technologies through formal trainings, and improved market accessibility, processing and utilization to be in place, especially by the government, to resuscitate and alleviate coffee production and consumption in Nigeria. Once coffee quality is assured, domestic and industrial consumption and utilization will improve.

Key words: Coffee processing, Coffee quality, Farmers' Socioeconomic status, Coffee production

INTRODUCTION

Coffee is the highest trading food product, and the choicest beverage by many consumers (Ballis, 2019). The high level of consumption and subsequent increased demand of coffee stems from its associated medicinal benefits. These include energy level improvement (as a stimulant), reduction of the human body's oxidative stress, and its crucial role in the alleviation of cardiovascular diseases and cancers (Nuhu, 2014). While the international community recorded a 1.9 % increase in coffee consumption to 167.58 million (60kg) bags for 2020/2021, (International Coffee Organization, 2021), coffee consumption in Nigeria is pegged at around a predicted 1000 tonnes per annum (Ang, 2016). This value is very low, compared to coffee consumption in other countries. For instance, France, a country with less than one-third of Nigeria's population, recorded a total coffee consumption level of about 366,000 tonnes in 2015 (Ang, 2016). One of the reasons for this low coffee utilization and coffee in the country is strongly attached to the inability of Nigeria coffee farmers to meet up with the required coffee demand and the deplorable processing quality of the locally-sourced coffee. While many factors may be responsible for this outcome, this paper seeks to investigate the impact of farmers' socio-economic status on their ability to meet up with production, processing, and utilization demands in Kogi State with secondary data obtained using data mining.

MATERIALS AND METHODS

This meta-analysis is based on secondary data synthesis and multi-study review adapted from three studies (Aderolu *et al.,* 2014; Mohammed, Ayanlere, & Ekenta, 2013; Ayoola, Ayoola, & Ladele, 2012). All studies of interests performed quantitative research using a combination of descriptive and explorative survey approaches. Researchers (Aderolu *et al.,* 2014; Mohammed, Ayanlere, & Ekenta, 2013; Ayoola, Ayoola, & Ladele, 2012) focused on factors influencing production along with marketing of coffee in Kogi, Nigeria. Mohammed, Ayanlere, & Ekenta (2013) emphasized the importance of making coffee production profitable. The authors also examined the factors hindering the profitability of farmers cultivating coffee. All studies provided reliable data collection procedures and insights on the salient factors that debilitate the sailing of coffee production in Nigeria as well as feasible recommendations to correct these aberrations. No author declared a conflict of interests. This study is primary a descriptive in nature with extensive use of descriptive analysis using statistical tool such as frequencies with a minimal manipulation of variables. Due to the population focus of the primary data employed in this study, this paper narrows its lenses, to a great extent, on Kogi State, and largely Kabba-Bunu Local Government Area. The Kabba-Bunu Local Government area is identified as a house to the highest number of coffee producers in the state.

Data mining (2021)

ISSN: 2814-0508

Many of the farmers, about 48 % of farmers were >61, followed by the 51-60 age bracket with a frequency distribution of 21.78 %. The youths had the lowest population with only 4.44 % for the 21-30 years' age bracket. The results revealed a great disparity in the participation level of males and females in coffee production. A significant proportion of the sampled coffee farmers were males with a percentage distribution of 88.22 %.

A moderate exposure to education was observed among the surveyed farmers. Many attended schools up to the secondary level with percentages of 22.44 %, 27 %, 30.67 %, and 19.89 % for no formal education, primary, secondary, and university tiers, respectively. Only 7.5 % of the farmers have formal training on coffee training and new technologies. That leaves 92.5 % farmer with no formal coffee production and new technologies training.

Approximately 98 % of farmers are married with an average family size of 6-10 (over 50 % of farmers). Although the average farmer's income could not be ascertained, other parameters such sources of finance for coffee cultivation and production, link to coffee market, and mode of land inheritance were used in evaluating farmers' financial statuses. About 82.84 % of the farmers depend on their personal savings for their coffee farms production activities. Most coffee farmlands were passed on to current owners through inheritance (90.56 %), and their sizes largely varied between 1 to 10 hectares (68.22 %, mean 1.5 ha). Additionally, 87.5% used the dry method for their coffee processing while the rest 12.5 % opted for the wet processing technique. Many of the farmers (76 %) accessed ready coffee markets through agents who serve as middlemen while just 4.5 % farmers directly marketed their products. The efforts of the government and cooperative societies only resulted in creating 19.5 % market availability for the farmers. Nevertheless, 66.91 % of the evaluated farmers relied on the expertise of hired hands in coffee cultivation.

DISCUSSION

The socioeconomic status (SES) is a classification system that depicts the social and economic standing of a person in the society in relation to others. Variables such as income level, level of education, work experience, type of work, type of place of residence, and social status in the community are indicators of an individual socioeconomic status (Darin-Mattsson, Fors, and Kåreholt, 2017). Regardless, measures and indicators of socio-economic statuses vary from one location and culture to another (Omonijo *et al.,* 2015). However, income, education, and occupation are commonly employed across board, including Nigeria, to determine an individual's socioeconomic status. Classification based on socioeconomic variables reveals three distinct classes of SES namely: High SES, middle SES, and low SES.

According to Ayoola, Ayoola, & Ladele (2012), *C. arabica* cultivation is primarily undertaken by small-scale farmers (low SES), and this is confirmed in this study. The farmers' socioeconomic status (SES) is pivotal to several decisions including the success rate of cultivation and processing through application of new technologies, appropriate agronomy practices, size of farmland available for coffee cultivation, and finance ploughed into cultivation. Of special importance is the choice of efficient coffee processing procedures.

In this research, many of the respondents were advanced in age, with a significant proportion above 50 years. This implies a disinterest and lack of youthful participation in coffee production. Unfortunately, this factor can negatively impact output as the older age groups may have lesser strength and capacity to bear the rigorous agricultural endeavor. As a result, there may be less enthusiasm to pursue long-term coffee investment which will directly and consistently reduce production output. The direct effect of this is the inability of farmers to meet up with the local demands of coffee. To improve the country's coffee production and subsequent utilization, manpower resources must be revived through extensive inclusion of the youths in various coffee production programs.

In the same regard, literacy level in farmers is an advantage as it can boost the uptake and adaptation of novel, advanced and technical practices, particularly in coffee processing. Although no wide margin existed among the four tiers of the educational system used in Nigeria among the farmers, an absolute consideration of farmers' exposure still reveals a low literacy level among them. The low literacy level, combined with non-existing formal training on coffee and exposure to new technologies, has a direct and proportional effect on the processing technique adopted. The wet processing technique is the preferred method for coffee due to the excellent quality of the final product (Koskei, Patric, & Simon, 2015). As a result, wet-processed coffee are better priced, up to 20% premium and utilized, compared to dry-processed coffee (Duguma & Aga, 2019). In this case, a significant proportion of the farmers are still on the old dry-processing template, implying that many coffee produced are of inferior quality. Hence, they may not appeal to consumers because of the possible low-quality of final products from such coffee beans. According to Ang (2015), Nigeria has a growing coffee consumption culture but many of the coffee consumed are imported. The reason for this incidence, as well as the inability of local industries to use locally sourced coffee, as given by the Secretary-General of the National Coffee and Tea Association of Nigeria, is the low-quality of coffee (Oyibo, 2018). However, the low quality can be linked to the low and inefficient processing techniques adopted by farmers. This phenomenon can be greatly improved with adequate exposure to formal education, trainings, and proper dissemination of new technologies. The government must set up enticing and incentive-rich platforms to retain education-wise farmers in coffee processing. Otherwise, coffee processing will continue its downward spiral movement as farmers with the hope of better jobs will move out from the sector.

Coffee processing, like many other agricultural ventures, is labor-demanding. However, many farmers, as shown by Ayoola, Ayoola, & Ladele (2012), and Mohammed, Ayanlere, & Ekenta (2013) complain of shortage of manpower. As a result, they opt for a large family system, depending on the children for cheap labor. The demerit this phenomenon holds is that many farmers may not put in concerted efforts to procure paid expertise for adequate management, which in turn, has an overall adverse effect on product cultivation and processing.

Lastly, the lack of adequate funding for coffee farmers poses a huge setback in the ability of the farmers to produce high quality coffee products. Many of them depend on their meager savings for the agricultural exploits. Hence, they will source for cheap methods and quantity over quality and excellence which may come at a greater price.

In conclusion, low socioeconomic status of farmers is a great impediment to coffee production, processing, and subsequently, utilization both for commercial and personal purposes.

ABSTRACT

The study assessed the socio-economic variables of cashew farmers in Kogi State. Two towns within Kabba-buni Local Government Area (Araromi-wata and Okebukun) were purposively sampled. These areas are known for the cultivation, production and marketing of cashew. A total sampling frame of seventy-five respondents was used. Structured interview schedules were used for data collection. Data were analyzed using descriptive statistics (frequency, mean, percentages and standard deviation). Age of farmers, educational level, farm size, household size, gender, membership of an association, and marital status of farmers constituted major socio-economic variables among cashew farmers in the study area. However, age, educational level, household size and farm size of the farmers have their mean values as 52±14, 2±0.16, 6±3, 5.7(±10.6), respectively. It is thus important for the government and other development partners in cashew production to develop policies that will enable the farmers to increase their farm holdings for higher productivity since they are still in their productive years. Adult literacy programmes should be encouraged and introduced to the study area to increase the educational level of farmers. Farmers that are members of association should be encouraged to participate more as this will go a long way in price determination for increased profit and access to trainings on improved production packages.

Key words: Cashew, Socio-economic variables, Farm holdings, Government

INTRODUCTION

Cashew (*Anacardium occidentale* L.) originated from Brazil in South America. It is commonly grown in tropical countries of Africa; Nigeria inclusive. It is a broad-leafed evergreen tree crop that thrives well in poor soils and dry sandy locations. There are tons of write-ups and studies about Nigeria's agricultural misadventure. However, we can bring some focus to a segment that can be regarded as a low hanging fruit in the Agricultural sector – Cashew. Nigeria is one of the largest producers of Cashew in the World. Furthermore, the International Nut and Dried Fruit Council (INC) in 2014 valued the global cashew market a whopping $4.69 billion. It is difficult to assess the production volumes across the various producing nations but the Food and Agriculture Organization (FAO) estimates that the production of raw cashew nuts (RCN) has grown from 0.29 million tons in 1961 to 2.60 million tons in 2013 and West Africa's share of the market has tripled in the past decade. Cashew grows almost everywhere in Nigeria but it is concentrated primarily across the three southern geopolitical zones as well as the middle belt. The major producing Nigerian states are Benue, Kogi, Kwara, Oyo, Enugu, Abia, Anambra, Ekiti and Imo. The National Cashew Association of Nigeria (NCAN) reported that Nigeria earned US$ 402 million (N144.7billion) from the export of RCN to Vietnam and other countries in 2017. In addition, the National Bureau of Statistics (NBS, 2017) reports that cashew exports increased by 463 percent from N2.4bn in first quarter 2017 to N13.5bn in second of 2017 on a quarter-on-quarter basis. The production of cashew can solve economic, social and environmental problems in Nigeria.

Cashew contributed less than 2 percent to total agricultural exports in the first quarter but contributed 45.4 percent to the sectorial export in the second quarter and 8.2 percent of total non-exports. The value makes the product the seventh-largest export product in the second quarter of 2017. Price per tonne of cashew nuts was put at US$1,800 and the Price per tonne of processed cashew was put at about US$12,000.

Traditionally too, the agriculture sector and rural economy especially in least developed countries (LDCs), have been characterized by the predominance of a small landowning class, tenants, sharecroppers, and landless labourers who are at the core of the poverty problem (Imran et al., 2009). Meanwhile, Krishna et al (2016) considered gender, age, income and education as the main attributes of socioeconomic variables. Similarly, socioeconomic status has been operationalized in a variety of ways, most commonly as education, social class, or income (Alexander et al., 2017). Therefore, the study assessed the socio-economic variables of cocoa farmers in Kogi State. Meanwhile, farmers' decisions with respect to production and land use are intensely guided by socio-economic factors. On many occasions, the farm size of farmers affects agricultural productivity. This is usually common when the land in question is fragmented, that is, if the land is divided into smaller pieces and allocated to individual farmers. The size of the farms makes mechanized and commercialization farming almost impossible on such land (Marocchino, 2009). In addition, the productivity of farmers to some extent could be attributed to the farmers' years of experience. According to Carter (2009) productivity is achieved, if a farmer is versed in his farming business. That is he cultivates his crops at ease with little or no assistance from extension agents. He has full knowledge of his farming calendar, cropping system, as well as land use patterns and/or system. This therefore underpins the necessity to carry out the research work on the variables of the cashew farmers in the study area. The objective of the study was to profile the socio economic variables of cashew farmers in the study area.

MATERIALS AND METHODS

The study was conducted in Kogi State, Nigeria. The state is in the north central region and falls in to the guinea savannah and tropical rain forest agro ecological zone of the country. Two towns within Kabba-buni Local Government Area (Araromi-wata and Okebukun) were purposively sampled. These areas are known for the cultivation, production and marketing of this crop. Forty farmers were randomly sampled from each of the towns. A total sampling frame of eighty respondents was used. Structured interview schedules were used for data collection from respondents. Data were collected on socio economic variables such as age, educational level, gender, household size, farm size and membership of farmers' group, respectively. Additional information was gathered through informal discussions with the farmers and by personal observations of the crop in some of the farmers' fields. However, during the process of data cleaning only seventy-five questionnaires were used for analysis and data were analyzed using descriptive statistics such as frequency, means, percentages and standard deviation.

RESULTS AND DISCUSSION

Table 1 shows the socio-economic variables of cashew farmers in Kabba-buni Local Government Area (LGA) of Kogi State, Nigeria. The table reveals that majority of the farmers (89.33%) were men. This result is in conformity with Akinpelu et al (2021) who reported that majority of cashew farmers (62.50%) in Oyo State were male. In addition, Lawal et al (2019) affirmed that majority (77.01%) of cocoa farmers in Boki Local Government Area of Cross River State are male. This aligns with the submission by Girei et al (2013) who reported that men are more in a crop that is perceived to have commercial value in Africa. The implication of this is that cashew farming in the study area is largely dominated by male gender and probably because cashew is a cash and perennial crop. However, the result is contrary to Ibekwe (2008) who observed that women play a vital role in food production. Moreover, the mean age of the farmers is 52 years. This also conforms to the findings of Akinpelu et al (2021) who reported 53 years as the mean age for cashew farmers in Oyo State. Osuji et al (2013) also reported that age might have a tremendous influence on productivity, efficiency and utilization of farm resources. The implication of this is that cashew farmers in the study area appear to be in their productive years. The result of the average farm size (5ha) put into cultivation by farmers may perhaps be due to the fact that land owners are reluctant to put their farms into the cultivation of perennial crops. This assertion corroborates Osuji et al (2013) who submitted that majority of the food crop farmers operated on a small scale bases (cultivating less than 3.0 hectares). Similarly, the table reveals that about 44 percent of the farmers had no access to formal education with average years of educational level being about 2 years. This also conforms to Akinpelu et al (2021). The implication of this is that the farmers may perhaps not have access to agricultural production and market information system (MIS) with respect to both production and marketing of the crop. Furthermore, the table reveals an average household size of 6 persons. This conforms with Osuji et al (2013) and Ibitoye et al (2012). It however deviates from the findings of Akinpelu et al (2021). They reported an average household size of 7 and 8 persons in their study on the socio-economic variables of arable and cash crop farmers in Imo, Kogi and Oyo States, respectively. This implies that the farmers may

ISSN: 2814-0508

perhaps utilize members of the household as labour for some operations relating to the production and marketing of the crop. This tends to perhaps reduce some labour and transaction costs that may be incurred on the crop. Moreover, the table shows that about 70 percent of the farmers belong to one association or the other. The implication of this is that the farmers will be able to get needed improved production packages from the association as well as basic information on the production, processing technique and marketing of cashew in the study area.

Table 1: Socio economic variables of Cashew Farmers in Kogi State

CONCLUSION

The study assessed the socio-economic variables of cashew farmers in Oyo State. Age, educational level, household size, farm size, gender and membership of association constituted the socio-economic characteristic factors influencing cashew farming in the study area. More efforts should be made to encourage youth to take up cashew farming as an enterprise to bridge the gap that will be created by the ageing farmers. In addition, adult literacy programme should be introduced to the study area to increase the educational level of farmers. Similarly, farmers should be given incentives to increase their farm holdings for higher productivity. Farmers that are members of association should be encouraged to improve on their participation as this will go a long way in price determination for increased profit and access to training on improved production packages. This will encourage and improve cashew farmers' access to market information and as such will be able to sell the crop for more profits.

ACCESS TO FINANCE AND RESILIENCE OF HORTICULTURAL HOUSEHOLDS TO ECONOMIC SHOCKS DURING COVID-19 PANDEMIC IN NIGERIA

Adegbite, O.O. and Adeoye, I.B.

National Horticultural Research Institute, P.M.B 5432, Idi-Ishin, Ibadan, Nigeria

Corresponding author's e-mail: iyabs1@gmail.com

ABSTRACT

Economic shocks such as those facilitated by the COVID-19 pandemic pose severe threats to livelihoods and efforts to achieve food and nutrition security in Nigeria. However, dearth of empirical evidence exists on how access to finance could play a major role. The study examined the economic shocks, coping mechanisms and the relationship between access to finance and resilience to economics shocks among horticultural farming households in Nigeria during COVID-19 pandemic. Secondary data from the 2019 Nigeria General Household Survey-Panel and the COVID-19 National Longitudinal Phone Survey, 2020 was utilized. A total of 2,656 horticultural households were stratified and used for the study. Data was analyzed using descriptive and correlation analysis. Findings showed an increasing trend in the share of households affected by economic shocks such as income loss. A mix of more negative mechanisms such as reducing food consumption than the positive ones (relying on savings) were employed and could increase vulnerability. Although, only 33% had access to finance, results showed that access to finance could increase the resilience of horticultural households to economic shocks. The study recommends the need to strengthen the financial access of horticultural farming households to build resilient food systems and recover from the negative consequences of shocks during the COVID-19 pandemic and against future crises.

Key words: Horticultural households, Economic shocks, Financial access, Resilience, COVID-19, Nigeria

INTRODUCTION

Horticultural sector in Nigeria has evolved as a vital component of agriculture. Through activities such as production, distribution, marketing, processing and utilization of fruits, vegetables, spices, ornamentals and landscape plants, the sector offers a wide array of economic opportunities to Nigeria's over 202 million people (World Bank, 2019a). While agriculture significantly contributes about 22% to Nigeria's gross, the horticultural sector has potentials to achieve food and nutrition security, generate income and foreign earnings, employment, crop diversification, agribusiness development, poverty reduction and sustain livelihoods (World Bank, 2020; Ibeawuchi et al., 2015). Despite these potentials and efforts of the Government of Nigeria to transform agriculture, the horticultural sector is quite under developed due to challenges such as scattered production, poor access to finance leading to low investments, low inputs and yields and high postharvest losses (Ibeawuchi et al., 2015). In addition to a failing infrastructure, limited access to markets, major dependence on rain-fed and labour intensive production system and a lack of policy coherence (van der Waal, 2015).

Recently, these challenges are further exacerbated by the COVID-19 pandemic with the first confirmed case in Nigeria on February, 27, 2020 (NCDC, 2021). Since then, the Nigerian Government had implemented various measures such as social distancing, lockdowns, limited mobility and restricting market access to specific days to curb the spread of COVID-19 (Reuters. 2020). Although, agriculture related activities (including horticulture) are termed "essential" and are exempted from lockdowns, the lockdown measures created greater challenges to economic activities including farm labour availability, livelihoods, disruptions in agricultural input and output markets and increases in food insecurity, affecting more vulnerable households, with impacts expected to continue through 2021 and into 2022 (World Bank, 2021). While the pandemic poses severe challenges to most horticultural value chain activities due to the high perishability of horticultural crops, it also presents an opportunity to fast-track horticultural transformation to build its resilience in the face diverse challenges, including the food insecurity of Nigerians and a changing climate.

Building resilience refers to how financial services allow people to prepare for economic shocks, respond to them, adapt and recover afterwards (Gash and Grey, 2016). While, economic shocks such as those presented by COVID-19 pandemic may reduce income, deplete resources, and viable livelihood opportunities, households in developing countries use a variety of strategies to cope with shocks. Some of the strategies include income diversification, sale of assets, using savings, reallocating labor, borrowing from friends, families and financial institutions, reducing food consumption, buying on credit and selling livestock (Gash and Grey, 2016). Access to financial services such as savings, credits and insurance have progressively been touted as an operative way to recover from negative economic shocks, invest in modern technology, capture economic opportunities, access knowledge and best practices which can increase productivity (Van der Waal, 2015). However, no study has examined the relationship between access to finance and resilience of horticultural households to economic shocks during COVID-19 pandemic in Nigeria. In order to fill the research gap, this paper aims to examine the economic shocks experienced by horticultural households, coping strategies and the relationship between access to finance and resilience of horticultural households to economics shocks during COVID-19 pandemic in Nigeria. Findings from this study would provide insights into policy responses to strengthen the resilience of horticultural households in the face of current and future economic crises.

MATERIALS AND METHODS

The study analyzed secondary data from the World Bank Living Standards Measurement Study and the Integrated Surveys on Agriculture (LSMS-ISA) comprising the 2019 Nigeria General Household Survey-Panel (GHS -Panel, Wave 4) and the COVID-19 National Longitudinal Phone Survey (NLPS) 2020 (World Bank, 2019b; 2020b). The study utilized round one and round eight of the Nigeria COVID-19 NLPS collected from 20 April - 11 to May 2020 and from 5 to 21 December 2020 respectively. The households interviewed in the COVID-19 NLPS were drawn from the sample of agricultural households interviewed in 2019 GHS-Panel. The extensive data collected in the GHS-Panel just over a year prior to the COVID-19 pandemic provides a rich set of background information on the Nigeria COVID-19 NLPS agricultural households which can be leveraged to assess the effects of the pandemic. For the purpose of this study, the agricultural households were first stratified into horticultural households and non-horticultural households. Next, a total of 2,656 horticultural households were stratified and utilized for the study. Information on horticultural crop farming activities, economic shocks, coping mechanisms and access to finance during the COVID-19 pandemic were obtained and analyzed using descriptive and correlation analysis.

RESULTS AND DISCUSSION

COVID-19 and economic shocks of horticultural farming households

Results (Fig. 1) showed that as at April, 2020 (after the start of the COVID-19 pandemic in Nigeria), 30% of the horticultural farming households have been affected by various economic shocks. These include job/ income loss, disruption of farming activities, increase in price of major food items consumed, increase in the price of farm inputs, fall in the price of farm output, non-farm business closure, looting of cash and other property, illness, injury, or death of income earning member of household and "others" such as breakdown of equipment and limited funds. However, by December, 2020 the proportion of households affected by these shocks had increased to 34%. This suggests that horticultural farmers are likely to become more vulnerable to economic shocks as the COVID-19 pandemic extends which could also affect their livelihood opportunities and abilities to cope with or recover from shocks.

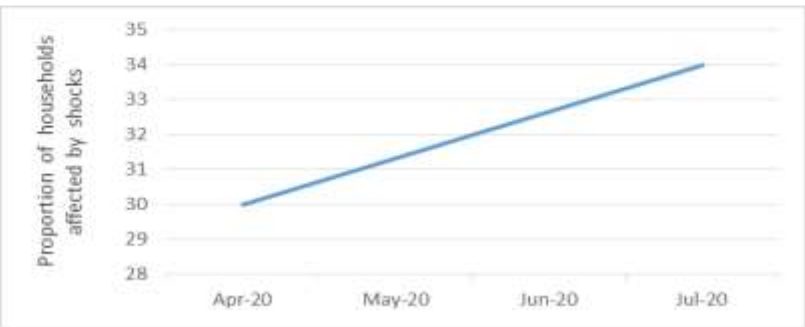

Figure 1: Exposure to shocks during COVID-19 pandemic

ISSN: 2814-0508

Categories of coping mechanisms

Findings showed that the most common strategies employed by horticultural households to cope with economic shocks (Fig. 2) are reducing food consumption, doing nothing, reliance on savings and engaging in other income activities. "Others" include reducing production to subsistence, cutting down on farm inputs and selling outputs at giveaway prices. According to Gash and Grey (2016), coping mechanisms could be categorized into positive and negative. The use of positive coping mechanisms such as relying on savings and diversifying economic activities lead to the resilient pathway through which households are able to recover from shocks and become better. Conversely, the negative coping mechanisms such as reducing food consumption, selling of assets or outputs at giveaway prices lead to the vulnerability pathway whereby households become worse off than before resulting in outcomes such as food and nutrition insecurity, poor health and economic status. Results showed that overall, a mix of more negative mechanisms than the positive ones (29%; 30%), sole negative (15%; 22%) and sole positive (5%; 6%)) mechanisms were employed as at April and July, 2020 respectively by horticultural farming households.

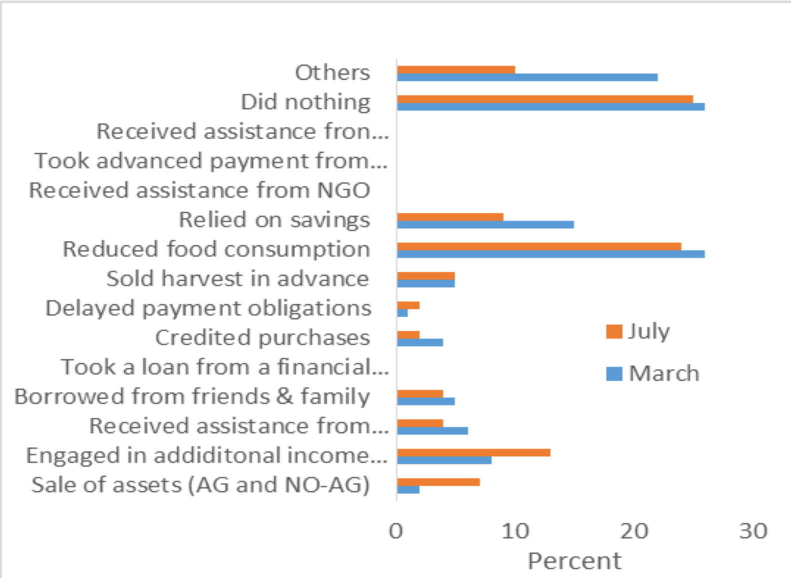

Figure 2: Distribution of respondents by use of coping mechanisms

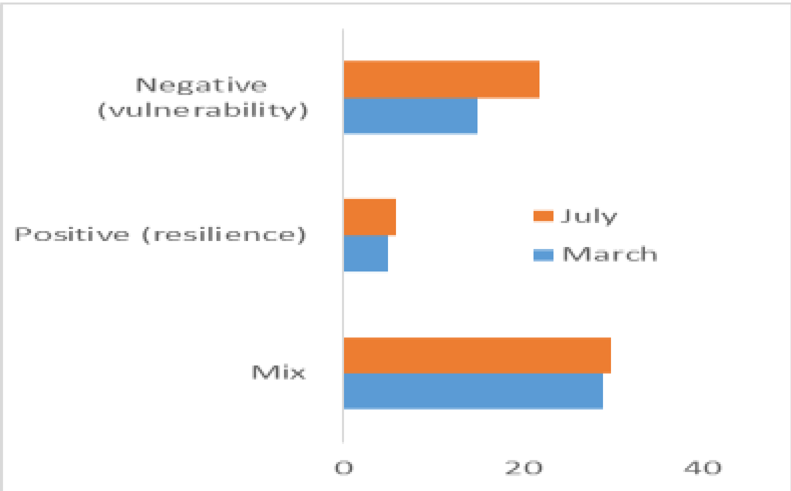

Figure 3: Categories of coping mechanisms

Access to finance and resilience of horticultural households to economics shocks

While more than three-quarter (78%) of horticultural households in this study indicated that the coronavirus outbreak constituted a major threat to the finances, only 33% had access to finance (Table 1). According to Demirguc-Kunt and Klapper (2013), access to financial services, such as credit, savings and insurance facilitates several livelihood opportunities which include consumption smoothening, savings and capital accumulation, reduce exposure to shocks and investment in economic opportunities. Overall, a positive relationship exists between access to finance and resilience of horticultural farming households. The insignificance of the relationship could be because only a small share (4%) of households who have access to finance use sole positive mechanisms (which has a resilience pathway). Notwithstanding, evidence suggests that access to finance has the potential to strengthen the resilience of horticultural households to cope with and recover from economic shocks during COVID-19 pandemic.

Table 1: Relationship between access to finance and resilience to economic shocks

	% Coping mechanism								% Pooled access to finance
	Sole +ve	Inc_div	Rely_sav	Assist_ friends	Borrow_ friends	Took a loan	Assist_ NGO	Assist_ Govt	
Access to finance	4.27 (38)	0.82 (7)	4.06 (36)	1.53 (14)	1.94 (17)	0.02 (0)	0.15 (1)	0.15 (1)	33.34 (885)
Estimated correlation	0.008	-0.053	0.016	0.012	-0.005	-0.002	0.034	0.016	
P-value	0.684	0.002	0.429	0.546	0.796	0.989	0.167	0.447	

Source: Authors' estimation

Note: Sole +ve = sole positive mechanism; Inc_div = Income diversification; Rely_sav = Rely on savings; Assist_NGO = Received assistance from NGO; Assist_Govt = Received assistance from Government

The significant negative relationship between access to finance and income diversification implies that most households would only diversify income sources to cope with shocks but invest in horticultural farming with increased access to finance which further confirms the viability of horticultural production.

CONCLUSION

Findings suggests that more horticultural farming households are likely to become vulnerable to economic shocks as the COVID-19 pandemic prolongs due to an increasing trend in the share of households affected by shocks. Moreover, the majority could be limited in their abilities to maximize economic opportunities and recover from shocks due to a low level of access to finance. Findings suggest a crucial policy issue to address if the goal is to build the resilience of horticultural farmers in Nigeria against economic shocks and to achieve important outcomes such as food and nutrition security. The use of sole negative coping mechanisms or a mix of more negative mechanisms than the positive ones would in due course retard the progress made so far in transforming horticulture, make farmers worse off than before and could lead to the total collapse of the sector. The study recommends the need to strengthen the financial access of horticultural farming households to build resilient food systems and recover from the negative consequences of economic shocks during the COVID-19 pandemic and against future crises.

COMPLIANCE WITH COVID-19 PROTOCOLS AMONG YOUTHS INVOLVED IN FOOD SECURITY COMPETENCE ENHANCEMENT INITIATIVES DURING LOCKDOWN IN OYO STATE

Olajide-Taiwo, L.O. and Olajide-Taiwo, F.B.

National Horticultural Research Institute, P.M.B. 5432, Idi-Ishin, Ibadan

ABSTRACT

Embarking on food security competence-enhancement initiatives were expedient during COVID-19 lockdown. This study assessed the level of compliance with COVID-19 protocols among selected youths involved in various food-security competence-enhancement initiatives during lockdown in Oyo state. Purposive sampling technique was used to select 138 registered members of Oyo state Young Agropreneur (OYAP) who participated in at least one food security competence-enhancement initiative during the lockdown. Questionnaire using Google form was sent to e-mail addresses of the participants with one-week response framework. The 33 (23.9%) questionnaire returned was analyzed using descriptive and inferential statistics. Most (84.8%) respondents were male with average age of 31.72±6.91 years. Majority (84.8%) have agriculture-related profession with 30.3% having first degree and were OYAP members for two years (63.6%). Participation in farmer business school (81.8%) ranked highest while citrus and pineapple value chain (21.1%) ranked lowest among the six food security competence-enhancement initiatives. Highest ranking COVID-19 protocol complied with were use of nose mask (78.8%) and hand washing (60.6%) while removal of cloth worn out on getting home (30.3%) ranked last. Rating of COVID-19 protocols compliance was high among 66.7% of the respondents. There was significant relationship between compliance with COVID-19 protocols and educational level of the respondents (R = 2.102, p = 0.045). Continuous public health education to enhance compliance with COVID-19 protocols in public and private places is advocated to enhance sustainable food security and health.

Key words: Young agropreneur, COVID-19 protocols, competence, health education

INTRODUCTION

Food security exists when all people, at all times, have physical, social, and economic access to sufficient, safe and nutritious food which meets their dietary needs and food preferences for an active and healthy life (World Food Summit, 1996). Food security dimensions are availability, accessibility, utilization and stability (FAO, 2006). Food security is one of the key focus of the Economic Recovery and Growth Plan (ERGP) and Agriculture Promotion Policy (APP) of the current government of Nigeria (Ministry of Budget and National Planning, 2017; Federal Ministry of Agriculture and Rural Development, 2016).

However, the advent COVID-19 epidemic from China in late 2019, later declared as worldwide pandemic on March 11 2020 came with social and economic challenges across all sectors including agriculture with food insecurity risks (World Health Organization, 2020; Olajide-Taiwo, 2020). Government of several countries including Nigeria employed restriction of movement as a strategy to curb spread of the disease. Oyo state government in Nigeria also follow suit in observing the lockdown for some time. Howbeit, some essential and economic activities such as agriculture and food security-related were allowed.

During the lockdown in Oyo state, several food security competence-enhancement initiatives were carried out in order to forestall COVID-19-induced food insecurity. The significance of competence enhancement as a guarantee for continuous food security cannot be overemphasised (Olajide-Taiwo et al, 2009). Food security competence-enhancement initiatives for sustainable food security despite COVID-19 and lockdown was essential in Oyo state. Hence, there was the need to choose between adherences to COVID-19 protocols when embarking on food security competence-enhancement initiatives during lockdown or face food insecurity during and after the lockdown. This study focus on Oyo state Young Agroprenure (OYAP) who participated in at least one food security competence-enhancement initiative during the lockdown. The general objective of this study was to assess compliance with COVID-19 protocols among youths involved in food security competence-enhancement initiatives during lockdown in Oyo state. Specifically, the study addressed the following objectives:

i. Analyse personal characteristics of youths that are involved in food security competence-enhancement initiatives during lockdown.

ii. Examine the food security competence-enhancement initiatives the youths embarked upon during lockdown.
iii. Determine their compliance with COVID-19 protocols when embarking on food security competence-enhancement initiatives during lockdown.
iv. Identify the factors responsible for level of compliance to COVID-19 protocols among the youths.

MATERIALS AND METHODS

Population of the study include all the 138 registered members of Oyo Young Agropreneur (OYAP) who participated in at least one food security competence-enhancement initiative during lockdown in Oyo state. Purposive sampling of all the participants was made due to small population size. Data were collected using Google form-designed questionnaire sent to their email addresses. They were given a timeframe of one week to respond. Items assessed in the questionnaire include respondents' personal characteristics, participation in food security competence-enhancement initiatives and observance of COVID-19 protocols. Observance of COVID-19 protocols was measured using a list of five COVID-19 protocols. Respondents were requested to indicate their frequency of observance of the protocols during food security competence enhancement initiatives as "Yes, very frequent" = 3, "Yes, frequent" = 2, "Yes, not frequent" = 1 or "No" = 0. This give Maximum COVID-19 Protocol Observance Score (COVID-19 POS) = 15 and Minimum = 0. Mean score and above = "High" COVID-19 POS while scores below the mean = "Low" COVID-19 POS. The 33 (23.9%) questionnaire returned within one week was analysed using descriptive (frequency counts, percentages) and inferential (linear regression) statistics.

RESULTS AND DISCUSSION

Personal information

Most of the respondents were male (84.8%). Almost half (48.5%) were between 31 - 40 years' age bracket with an average age of 31.7±6.91 years. Professionally, majority (84.8%) have agriculture-related background and most of them (63.6%) have been members of OYAP for two years. They have one form of education or the other up to post graduate level (Table 1). The personal characteristics of the youth portrays a well-informed, energetic and professionally advantaged group of people in agriculture. The conspicuously high educational status of the youth is capable of positioning them to have access to various forms and sources of information about COVID-19 and the implications for their health and performance in agriculture.

Table 1: Personal Characteristics of Respondents

Variable	Category	Frequency	Percentage
Sex	Male	28	84.8
	Female	5	15.2
Age (Years)	21 – 30	15	45.5
	31 – 40	16	48.5
	41 and above	2	6.0
Mean age	31.72		
Standard deviation	6.91		
Profession	Agriculture-related	28	84.8
	Others	5	15.2
Year of OYAP membership	1	5	15.2
	2	21	63.6
	3	7	21.2
Mean year of OYAP membership	2.1		
Standard deviation	0.17		
Membership status	Executive	15	45.5
	Non-executive	18	54.5
Educational qualification	MSc	9	27.3
	BSc	10	30.3
	HND	6	18.2
	OND	4	12.1
	Others	4	12.1

Participation in food security competence-enhancement initiatives

The youths were involved in a total of six food security competence-enhancement initiatives during the lockdown in Oyo state. Out of these initiatives, participation in farmer business school ranked first involving 81.8% of the youths while participation in citrus and plantain value chain involving 21.2% of the youths ranked last (Table 2). The consciousness of majority of the youth to involve in famer business school could be adduced to the paradigm shift in agriculture from being a way of life to being a business in Nigeria (Oredipe, 2013). Agribusiness with emphasis on value chain was brought to the front burner through Agricultural Transformation Agenda (ATA) of Goodluck Ebele Jonathan-led administration. This metamorphosed into Agriculture Promotion Policy (APP) of the Muhammadu Buhari-led government in the country. Agriculture value chain is now seen as a means to transform the economy through import substitution and job creation among other benefits (Federal Ministry of Agriculture and Rural Development, 2016; Oredipe, 2013).

Table 2: Ranking of Respondents According to their Participation in Different Food Security Competence-enhancement Initiatives during Lockdown

Initiative	Yes	No	Rank
Farmer business school	27 (81.8)*	6 (18.2)	1
Snail production	22 (66.7)	11 (33.3)	2
Organic tomato production	18 (54.5)	15 (45.5)	3
Maize production	14 (42.4)	19 (57.6)	4.5
Research grant writing	14 (42.4)	19 (57.6)	4.5
Citrus and plantain value chain	7 (21.2)	26 (78.8)	6

*Figures in parentheses are percentages

Compliance with COVID-19 protocols among the youths

Compliance with COVID-19 protocols when participating in food security competence-enhancement initiative during lock down in Oyo state was high among 66.7% of the youths (Figure 1). All the respondents complied with use of face mask, washing of hands and physical distancing at the venue of training. Although, level of compliance varies from one person to another. Most of them very often complied with use of face mask (78.8%) followed by washing of hands (60.6%) and physical distancing (57.6%). Less than half very often complied with bathing (45.5%) and removal of cloth (30.3%) at home when they return from training venue. Generally, the level of compliance to the COVID-19 protocol was higher at the training venue than at home (Table 3). This could be due to enforcement at the training venue while the home provided a more relaxed atmosphere.

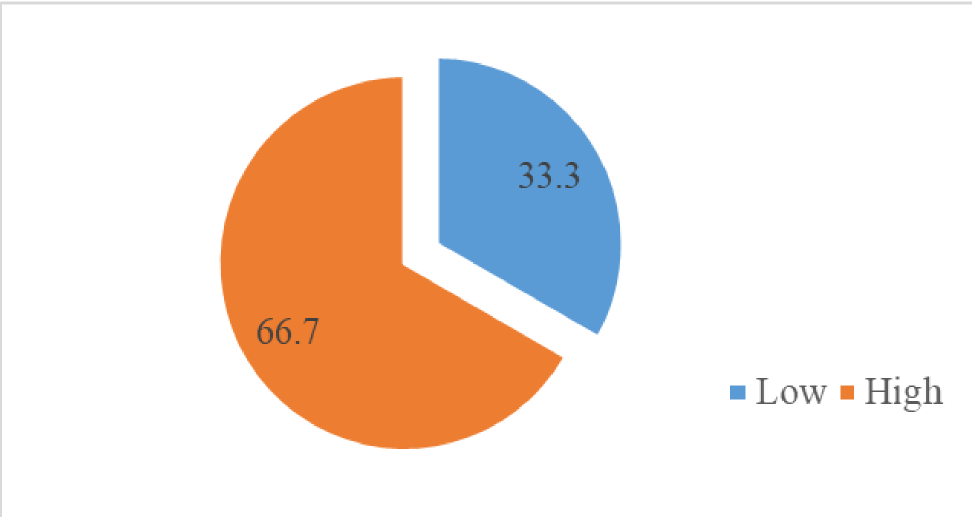

Figure 1: Rating of COVID-19 compliance among respondents in percentages (n = 33)

Table 3: Percentage Distribution of Respondents According to their Compliance with COVID-19 Protocols (n = 33)

Compliance	COVID – 19 Protocols				
	Use of face mask	Washing of hands	Physical distancing	Removal of cloth at home	Bathing at home
No	0.0	0.0	0.0	21.2	9.1
Yes, not often	12.1	6.1	15.2	30.3	15.2
Yes, often	9.1	33.3	27.3	18.2	30.3
Yes, very often	78.8	60.6	57.6	30.3	45.5

Factors responsible for level of compliance to COVID-19 protocols among the youths

Compliance with COVID-19 protocols among the respondents was significantly related with level of education (R = 2.102, p = 0.045). Other personal variables of the respondents did not have any significant effect on their compliance (Table 4). Level of education enhances assimilation and response to changes especially in novel cases such as COVID-19 (Olajide-Taiwo, 2015; Glanz and Rimer, 2005). The level of education of the youths is very high, this could be responsible for their high level of compliance with the COVID-19 protocols especially at the training venues.

Table 4: Regression Analysis Showing Correlation between Compliance with COVID-19 Protocols and Selected Personal Characteristics of the Respondents

Model	Standardized Coefficient	R	Significance (p)
Constant		1.561	0.131
Sex	0.089	0.482	0.634
Age	0.030	0.160	0.874
Level of education	0.401	2.102*	0.045
Profession	- 0.032	- 0.173	0.864
Year of OYAP membership	- 0.023	- 0.119	0.906
Participation in food security competence-enhancement initiative	0.148	0.751	0.459

*Significant at 0.05 level

CONCLUSION AND RECOMMENDATIONS

Compliance with COVID-19 protocols was high among the youths when engaging in food security competence-enhancement initiative during lockdown in Oyo state. Less compliance with COVID-19 protocols took place among them outside the venue of the competence-enhancement activities. Educational qualification contributed significantly to observance of COVID-19 protocols among the youths. Hence, there should be continuous public health education to enhance compliance with COVID-19 protocols among the populace to enhance sustainable food security and health.

ABSTRACT

Cocoa production was important to the economy of Nigeria in the past. Cocoa was a major foreign exchange earner for Nigeria in the 1950s, 1960s but due to investments in the crude oil sector in the 1970s and 80s, Nigeria's share of world output declined. Cocoa contributed 0.05% to GDP in 2016 from 0.3% in 2010. The contribution of cocoa to Nigeria's agricultural GDP continues to decrease and attention continues to shift from cocoa production. This study therefore examined the trend of cocoa production in West Africa. Frequencies, percentages and charts were used for analysis in this study. Data on area of land cultivated (hectares), yield(kg/ha) and production in tonnes were used in the study. Secondary data from FAO (Food and Agricultural Organisation) were used for this study. Four countries with the highest cocoa beans production were selected for this study. They are Cote d'Ivoire, Ghana, Nigeria and Cameroun. Fifty-eight years of cocoa beans production were presented in the data (1961-2018). The average land cultivated over the years for the four countries were 1,475,304, 1,333,895, 857,036.9 and 447,355.5 hectares respectively. The average yield was Cote d'Ivoire (5200.12hg/ha), Ghana (3332.69hg/ha), Nigeria (2819.15hg/ha) and Cameroun (2831.59). The average production in tonnes Coted'voire (813,349), Ghana (453,507), Nigeria (270,561.8) and Cameroun (146,328). Nigeria ranked third in area of land, yield and production, this in spite of the country's vast land mass and high production level a few decades ago. The right policies should be put in place to boost cocoa beans production in Nigeria; this way, cocoa will once again help contribute to Nigeria's GDP as it did in the past. It will also regain the central place it occupied in the West African sub-region.

Key words: Area, Cocoa Beans, Production, West Africa, Yield

INTRODUCTION

Cocoa (*Theobroma cacao)* is a tropical perennial tree crop which is the product of the fruit of the cocoa tree. Cocoa is a native to the Americas and was a valuable crop in the earliest South American cultures. It is one of the major agricultural exports from West Africa. West Africa is the world leader because it produces over 99% of African cocoa. Over the past many decades, many West African nations, have remained in the forefront of cocoa production far higher than other areas of the globe with the growth of 2-3 million tons since the 2000s (Fountain and Hütz-Adams, 2015). In West Africa, cocoa is mainly grown by smallholder farmers who traditionally planted their cocoa at random under thinned forest shade. It is a low input cultivation system which uses the forest soil fertility and the existing shade. This simple method explains that cocoa is cultivated on about six million ha of the West African forest zone which provides about 70 percent of the total world production. The by-products of cocoa beans (liqueur, paste, butter, cake and powder) are raw materials in the chocolate industry and its best-known end product is chocolate. Cocoa beans are produced in tropical zones around the Equator, where the hot and humid climate conditions are well suited for growing cocoa trees. About 70 percent of the world's cocoa beans are produced from four West African countries namely Côte D'Ivoire, Ghana, Nigeria and Cameroon. Côte d'Ivoire and Ghana are the two largest producers of cocoa, accounting for more than 50 percent of the world´s cocoa followed by Nigeria and Cameroon. West African production of cocoa is dominated by Côte d'Ivoire. In 2005, 1.3 million tonnes of cocoa were produced by Côte d'Ivoire, Ghana produced 600,000 tonnes, which gave almost 60% of the world's cocoa. Nigeria produced 175,000 tonnes and Cameroon 166,000 tonnes. These four countries are among five primary producers of cocoa in the world. In 2016, Côte D'Ivoire alone produced approximately 1.6 million metric tons of cocoa beans. In terms of annual production size, the eight largest cocoa-producing countries are Côte D'Ivoire, Ghana, Indonesia, Nigeria, Cameroon, Brazil, Ecuador and Malaysia. These countries represent 90 percent of world production. Production from Côte D'Ivoire alone is 40 percent of the world's market share and constitutes 1.2 million metric tonnes per annum (UNCTAD, 2009). In 2000, 80 percent of the commodity exports from Côte D'Ivoire was raw cocoa which was over 50 percent of all exported goods and services, and 21 percent of GDP (Bogetic *et al.*, 2007). The cocoa production increased from about 2,000,000 tons in 2000 to about 3,000,000 tons in 2010.

Cocoa flourishes well only in hot, rainy climates with cultivation generally confined to areas not more than 20 degrees north or south of the equator. The ideal climatic conditions for the growth of cocoa is a mean shade temperature of 27°C, with daily variation less than 8°C, and well-distributed rainfall of at least 12 cm (Kishore, 2010). Annual rainfall between 1,100mm and 3,000mm with a dry season not more than three months with the minimum rainfall level of about 100mm per month is required for good output. Cocoa is usually grown directly from the seed but can also be grown from seedlings raised in nurseries. When the seedlings grow to a height of about 5 cm or so, they are transplanted at a distance of about 3 or 4 meters (Lundstedt *et al.* 2009). The Shady plants can also be planted in between the rows, in order to protect the young plants from strong winds and direct rays of the sun. The most commonly grown type of cocoa may give a first small yield after about five years, though the period considerably varies with local conditions and farming methods. But a full crop cannot be expected for at least ten years. The economic life span of the cocoa tree is not known; but under the best conditions of weather, soil and management, it can be kept almost in indefinitely bearing (Kishore, 2010). The world production of cocoa beans has experienced irregular pattern due to heavy dependence on weather in production, low farm-gate prices, pests and diseases. For example, in 2003/04 season, the global production of cocoa beans continued to rise for the fourth successive year, with output exceeding the recorded production levels of 2002/03 by almost 10 percent to reach 3.5 million tons (ICCO, 2003). ICCO reported that in 2003/04, Cote D'Ivoire defied fears of decline and instead recorded a substantial increase to reach 1.4 million tons, despite two years of political and social unrest. During the same season, good weather, higher farm gate prices, combined with effective government-backed of mass spraying of crops contributed to a substantial increase in yields, propelling Ghana's output to a record of 736,000 tons. However, during 2006/07 season, world production dropped by almost 9 percent from the previous season to 3.4 million tons, mainly as a consequence of unfavourable weather conditions in many cocoa producing areas (ICCO Annual Report, 2006/07).

In the last several years, cocoa output rose to significant levels in the producer nations around the world. Beginning in 1960, world cocoa production has surged notably between 1.2 to 3.6 million tonnes. This increment occurred amidst many shocks triggered by fiscal restructuring programmes, proliferation of crop infestations, plant viruses and price market manipulation, much of which have impacted yield. The key producers in the equator where cocoa beans are grown with dominance of global output consists of West African nations of Cote d'Ivoire (39%) and Ghana (21%) (Lass, 2000; ICCO, 2014). West Africa being a prominent production area stretches from Guinea to Cameroun where most cocoa plants thrive (Ashitey, 2012). The other marginal producing nations in the continent of Africa with lesser profile and output are concentrated throughout the Sub-Saharan region. All in all, the cocoa marketplace transactions are categorized particularly by substantial presence of production activities flourishing in areas where yearly global output hinges on variabilities and attributes of the West African climate (Hatløy *et al.*,2012). In the process, over the past many decades, many West African nations, have remained in the forefront of cocoa production far higher than other areas of the globe with the growth of 2-3 million tons since the 2000s (Fountain and Hütz-Adams, 2015).

Objective of the study

The main objective is to assess the trend of cocoa beans production in West Africa.

The specific objective of the study is to compare cocoa yields/production among cocoa producing countries in West Africa.

Hypothesis Testing: There is no significant difference in the means of yield of cocoa beans in Cote d'Ivoire, Ghana, Nigeria and Cameroun.

MATERIALS AND METHODS

The study area is West Africa. Data from Food and Agriculture Organisation (FAOSTAT, 2020) was used for analysis in this study. Data on area harvested, production and yield of cocoa was used for this study. Data on cocoa from years 1961-2018 was used for analysis. Four countries with the highest cocoa production in West Africa were considered in this study. The countries are Cote d'Ivoire, Ghana, Nigeria and Cameroun. Descriptive

Statistics including frequency, percentage and charts were used in this study.

RESULTS AND DISCUSSION

Table 1 presented the area of land harvested for cocoa beans in West Africa. Between 1961-1970 Nigeria had the least area harvested for cocoa beans while Ghana had the highest. This was the period that Nigeria made a lot of money from the sales of cocoa beans locally and internationally. This showed that Nigeria despite low area compared to other countries still maximised their production and returns from it. From 1981-2018, even though the area of land harvested for cocoa beans increased yet the contribution of cocoa sale, export and agriculture to the economy dwindles. Figure 1 showed the trend of area of land harvested for cocoa beans in West Africa. As shown in the diagram the area of land for Coted'voire has been increasing over the years no wonder they are the highest producer in West Africa.

Table 1: Area of land harvested for Cocoa Beans in West Africa

Year	Coted'voire	Ghana	Nigeria	Cameroun
1961-1970	2963130	14749100	700000	3458000
1971-1980	5161670	12170000	700000	3502556
1981-1990	10439250	7741053	6379500	3830690

Figure 1: Area of land harvested for Cocoa Beans in West Africa

Table 2 showed the production of Cocoa beans in West Africa. Between 1961-1970 Nigeria had the second highest cocoa beans production after Ghana and still contributed a whole lot to the economy even when Ghana's economy had that time been not buoyant. In 2011-2018 Nigeria s now the third largest with Ghana being the second. Ghana's economy has greatly improved while Nigeria's economy is dwindling and agriculture contributing less than 5% to her GDP. In Figure 2 for other West African countries their production levels were increasing over the years but this is not so for Nigeria. Even though the production levels increased over the years but it starts to dwindle down from 2011-2018.

Table 2: Production of Cocoa Beans in West Africa

Year	Cote d'Ivoire	Ghana	Nigeria	Cameroun
1961-1970	1210241	3854200	2033180	809163
1971-1980	2386241	3191920	1840000	1049063

2011-2021	17946374	8521497	3272828	2817179
Average	813349	453507	270562	146328

Source: FAOSTAT, 2020 Note: Production in kg/ha

The yield of cocoa beans in West Africa is presented in table 3. In 1961-1970 Coted'voire had the highest average yield of 36887 while Cameroun had the least 21317 tonnes. In 1971-1980, 81-90,91-2000,2001-2010, 2011-2018 Coted'voire keeps having the highest yield. Nigeria keeps being the third largest except in 1991-2000 when she beats Ghana to become the second largest. Figure 3 presented the yield of cocoa beans in West Africa.

The value of F is 408.84 at a significant level p<0.01. The null hypothesis [Ho] which says that there's no significant difference in the yield of cocoa beans in the four West Africa countries is rejected while the alternative hypothesis is accepted. Therefore, there is significant difference in the yield of cocoa beans in Coted'voire, Ghana, Nigeria and Ghana. The difference might be due to the right policies put in place by the country's governments to boost production in their respective countries.

Figure 3: Yield of Cocoa Beans in West Africa   Note: yield in tonnes

CONCLUSION

Nigeria ranked third in area of land, yield and production, this in spite of the country's vast land mass and high production level a few decades ago. The right policies should be put in place to boost cocoa beans production in Nigeria; this way, cocoa will once again help contribute to Nigeria's GDP as it did in the past. It will also regain the central place it occupied in the West African sub-region.

ABSTRACT

The study estimated Cobb-Douglas production function of vegetable in Ezza south local government area of Ebonyi state, Nigeria. Data were generated from sixty (60) vegetable farmers randomly selected from twelve (12) major Farming communities that make up the LGA with the aid of a well-structured questionnaire. Data were analyzed using Cobb-Douglas production function. From the result, the R^2 (0.463) showed that over 46% of the variations in output were jointly accounted for, by the explanatory variables included in the model. Moreover, land (0.471), seed (0.272) were positive and significant at 1% levels but farm size and fertilizer were positive but significant at 5% level. Herbicide (-0.331) was negative but significant at 5% level while labour (0.054), fertilizer (0.143) and pesticide (0.264) were positive and insignificant. Results also showed that return to scale in vegetable production in the area was 0.873, implied decreasing return to scale in vegetable production in the area.

Key words: Cobb-Douglas, Production function, Vegetable, Ezza South, Ebonyi

INTRODUCTION

Vegetable is one of the important sources of vitamins, minerals, dietary fiber and are essential in prevention of diseases (Abdulai, 2006). Vegetable production is of great economic importance as its value chain can provide income and reduces poverty and unemployment (Schreinemacher et al., 2018). Vegetable production has the potential to increase food security and create employment (Smith and Eyzayuirre, 2007). Insufficient intake of fruit and vegetables is estimated to cause around 14% of gastrointestinal cancer deaths, about 11% of ischemic heart disease deaths and about 9% of stroke deaths (WHO, 2020). The World Health Organization recommended con-sumption of 400 g of fruits and vegetables daily to maintain good health. Vegetables production is profitable, and the actors will require adequate knowledge, capital, and new methods of production.

In economic theory, a production function is described in terms of maximum output that can be produced from a specified set of inputs, given the existing technology available to the farm (Battese, 1992). In general, a production function is a specification of how the quantity of output behaves as a function of the inputs used in production. This concept can be applied at the level of individual farms. Various specific mathematical forms have been put forward for the production function, but the most commonly used is that developed by Charles Cobb and Paul Douglas in the second quarter of the 20th century. Here's their specification:

Y=AKαN1−α0< α <1 ………………..(1)

Here, Y = aggregate output, K = capital input, and N = labor input

Cobb-Douglas Production Function was widely used in economics and productivity studies across many sectors (Dennis et al., 2010). Fraser (2002) saw the omission of technical change in the specification of the Cobb-Douglass model as a serious limitation to the acceptance of its assumptions. By failure to recognize technical change, Amuka et al (2018), Fraser says Cobb and Douglas assumed that technology was constant within the period of their study, which does not hold in the real sense of it. The neoclassical economists also attacked the model on the bases that the productivity theory is more of an abstraction than a quantifiable. Douglass while responding to the criticisms noted that the critics were so hostile even to the extent of recommending for the work to be thrown into the waste basket and further research in it stopped. In the defense of the model, from criticism, Cobb-Douglass model started receiving research interest with positive comments and positive empirical result. Miller (2008) accepts that Cobb-Douglass model is very simple to use and can fit many data sets very well for empirical forecasting. Many studies have equally been done in developing as well as developed countries, trying to validate the Cobb-Douglass model. Results of such studies have differed, making it difficult to make a definite conclusion about the Cobb-Douglass postulation. Hence, up to this point, the applicability of constant returns to scale production as postulated by Cobb-Douglass is still at the centre of research interest around the globe (Amuka et al, 2018).

Cobb-Douglas model was based on the assumption of constant return to scale, implying that in the production decision, whenever the inputs used to produce a given output is doubled, total output will automatically double. Adetunji et al. (2012); Abidemi (2010) and some other studies have been done to validate the applicability of Cobb-Douglass laws of production with Nigerian data. Adetunji et al. used macro data to study the application of laws of production as propounded by Cobb-Douglass model. Their result shows that production function in Nigeria follows the constant returns to scale as predicted by Cobb-Douglass model, which means that doubling input use will double output in the country, hence, the estimation of Cobb-Douglas production function of vegetable in my own Local Government Area, Ezza South LGA, Ebonyi State of Nigeria

MATERIALS AND METHODS

The study was carried out in Ezza South Local Government Area of Ebonyi State. The LGA is made up of twelve (12) farming communities. Agriculture is the mainstay of the economy. According to (NPC, 2006), Ezza south has a population of 133,625 people and the total land mass 324 square kilometers.

A multi-stage random sampling technique was used for the study. The study area is made up of twelve (12) major farming communities to include Amuzu, Amana, Amagu, Ameka, Amezekwe, Amudo, Echara, Ezzama, Ikwuator, Nsokkara, Okoffia and Umunwagu.

Stage1: One (1) village was randomly selected from each of the twelve (12) major farming communities to give twelve (12) villages.

Stage2: Five (5) small scale tomato farmers were randomly selected from each of the twelve (12) villages to give sixty (60) small scale tomato farmers.

Model Specification

$Y=f(x_1, x_2, x_3, x_4, x_5, x_{6,} e)$ ………………(2)

Where,

Y=value of output in naira; X_1=Land (hectarage); X_2=labour (Mandays); X_3=Seed (Naira); X_4=Fertilizer (Naira); X_5=Herbicide (Naira), X_6=Pesticides (Naira)

Cobb-Douglas (Double Log):

$Log\ Y = Log\ a_o + a_1Logx_1+a_2Logx_2+a_3Logx_3+a_4Logx_4+a_5Logx_5+ a_6Logx_{6+}et$……. (3)

Where,

Log = Natural Logarithm; Y = Output; X_1 --- X_5 = Inputs (Variables defined in equation 4); a_1-a_5 = Regression coefficients; et = error term; a_o = Regression constant

RESULTS AND DISCUSSION

Table 1: Cobb-Douglas Production Function of Vegetable in the Study Area

Variables	Coefficients	t-values
Land	0.471	3.291***
Labour	0.054	0.283***
Seed	0.272	2.763***
Fertilizer	0.143	1.248^{NS}
Herbicide	-0.331	-2.483**
Pesticide	0.264	1.622^{NS}
Constant	7.360	9.423***
R^2	0.463	

Source: Field Survey, 2020

NOTE: *** and ** = 1% and 5% level of significance respectively, ^{NS} = Not significant

From the table, the R^2 value of 0.463 showed that over 46% of the variations in output were jointly accounted for, by the explanatory variables included in the model. However, land (0.471), labour (0.054) and seed (0.272) were positive and significant at 1% levels. This implied that increase in the three production inputs would lead to increase in the output of vegetable in the study area. Herbicide (-0.331) was negative and significant at 5% level. This implied that usage of the input should be minimized if output is to increase. Furthermore, fertilizer (0.143) and pesticide (0.264) were positive and insignificant, meaning that, with or without, the two inputs factors, output of vegetable could increase in the area. These findings were in consonance with FAO (1998), that land is the most fundamental resource in the rural economy and that, though, very important cannot be productive without labour and other production inputs.

Table 2: Return to Scale in Vegetable Production in the Study Area

Variables	Production Elasticities
Land	0.471
Labour	0.054
Seed	0272
Fertilizer	0.143
Herbicide	-0.331
Pesticide	0.264
Total (Return to Scale)	**0.873**

Source: Field Survey, 2020

From table 2, the coefficients of Cobb-Douglas production function were used as production elasticities. The sum of individual coefficients of Cobb-Douglas production inputs was used as a measure of return to scale in vegetable production, hence, return to scale was 0.873. This implied decreasing return to scale in vegetable production in the study area, meaning that continuous addition of the specified production inputs would result in a decrease in the output of vegetable in the long run. This result agreed with Akpan et al., (2012) whose work had 0.644 as return to scale in waterleaf production and maintained that, continuous increase in the utilization of the specified production inputs would result in a decrease in waterleaf output in the long run.

CONCLUSION AND RECOMMENDATIONS

From the major findings of the study; land, labour and seed were found to play a major role in vegetable production. There was a decreasing return to scale in vegetable production in the area. The study recommended Government and individual assistance to the farmers in the area of access to loan, land, improved varieties of seed and other production inputs.

FOOD INSECURITY STATUS AMONG COCOA FARMING HOUSEHOLDS IN ONDO STATE, NIGERIA

Oluyole, K.A. and Dada, A.O.

Economics Section, Cocoa Research Institute of Nigeria, PMB 5244, Ibadan

ABSTRACT

The study examined food insecurity status among cocoa farming households in Ondo State, Nigeria. Although studies abound on food security however there is a dearth of knowledge on food insecurity, therefore, a necessity for this study. Multi-stage random sampling technique was used to select respondents (farmers) for the study. The first stage was the purposive selection of three Local Government Areas (LGAs) from the State. Second stage was the random selection of 15 cocoa producing communities from the three selected LGAs, while the third stage was the random selection of 400 cocoa farming households from the selected communities (the selection was proportionate to size). Data were collected with the use of structured questionnaire. The data collected were analyzed using descriptive statistics, Food Security Index and Surplus/Shortfall Index. The study revealed that 63.5% of the respondents were above 50 years of age and the mean age of the farmers was 58 years. Also, majority of the respondents (73.8%) were male and 86.8% of the respondents were married. Some (41.75%) of the farming households were having more than 8 members per household and the mean family size was 8 persons per household. Most (55.0%) of the respondent households were food secured while 45.0% were food insecure. Shortfall index revealed that food insecure households fell short of the calorie requirement by 18.0%. The study recommended that effective household size management and family planning should be encouraged by the cocoa farming households to reduce their household size. This can be organized by government health workers and NGOs through rigorous campaign and seminars.

Key words: Food insecurity, status, cocoa, farming households, household size.

INTRODUCTION

Agriculture is the mainstay of the Nigerian economy. It provides employment for over 60 percent of the population. Apart from this, it also provides food for the teeming population, primary products that serve as raw-materials for agro-allied industries, generates income for the rural dwellers and also serves as an important source of scarce foreign exchange through agricultural exports (Oluyole, 2009). During the 1960s, agriculture contributed about 85.5% of the total export and hence became the major source of foreign exchange earnings. However, by 1984, its contribution to export dropped to 2.6 percent while in 2004, the contribution dropped to as low as 0.81 percent. However, the production figure of cocoa (as an important agricultural product) as at 2014 was 48,000 metric tonnes (ICCO, 2015). The progressive reduction in the contribution of agricultural export to the total export was due to the withdrawal of priority attention hitherto given to agriculture and the consequent dependence on oil sector since its discovery in the late 60's. The withdrawal of priority to the agricultural sector which resulted in the reduction of agricultural production has led to the reduction in food supply. Also, the growing urbanization and rapid population growth rate have affected the Nigerian economy negatively and put pressure on attaining sufficiency in food production from the country's agriculture. Consequently, food production has failed to respond adequately to food demand, thus creating food supply-demand gap. Food is a basic necessity of life. Its importance at the household level is obvious enough since it is the basic means of sustenance. However, it has been established that the quantity and quality of food consumed by households affects their health and economic well-being. This in turn have significant repercussions on the general level of economic activities and productivity, leading to food insecurity. According to Esobhawan (2007), food security exists when all people at all times have physical and economic access to sufficient, safe and nutritious food to meet their dietary needs and food preference for an active and healthy life. The main goal of food security is for individuals to be able to obtain adequate food needed at all times and to be able to utilize the food to meet the body's need.

Food security is of three folds. These are food availability, food accessibility and food utilization. Thus, the highest state of food security requires not only making food available, but the food must be accessible and also should be nutritiously well utilized within the body system. However, lack of access to enough quality food leads to food insecurity. According to Oluyole (2009), food insecurity is the inability of a household or nation to

ISSN: 2814-0508

meet largest consumption levels in terms of quantity and quality of food in the face of fluctuating production, prices and incomes. Hence, food insecurity is the limited or the uncertain availability of nutritionally adequate and safe foods. According to Oluyole (2009), cocoa farming households in Nigeria had to grapple with the problem of food insecurity due to the fact that cocoa farmers do not have well established farming system with cocoa cultivation. The reason being that the shade that is being provided by cocoa trees (especially at the mature stage of cocoa) do not allow food crops grown under it to do well, (Ojo, 2005). The effect of this is food shortage which invariably leads to food insecurity among cocoa farming households thus the need for empirical investigation to know the extent of food insecurity in the study area. This study therefore finds it quite imperative to determine the food insecurity status among rural cocoa farming households to ascertain its severity.

Objectives of the study

1. To analyze the socio-economic characteristics of the respondents in the study area;

2. To analyze the extent of food insecurity among the cocoa farming households.

MATERIALS AND METHODS

The study was carried out in Ondo State, Nigeria. The state has 18 Local Government Areas (LGAs), out of which, 15 LGAs produce cocoa. The study made use of primary and secondary data. Primary data were collected through the administration of structured questionnaire to respondents while the secondary data were obtained from secondary sources such as Journals, Nigerian Bureau of Statistics, Central Bank of Nigeria and Annual Reports of Cocoa Research Institute of Nigeria. A multistage sampling procedure was adopted in the selection of the respondents. The first stage was the purposive selection of three Local Government Areas based on the predominance of cocoa producing activities in these areas. These areas were Idanre, Okeigbo/Ileoluji and Ondo East. The second stage was the simple random sampling technique to select 15 communities that is, 5 communities per Local Government Area while the third stage was the proportional selection of 400 farmers from the 15 communities (the selection was proportionate to size). Data were collected from the selected farmers with the aid of structured questionnaire and the data retrieved from the questionnaire were analysed using Descriptive statistics (such as frequencies and percentages), Food Insecurity Index and Surplus/Shortfall Index

Food Security Index

This was generated from the Cost-of-Calorie (COC) function proposed by Greer and Thorbecke (1986).

$$\ln X = a+bC \text{ ……………………….(i)}$$

Where:

X = Food expenditure (N);

C = Calorie consumption (Kcal.).

From the COC function, Z was calculated.

Hence,

$$Z = e^{(a+bL)} \quad \text{…………………….(ii)}$$

Where:

Z = Cost of minimum recommended energy level (N)

L = Recommended daily energy level (2450kcal.) (FAO, 2007);

a = Intercept;

b = Coefficient of the calorie consumption;

e = A mathematical constant (2.71828).

Any household whose average cost of daily calorie consumption is equal to or more than Z is said to be food secure, while any household with average cost of daily calorie consumption lower than Z is said to be food insecure.

Surplus/Shortfall Index

This tool was used to measure the extent to which a household is food secure or insecure. The Index is given as:

$$P = 1/N\sum_{J=1}^{m} G_j \quad \text{……………………….(iii)}$$

$$G_j = (X_j - L)/L \text{………………………….(iv)}$$

Where:

P = Surplus/Shortfall Index;

L = Recommended daily per capita requirements (2450Kcal.);

G_j = Calorie deficiency faced by household$_j$;

X_j = Per capita food consumption available to household$_j$;

N = Number of households that are food secure (for Surplus index) or food insecure (for Shortfall index).

In implementing food security policies and programmes, the value of the index could be monitored over time and compared among the different groups of population.

RESULTS AND DISCUSSION

Table 1 shows the socio-economic characteristics of the farmers. It shows that 63.5% of the respondents were above 50 years of age and the mean age of the farmers was 58 years. This shows that most of the farmers in the study area were relatively old which will have a consequent effect on their productivity. Hence, there's need to encourage youths into cocoa farming in the area. Table 1 also revealed that 73.8% were male headed households while the female headed households constituted 26.2% of the sampled farming households. This implies that male headed households dominated cocoa farming sector in the study area. This finding is in line with Oluyole (2009) who attributed the dominance of the males over the females to the fact that male children are considered as those that can inherit farm lands in the study area. Distribution of the respondents by marital status indicated that 86.8% were married, 5.0% were single, 2.3% were divorced/separated and 6.0% were either widowed or widower. This shows that most of the respondents in the study area were married, which made them to have more hands for farming operations. Furthermore, 44.0% of the households had 5-8 members, 14.25% had 1- 4 household members while 41.75% of the farming households were having more than 8 members. The mean family size of 8 persons indicated that the respondents maintain large household size which may have negative effect on their food status and increase their probability of being food insecure.

Table 1. Socio-economic characteristics of the respondents

Variables	Frequency	Percentage
Age of household head (Years)		
< 30	16	4.00
31-40	33	8.25
41-50	97	24.25
51-60	90	22.50
61-70	77	19.25
71-80	51	12.75
> 80	36	9.00
Total	400	100.00
Sex		
Male	295	73.80
Female	105	26.20
Total	400	100.00
Marital Status		
Single	20	5.00
Married	347	86.80
Divorced/Separated	9	2.20
Widowed/widower	24	6.00
Total	400	100.00
Household size		
1-4	57	14.25
5-8	176	44.00
> 8	167	41.75
Total	400	100.00

Sources: Field data, 2019.

Table 2 presents the food insecurity status among the sampled households. Based on the daily calorie (R) of 2450 Kcal., it was observed that 55.0% of the households were food secure while 45.0% were food insecure. The average household daily per capita calorie intake for the food insecure and food secure households in the study area were 1845.63Kcal and 2964.60Kcal respectively. This shows that food insecure households consume lesser calorie to what is considered as minimum requirement (2450Kcal) while the average calorie intake for food secure households was 2964.60Kcal which is higher than the minimum required calorie for human development. The food surplus/shortfall index (P) which measures the extent of deviation from the food security line, shows that the food secure households exceeded the calorie requirement by 31.0%, while the food insecure households fell short of the required calorie by 18.0%. Also, the mean household size of the adult equivalent was 6.35 for the food secure households and 9.92 for the food insecure households. This is in line with *a priori* expectation that larger households with more population are likely to be food insecure. Food Security Index (FSI) for the food secure households in the study area was calculated to be 1.31 while it was 0.82 for the food insecure households. Also, the average household size for the population was 8 persons; while the food secure households have an average household size of 6 and the food insecure households have average size of 10 persons.

Table 2: Summary of Food Insecurity Status for Cocoa Farming Households

Variables	Households	Status
Food Security Indices	Food secure	Food Insecure
Recommended daily per capita calorie intake	2450Kcal.	
Number of households	220	180
Percentage of households	55.0	45.0
Mean of household size	6.35	9.92
Mean household daily per capita calorie consumption (Kcal)	2964.60	1845.63
Food Security Index	1.31	0.81
Shortfall Index	-	0.18

Source: Field data, 2019.

CONCLUSION AND RECOMMENDATION

The study revealed that 63.5% of the respondents were above 50 years of age and the mean age of the farmers was 58 years. This shows that most of the farmers in the study area are relatively old which will have a consequent effect on their productivity. Hence, there's a need to encourage youths into cocoa farming in the area. Also, majority of the respondent households (73.8%) were male headed households and 86.8% of the respondents were married. Most (41.75%) of the farming households were more than 8 members and the mean family size was 8 persons per household. Most (55.0%) of the respondent households were food secured, while 45.0% were not food secure. The food secure households had an average daily per capita calorie consumption of 2964.60Kcal which exceeded the minimum calorie expected by 31.0% while the farming households that were food insecure had an average daily per capita calorie consumption of 1845.63Kcal which was lower than the minimum calorie requirement by 18.0%.

It is recommended that effective household size management and family planning should be encouraged by the cocoa farmers to reduce their household size. This can be organized by government health workers and NGOs through rigorous campaign and seminars.

ATTITUDE OF WOMEN COCOA FARMERS TOWARDS AGRICULTURAL EXTENSION SERVICES IN ONDO STATE, NIGERIA

Williams, O.A.

Cocoa Research Institute of Nigeria, PMB 5244, Ibadan, Nigeria

Corresponding author's e-mail: oa_williams@yahoo.com

ABSTRACT

The study diagnosed the attitude of cocoa women farmers in Ondo Sate Nigeria towards agricultural extension services. Multistage sampling procedure was used to select 60 respondents, from which information were solicited, using a well-structured questionnaire. The study was purposely carried out in the state being the highest cocoa producing area in Nigeria while three highest cocoa producing LGA were purposively selected. Similarly, simple random sampling technique was used to select the two highest cocoa producing communities in each LGA. Snowball techniques were used to select 10 women cocoa farmers per community, to give sample size of 60 respondents. The study revealed a mean age of 43.29 ±11.04 and majority (78%) were married. Respondents' (60%) primary occupation was farming. Respondents (62.78%) completed both primary and secondary school. Majority of the respondents (81.67%) were aware of the agricultural extension services. Eight major constraints debarring cocoa women farmers' participation in extension services were identified, among them were finance where all respondents (100%) attested as the major challenge, gender inequality (98.30%) and lack of collateral (75%). Respondents (68.33%) had medium attitude towards the extension services in the study area. Furthermore, there were negative and significant relationship between women cocoa farmers' attitude and the agricultural extension services programme, on distribution of improved cocoa pods ($r = -0.5$; $p< 0.01$), loan and credit facilities ($r = -0.346$; $p= 0.01$) and market channel (($r = -0.318$; $p<0.01$). Government should provide equal opportunity on training for both genders, this will encourage women cocoa farmers to participate and their farming needs will be met.

Key words: Agricultural extension, attitude, cocoa, Nigeria and women farmers.

INTRODUCTION

Agricultural extension services still do not attach much importance to reaching women farmers or women on the farm. Policy makers and administrators typically still assume that men are the farmers and women play only "supportive role" as farmers' wives (Samanta, 1994). Agricultural extension strategies traditionally have focused on increasing production of cash crops such as cocoa, by providing men with training, information, and access to inputs and services. Nigeria is the fourth cocoa producing countries the world (FAOSTAT, 2015). In cocoa production, women are responsible for more than half the world's food production, overal to 60 to 80% of basic foodstuff in Africa (Fresco, 1998). Despite all the socio-cultural factors militating against their accessibility to basic resources needed, for sustainable livelihood to perform triple role as producers, reproducers and community service provider. Yet women's substantial contribution continues to be systematically marginalised and undervalued in conventional agricultural and economic policies, while men's contribution remains the central, often the sole, focus of attention. Nigerian agriculture aims at involving women in agricultural production, but facing lack of women participating in agricultural extension progammes; although, some activities were put in place to bringing women farmers into the forefront of agricultural production programmes. It is however, difficult to really specify, where the problems of ineffective delivery of agricultural extension services to women farmers lie.

Though, so many factors are responsible for poor dissemination of extension service to women farmers, it is quite beneficial to note that the attitude of cocoa female farmers might as well be a contributing factor to ineffective delivery of extension service programme. Attitude can be defined as the degree of positive or negative effect, associated with psychological objects, However, it is pertinent to note that, the success of any extension programme depends largely on the attitude of the duo (Clientele and Agent) (Oladosu, 2006).

Several studies and researches have been carried out on the attitude of women farmers to agricultural extension programmes, (Barasa, 2006). There has been little or no farm-level information regarding their attitude to extension services particularly, in a

ISSN: 2814-0508

male-dominated cash crop like cocoa. This paper aims to bridge this information gap by assessing the attitude of women cocoa farmers in the study areas towards extension services. The Objectives of this study are to: Identify the socio-economic characteristics and awareness of cocoa women famers on extension services. Examine the constraints faced by cocoa women farmers in accessing extension services. Determine the attitude and access the impact of extension services on women cocoa farmers. The hypothesis of the study was stated in a null form: There is no significant relationship between the attitude of women cocoa farmers and their access to basic extension services.

MATERIALS AND METHODS

Multi-stage random sampling methods was used in selection of respondents for the study. The study was purposely carried out in Ondo state being the highest cocoa producing state in Nigeria. The classification is based on CRIN cocoa survey (CRIN, 2007). Three highest cocoa producing Local Government Areas were purposively selected. In each community, 10 women coco farmers (of which primary and secondary occupation was cocoa farming) were randomly selected. Idanre (Owena 10 and Ipinlerere 10), Odigbo (Bolorunduro 10 and Agbala 10) and Ondo West (Abusoro 10 and Kajola 10). Thus giving rise to 60 respondents. Descriptive statistics such as frequencies, percentages, mean, standard deviation and inferential statistics used was correlation analysis to test for the significant relationship between the attitude scores of cocoa women farmers and their access to basic extension services in the study areas.

RESULTS AND DISCUSSION

The socio economic characteristics of cocoa women farmers

Table 1 showed that, 50% of cocoa women farmers' age were between 31-50 years (x=43.29 ± 11.04). This indicated that most of the women in this study areas, were in their middle age group, and can actively participate in cocoa farming. About 78.33% were married having husbands and children to cater for. This trend seems to agree with the findings of Fabiyi *et. al* (2007) where about 50% of the sampled women were married. However, on their level of education, majority of the respondents (61.67%) have completed both primary and secondary school education, while only 6.67% have attended tertiary institution. Majority of the respondents were Christian 50.00%. Millett (1997) opined that religion is used as a way of legitimising male dominance and patriarchy has God on its side.

Majority (60.00%) chose farming as their primary occupation, while 40.00% combined other occupations with farming. This implies that farming constitutes their basic source of livelihood in the study area, which requires effective extension services. Respondents with household size ranging from 1-10 constituted the majority with the percentage of 76.66, this may have an advantage on the area of supply of farm labour. The findings also showed that 63.33% of the respondents have been farming for about 11-15 years, this is due to gender discrimination, which put women at a disadvantage. Majority of the respondents (78.33%) belonged to farmers group, by implication being a member of a group or society should facilitate their access to basic extension services.

Awareness

Table 2 shows the respondents' level of awareness on basic extension services, majority (81.67%) were aware of the extension services. This implies that cocoa women farmer was quite familiar with the services rendered by extension agents, however, the type of services received were not channeled towards women farming needs.

Constraints

Table 3 shows that all the respondents (100%) attested that, financial constraint was their major problem. The population of 75.00% respondents identified lack of collateral in granting loans as a constraint, Gender inequality, (98.30%) of respondents attested that household demands always debar them from attending extension programs, Administrative bottle necks (65.00%) while unavailability of extension agents was seldom a problem (28.33%), but their availability does not always channel towards women farmers felt needs also, such program is usually dominated by men, because extension services have predominantly male staff. This was supported by the studies of Barasa, 2006 that, despite the significant role played by women in agricultural production, processing and marketing in Nigeria, men have continued to dominate farm decision making.

Attitude

Table 4 shows the attitudinal scores of cocoa women farmers towards extension services. Majority 68.33% have medium attitude. Only 15.00% have high attitude while low attitude constitutes about 16.67%. This (medium attitude) may be due to their past experience from extension agents in service delivery, where majorly, men benefitted from the extension services than women. This may contribute to their inability to have high attitude towards agricultural extension services. Attitudinal barriers against women as described by Amaechina (2002) are deeply rooted in patriarchal-based socialisation where men are considered superior to women in socio-economic activities, resulting in low women presence in decision making bodies.

Impact of extension

In table 5, home economics, health and social issues with majority of 78.33%, were the prominent services rendered by extension agents to the respondents, it is often assumed that home economics services can substitute for agricultural training and information for women. Furthermore, respondents of (51.67%) attested that extension services had improved their storage facilities. Respondents 41.67%, received training on how their income and revenue can be increased, the women farmers further explained that, trainings were received alongside cocoa value chain. However, 38.33% of the respondents felt the impact of extension services on improved technologies. This is due to the fact that cocoa production is a male-dominated crop and consequently, women are often marginalised. In the same vein, only 35.00% of the respondents have felt the impact of extension services on accessing credit facilities, women were often viewed as not credit worthy and if they needed to be granted loan, it is with the assistance of their husbands. On technical-know-how (25.00%) while effective use of chemicals (15.00%), this explained the gender discrimination and cultural factor placing women on the rear position. Jack (2013), stated that, when new technologies result in a more profitable crop, or when a new processing machine increases income, evidence shows that, men often appropriate them.

Correlation Analysis showing linear relationship between the attitude of cocoa women farmers and their access to extension services

Table 6 showed that, there was an inverse relationship between access to improved cocoa hybrid pods and their attitude towards these services. This indicated that the women cocoa farmers have negative attitude towards this service, with the low strength of the relationship of 25.1% at P<0.01. This implies that, as there is increase in the distribution of improved cocoa pods by extension agents, there is decrease in the attitude of women. This can be deduced from table 3 above, where 70% of respondents, do not have access to this service. The respondents have negative attitude on how to acquire loan and credit facilities, the low strength of the relationship of 12.0% at p≤0.01by implication, women are seen as not credit worthy, as seen in table in 3.

Table 7: Correlation analysis on attitude of cocoa women farmers and their access to extension services.

Variable	Pearson correlation coefficient r	Coefficient of determination r^2	Precision	Percentage
Improved cocoa pods	-0.501**	0.251	000	25.1
Loan and credit facilities	-0.346**	0.120	000	12.0
Provision of market channel	-0.318**	0.101	000	10.1

Source: Field study 2020. **Correlation significant at 0.01 level.

Provision of market channel is negatively and significantly related to the attitude of cocoa women farmers in the study area. In which, the strength of the relationship was only 10.1% P≤0.01. This implies that, there was inverse relationship between the variable Increase in extension service on market channel influences the attitude of women cocoa farmers towards it, also, as seen in table 3, majority of the respondents (85%) do not have access to loan and credit facilities. Women are often marginalised and often reluctant to attend such programme, due to some constraints such as, household chores, sex preference by extension agents and inadequate number of women in cocoa farming as well as extension agents. Rafferty, (1988) reported that, agricultural extension programmes and other supporting services have traditionally, concentrated more on educating male farmers, and hence farm women still largely depended on their husbands for information on farm inputs and other resources necessary for farm decision making.

CONCLUSION

Majority of the cocoa women farmers were in their productive age and actively involved in cocoa production. They have medium level of attitude towards agricultural extension services, despite their level of awareness of the training programmes, health and social issues, and home economics skills have continued to be the most accessible extension services they benefitted majorly from. Major constraints debarring cocoa women farmers from attending training programs were capital, gender inequity and household demands. Based on the findings of this study, the following were recommended; women should be recognised as farmers, not only as farmers' wives. There should be provision of training in agriculture for women to acquire new skills and adjust schedules to fit women's existing workloads, not just home and family welfare topics. Better working relationships between extension agents and women cocoa farmers should be established, as this would enable them to voice their demands to fit their agricultural needs. Women cocoa farmers' seminars should be organised to share ideas with researchers and field staff, to promote farmer-to-farmer discussion among women. Extension agents who are not only technically competent and up-to-date, but who empathise with the needs of women farmers should be deployed, to facilitate participation of women in extension programmes.

ABSTRACT

This work studies the information on social economic factors affecting female participation in yam production in Ebonyi State, Nigeria. Respondents (150) were selected by random sampling using a structured questionnaire. Data was analyzed using descriptive statistics and Multiple Linear Regression. Majority of the respondents (72.7 %) were married. Highest number (47.3 %) of respondents were within >40 years of age. Highest number (38 %) of the respondents had no formal education. Highest number (41.3 %) of respondents earned between N100,000 and N199,000. Most of the respondents (44 %) had less than 2 hectares of land. Majority (43.3 %) of the women respondents had farming as the primary occupation. Majority (34%) of the respondents had between 11and 15 years of farming experience. Precision of the model that evaluates the factors influencing women farmers' participation in yam production shows that the variable in the model accounts for 91.1 % of the variations. Age, household size, educational level and primary occupation significantly affects involvement of women in participating in yam production in Ebonyi State.

Key words: Socio-economic factors, women participation, yam producing areas

INTRODUCTION

Nigeria has one of the lowest recorded female labour force participation rates well below that of their foreign counterparts. They have no or minimal part in decision making process regarding agricultural development, food security and food production. Gender inequality is therefore dominant in the sector and this constitute a bottleneck to agricultural development. The involvement of males and females in seed yam production activities and in different parts of the yam value chain is shaped by socially defined norms of behaviour, social roles and responsibilities (Ewuziem and Ironkwe, 2019). They face difficulties than men in gaining access to resources such as land, credit and improved inputs. Oladosu *et al*. (2018) analyzed gender differentials in accessing agricultural production resources among yam farmers However, there is need to determine the socio-economic problems influencing women participation in agricultural productivity in some yam producing areas of South-Eastern Nigeria. This work is therefore an attempt to contribute to the investigation of the socio-economic issues affecting women participation in yam production in Ebonyi State.

MATERIALS AND METHODS

Survey was carried out in Ebonyi State located in South-Eastern part of Nigeria which lies within latitudes 5° 40' and 6° 45' North and longitudes 7°30' and 8°30'East with mean temperature ranging between 27° to 30° C. Temperature is highest from February to April and it is about 31° C (Ogbodo, 2013). Agriculture is a major industry in Ebonyi State, an estimated eighty-five per cent of the population earn their living from agricultural activity). Crops grown in the area include; rice, yam, cassava, cocoyam, groundnut, cowpea and vegetables.

Sampling technique

A multi-stage sampling technique described by Aidoo (2009) was employed in the study with a sample group 150 respondents formed in the following manner:

1. Purposive and systematic sampling of three Local Government Areas (LGAs) in Ebonyi (Abakaliki, Afikpo and Izzi) State Nigeria where yams are currently grown intensively.

2. Simple random sampling were used to select 50 respondents from LGA

Data Collection

Data for this study was obtained by use of structured and validated questionaaire.

Data Analysis

Descriptive statistics was used to analyze socio-economic characteristics of respondents. Multiple linear regression model was used to determine social economic factors affecting female participation in yam production using Statistical Package for Social Scientist (SPSS version 21).

Simple model specification for the study is given as;

Y =α + β1logX1 + β2log X2 + β3log X3 + β4 logX4 + β5log X5+ β6 logX6 + β7log X7 + β8 logX8 + ϵ ………………eqn 1

Y = 1 if the person participated in Agriculture and Y = 0 if otherwise Variables X1…X8 represent;

X1 = Marital status (1 for married, 0 for otherwise), X2 = Age (years), X3 = Educational Level (years), X4 =Annual income (naira), X5 = Farm area (ha), X6 = Yam farming experience (years), X7 = Household size (number), X8 = Primary occupation, $\beta 1 - \beta 8$ are the slope coefficients of the regressors or multipliers that describe the size of the effect the independent variables are having on depensent variable, α represents the vertical intercept.

RESULTS AND DISCUSSION

Socio-economic characteristics of the respondents

Results of socio-economic characteristics of the respondents (Table 1) show that Majority of the respondents (72.7 %) were married whereas 27.3 % were not married. The dominance of women in the study area can be attributed to the restrictions that bar women from gaining access to agricultural resources. This agreed with the report of Zaidi *et al*. (2016) that women are considered to be dependents.

Highest number (47.3 %) of respondents were within >40 years of age, while the least number (6.7 %) of women yam farmers were within 25 to 30 years of age. The more number of older yam farmers reported might be attributed to practice of gender norms, which encourage only married women to have access to farmland. Some social and cultural norms, such as land acquisition might affect the number of farmers involved in agricultural productivity (Ameh and Iheanancho 2017).

Majority (38 %) of the respondents had no formal education, while 14% had tertiary education. This shows that most of the women farmers in the study area did not undertake any form of formal education.

Table 1: Socio-economic characteristics of respondents

Variable	Frequency	Percentage
Marital status		
Not married	41	27.3
Married	109	72.7
Age (years)		
25 -30	10	6.7
31 - 35	29	19.3
36 - 40	40	26.7
>40	71	47.3
Educational level		
No formal education	57	38.0
Primary	41	27.3
secondary	31	20.7
tertiary	21	14
Annual income (N)		
< 100,000	26	17.3
100,000 – 199,000	62	41.3
200,000 – 299,000	45	30
300,000 and above	17	11.3
Farm area (ha)		
<2	66	44
2 - 6	59	39.3
>6	25	16.7
Farm experience (yrs)		
<5	13	8.7
5- -10	27	18
11 - 15	39	26

16 - 20	59	39.3
>20	12	8
Household size (No)		
1 - 5	34	22.7
6 - 10	76	50.7
>10	40	26.7
Primary occupation		
Farming	65	43.3
Business	34	22.7
Civil service	41	27.3
Student	10	6.7

Women yam farmers (41.3 %, 30 %, 17.3 % and 11.3 %) earn annual income that ranged from N100,000 to N199,000, 200,000 to 299,000, <100,000 and 300,000 and above. Low income adversely affects productivity because it leads to low capital investment.

Most (44 %) of the respondents had less than 2 hectares of land, while 39.3 % had farm area that ranged between 2 and 6 hectares. This implies that most of the women were small-scale farmers.

The respondents (39.3 %, 26 %, 18 %, 8.7 % and 8 %) had farm experience that ranged from 16 to 20, 11 to 15, 5 to 10, <5 and >20 years. This shows that most of the women farmers have reasonable farming experience which will have positive impact on productivity.

Majority (50.7 %) of the respondents had the household size of between 6 and 10 while less number (22.7 %) had 1 and 5 household size. This observation further re-affirmed the claim that majority of the women farmers were married.

Majority (43.3 %) of the respondents were farmers while 6.7 % were students. This observation is supported by the earlier report that majority (72.7 %) of the respondents were married who engage in agriculture to generate income for household food.

The variables in the model that evaluates the factors influencing women farmers' participation in yam production (Table 2) accounts for 91.1 % of the variations observed. Age, educational level, household size and primary occupation significantly ($p < 0.05$) affected women participation in yam production in the study area.

Table 2: Multiple regression analysis of the factors influencing women farmers' participation in yam production

Socio-economic variables	Coefficients	Standard error	t-value	Sig.

Constant	1.45	0.06	23.66	0.000

R^2 = 0.830; Adj. R^2 = 0.822; R = 0.911; F-statistics = 99.22

CONCLUSION AND RECOMMENDATIONS

This study has shown that yam productivity in the study area was dominated by married women that were above 40 years of age and with no formal education. Majority of the respondents were small-scale farmer with annual income that ranged from N100,000 to N199,000 and cultivated less than 2 hectares of land. Farming was the primary occupation of the majority of the respondents who had reasonable farming experience. Age, educational level, household size and primary occupation were key determinants of women participation in yam production in the study area. To ensure sustainable food security it is recommended that government should enact a law ensure that land and all other resources are made available to women farmers.

ABSTRACT

The study assessed the socio-economic variables of cashew farmers in Osun State. Four towns within Ejigbo Local Government Area (Ika, Igbon, Ejigbo and Ilawo) were purposively sampled. These areas are known for the cultivation, production and marketing of raw cashew nuts (RCN). A total sampling frame of sixty-eight respondents was used. Structured interview schedules were used for data collection. Descriptive statistics such as frequency, mean, percentages and standard deviation were employed in data analysis. Age of farmers, educational level of farmer, farm size, household size, gender, membership of association, and marital status of farmers constituted major socio-economic variables among cashew farmers in the study area. However, age, educational level, household size and farm size of the farmers have their mean values as 53±16.0, 2±1.0, 6±4.0, 5±8.0, respectively. It is thus important for government and other development partners in cashew production to develop policies that will enable the farmers to increase their farm holdings for higher productivity since they are still in their productive years. Adult literacy programme should be introduced and encouraged in the study area to increase the educational level of farmers. Farmers that are members of association should be encouraged to participate more as this will go a long way in price determination for increased profit and access to trainings on improved production packages.

Key words: Cashew, Socio-economic variables, Government, Development Partners

INTRODUCTION

Cashew (*Anacardium occidentale* L.) originated from Brazil in South America. It is commonly grown in tropical countries of Africa; Nigeria inclusive. It is a broad leafed evergreen tree crop that thrives well in poor soils and dry sandy locations. There are tonnes of write-ups and studies about Nigeria's agricultural misadventure. However, we can bring some focus to a segment which can be regarded as a low hanging fruit in the Agricultural sector – Cashew. Nigeria is one of the largest producers of Cashew in the World. Furthermore, the International Nut and Dried Fruit Council in 2014 valued the global cashew market a whopping $4.69 billion. It is difficult to assess the production volumes across the various producing nations but the Food and Agriculture Organisation (FAO) estimates that the production of raw cashew nuts (RCN) has grown from 0.29 million tons in 1961 to 2.60 million tons in 2013 and West Africa's share of the market has tripled in the past decade (SB Morgen, 2016). Cashew grows almost everywhere in Nigeria but it is concentrated primarily across the three southern geopolitical zones as well as the middle belt. The major producing Nigerian states are Benue, Kogi, Kwara, Oyo, Enugu, Abia, Anambra, Ekiti and Imo. The National Cashew Association of Nigeria (NCAN) reports that Nigeria earned US$ 402Mn (N144.7bn) from the export of raw cashew nuts to Vietnam and other countries in 2017. In addition, National Bureau of Statistics (NBS, 2017) reports that cashew exports increased by 463 percent from N2.4bn in quarter one of 2017 to N13.5bn in quarter two of 2017 on a quarter-on-quarter basis. The production of cashew can solve economic, social and environmental problems in Nigeria.

Cashew contributed less than 2 percent to total agricultural exports in quarter one but contributed 45.4 percent to the sectoral export in the quarter two and 8.2 percent of total non-exports. The value makes the product the seventh largest export product in quarter two of 2017. Price per tonne of raw cashew nuts was put at US$1,800 and Price per tonne of processed cashew nut was put at about US$12,000.

Traditionally too, the agriculture sector and rural economy especially in Least Developed Countries (LDCs) have been characterized by the predominance of a small landowning class, tenants, sharecroppers, and landless labourers who are at the core of the poverty problem (Imran *et al.,* 2009). Meanwhile, Krishna *et al* (2016) considered gender, age, income and education as the main attributes of socio-economic variables. Similarly, socio-economic status has been operationalised in a variety of ways, most commonly as education, social class, or income (Alexander *et al.,* 2017). Therefore, the study assessed the socio-economic variables of cashew farmers in Osun state. Meanwhile, farmers' decisions with respect to production and land use are intensely guided by socio-economic factors. On many occasions, the farm size of farmers affects agricultural productivity. This is usually common when the land in question is fragmented, that is, if the land is divided into smaller pieces and allocated to individual farmers. The size of the farms makes mechanized and commercialization farming almost impossible on such land (Marocchino, 2009). In addition, the productivity of farmers to some extent could be attributed to the farmers' years of experience. According to Carter (2009) productivity is achieved, if a farmer is versed in his farming business. That is he cultivates his crops at ease with little or no assistance from extension agents. He has full knowledge of his farming calendar, cropping system, as well as land use patterns and/or system. The objective of the study was to profile the socio-economic characteristics of cashew farmers in the study area.

MATERIALS AND METHODS

The study was conducted in Osun State, Nigeria. The state is in the south west agroecological region and falls in to the tropical rainforest zone of the country. Four towns of Ika, Igbon, Ejigbo and Ilawo were purposively sampled. These areas are known for the cultivation, production and marketing of this crop. Seventeen farmers were randomly sampled from each of the communities. A total sampling frame of sixty-eight respondents was used for analysis. Structured interview schedules were used for data collection from respondents. Data were collected on socio-economic characteristics such as age, educational level, gender, household size, farm size and membership of farmers' group, respectively. Additional information was gathered through informal discussions with the farmers and by personal observations of the crop in some of the farmers' fields. Data were analyzed using descriptive statistics such as frequency, means, percentages and standard deviation with the aid of STATA Version 12.0.

RESULTS AND DISCUSSION

Table 1 shows the socio-economic characteristics of cashew farmers in Ejigbo Local Government Area (LGA) of Osun State, Nigeria. The table reveals that majority of the farmers (95.59%) were men. This result is in conformity with Akinpelu *et al* (2021) who reported that majority of cashew farmers (62.50%) in Oyo State were male. In addition, Lawal *et al* (2019) affirmed that majority (77.01%) of cocoa farmers in Boki Local Government Area of Cross River State are male. This is in consonance with the submission by Girei *et al* (2013) who reported that men are more in a crop that is perceived to have commercial value in Africa. The implication of this is that cashew farming in the study area is largely dominated by male gender and probably because cashew is a cash and perennial crop. However, the result is contrary to Ibekwe (2008) who observed that women play a vital role in food production. Moreover, the mean age of the farmers is 53 years. This also conforms to the findings of Akinpelu *et al* (2021) who reported 53 years as the mean age for cashew farmers in Oyo State. Osuji *et al* (2013) also reported that age might have a tremendous influence on productivity, efficiency and utilization of farm resources. The implication of this is that cashew farmers in the study area appear to be in their productive years. The result of the average farm size (5ha) put into cultivation by a little above 83 percent of the farmers may perhaps be due to the fact that land owners are reluctant to put their farms into the cultivation of perennial crops. This assertion corroborates Osuji *et al* (2013) who submitted that majority of the food crop farmers operated on a small scale bases (cultivating less than 3.0 hectares). Similarly, the table reveals that about 40 percent of the farmers had no access to formal education with average years of educational level being about 2 years. This also conforms to Akinpelu *et al* (2021). This implies that the farmers may perhaps not have access to agricultural production and market information system (MIS) with respect to both production and marketing of the crop. Furthermore, the table reveals an average household size of 6 persons. This is in conformity with Osuji *et al* (2013) and Ibitoye *et al* (2012). It however deviates from the findings of Akinpelu *et al* (2021). They reported an average household size of 7 and 8 persons in their study on the socio-economic variables of arable and cash crop farmers in Imo, Kogi and Oyo States, respectively. The implication is that the farmers may perhaps utilize members of the household as labour for some operations relating to production and marketing of the crop. This has the tendency to perhaps reduce some labour and transaction costs that may be incurred on the crop. Moreover, the table shows that about 64.71 percent of the farmers belong to one association or the other. The implication of this is that the farmers will be able to get needed improved production packages from the association.

Table 1: Socio-economic characteristics of Cashew Farmers in Kogi State

CONCLUSION

The study assessed the socio-economic variables of cashew farmers in Osun State. Age, educational level, household size, farm size, gender and membership of association constituted the socio-economic characteristic factors among cashew farmers in the study area. More efforts should be made to encourage youth to take up cashew farming as an enterprise to bridge the gap that will be created by the aging farmers. In addition, adult literacy programme should be introduced to the study area to increase the educational level of farmers. Similarly, farmers should be given incentives to increase their farm holdings for higher productivity. Farmers that are members of association should be encouraged to improve on their participation as this will go a long way in price determination for increased profit and access to trainings on improved production packages. This will encourage and improve cashew farmers' access to market information and as such will be able to sell the crop for more profits.

ABSTRACT

Seedlings production is a means of self-employment opportunity that generates income with relatively low investment expenditure for farmers. The objective of this study is to investigate seedlings production as a means of economic enhancement of farmers in the study area. Data were collected using well-structured questionnaires administered to seventy-eight (78) nursery owners in five urban local governments which are North East, Ibadan North, Ibadan Northwest, Ibadan Southeast and Ibadan Southwest. Descriptive statistics such as percentage and frequency distribution were used to analyse data objectives while the economic evaluation of nursery activities were estimated using Gross margin (GM) and Rate of return (RORT). The result showed that most of the respondents were within the age bracket of 21-30 years (29.5%) and 31-40 years (29.5%) respectively. The result also revealed that men involved in the establishment of the business (seedlings production) (78.2%) while majority of the respondents had tertiary education which accounted for (56.4%). It can also be deduced from the result that majority of the respondents were married (61.5%). The seedlings identified at the various nurseries consisted of twenty-one (21) species which were categorized under; ornamental plant (10 species), tree crops plant (9 species) and two (2) forest species. The economic analysis from this study showed that the rate of returns (RORT) was high with the highest returns on Umbrella tree (#1000). The study further revealed that the major constraints faced by the respondents in the study area were inadequate water supply, unavailability of enough land space and inflation. The other factors that affect the output of the seedlings production are change in weather condition, marketing and high cost of labour. Against these odds, establishment of nursery and seedlings production business is an attractive business to the people in the metropolis and specifically to the unemployed youths. Therefore, there is great need for Government and NGOs to provide enabling environment for the farmers in order for them to expand the existing nursery and adoption of this enterprise in order to reduce poverty and unemployment in the society.

Key words: Assessment, seedlings, production, economic enhancement

INTRODUCTION

Nurseries have the common goal of producing plant material for improving sites and establishment of plantation. They are established to produce seedlings, grown under favourable conditions at germination and early growth stage before transplanting to the field for planting purpose. Seedlings plant production nurseries can be an informal, small- scaled arrangement or a large commercial enterprise that vary in size, facilities (supplies, tools, equipment, etc.), types of seedlings produced, and operations (Larinde and Ruth, 2014). High quality seedlings are fundamental to the successful establishment of orchards and plantations, both for timber production and reforestation of degraded land/environments. Recently, the production of both cut flowers and home plants has continued to increase steadily in most urban and metropolises. The importance of ornamental plants in human life cannot be over-emphasized. Ornamental plants are not only sources of medicinal herbs (Fakayode *et al*., 2008) but also serve as environmental stimulants that trigger pleasant memories. These plants also play crucial role in cooling the atmosphere through the evapo-transpiration process on their leaves and other parts thereby preventing health hazards (Omokhua *et al,* 2002).

People are increasingly realizing the need for planting trees, shrubs and grasses for different purposes, especially in the urban and metropolises. Plant seedling nurseries provide employment opportunity for the urban youths. The job including skilled-labour such as green-house and nursery managers and jobs for individuals involved in the cultivation and marketing of the ornamental plants (Fakayode *et al.,*2008).

To the nurserymen, gone are the days when forestry was seen as a business with a long gestation period between the time of investment and the time of dividend. Small-scale nursery establishments are highly profitable business ventures in Nigeria due to the short time between the production and sale of most of the plants involved (Aiyeloja and Larinde, 2006).

However, the contribution of nursery enterprise (which is a self-employment business) in economic development both to the individual and to the nation's economy cannot be overemphasized (Babalola, 2008). Nursery establishments are highly profitable business ventures in Nigeria due to the short time between production and sale of most of the plants involved (Aiyeloja and Larinde. 2006). Despite all the great potentials of the ornamental plants business to improve the economy of nations, the sector in Nigeria has been hampered by many problems. It has also received very little attention in the nation's perspective plan for agricultural development (Oseni, 2004). This research work focuses on the assessment of the seedlings production as a means of economic enhancement among farmers in the study area. The objectives of research work are to examine socio-economic status of the farmers, the factors affecting the output of seedlings plant production and profitability level of the seedlings production.

MATERIALS AND METHODS

The study was conducted in Ibadan, the capital city of Oyo State. The city consists of five local governments within the metropolis which are North East, Ibadan North, Ibadan Northwest, Ibadan Southeast, and Ibadan Southwest. The city of Ibadan is located approximately on longitude 3°55 East of the Greenwich Meridian and latitude 7°23 North of the Equator at a distance some 145 kilometers Northeast of Lagos. The population of Ibadan metropolis at 2016 is estimated to be 3.16 million. The primary data were gathered by the use of well-structured questionnaire that was administered to the respondents during the field work. Multi-Stage sampling procedure was used to sample the respondents for proper data collection during the field survey which include; identification of nursery, selection of the farmers/ horticulturist. Seventy-Eight (78) well-structured questionnaires was randomly distributed to the respondents and allowed them to have equal chance when the survey was being carried out.

The rate of money return was estimated using the formula;

$$RORT = \frac{TR - TC}{TC} \times 100$$

Where TR = Total revenue and TC = total cost.

RESULTS AND DISCUSSION

Table 1 shows that there are more males (78.2%) in seedlings production than females (21.8%) in the study area. It is attributed to the fact that activities involved in seedlings plant production might be tedious and could be handled by men than female. The age distribution shows that less than 20 years (1.3%), 21-30 years (29.5%), 31-40 years (29.5%), 41-50 years (10%), 51-60 years (10%), and 60 years and above (6%). This implies that respondents within the age bracket 21-30 and 31-40 have the highest percentage (29.5%) and more involved in seedlings production. This contradicts the proposition of Gantam and Medhur (2000) who said that older people of age are more in to farming than younger people in Africa. The table further shows that about (56.4%) of the respondents had access to tertiary education followed by secondary (20.5%), primary (9%), others (7.7%), and no formal education (6.4%) respectively. This reveals that the literate level of the respondents in the study area was above 50%; average which has enhances increase in knowledge of the respondents in the study area. Therefore, it corresponds to the findings of Adejoba and Oyewale, (2012) as the level of education attainment increase also level of knowledge increases. The result also revealed that the respondents' family size of 3 has the highest percentage of (34.6%) while respondents with family size of 1 had the lowest percentage of (12.8%). This implies that the family size of most respondents is not fairly large and these enable them not to get a better source of income and also they cannot rely on their family size for labour, this is in agreement with Sunderlin, (2005). The respondents' year of farming experience reflected that majority of the farmers had experience within 1-10 years with the highest percentage of (51.3%). This contradicts the propositions of Ogboma (2010) who said that personal experiences were the source of information used by the farmers.

Table 1: Socio-Economics Characteristic of Respondents

Source: Field survey, 2020

The result of the economic analysis from this study shows that Ornamental seedlings had the highest economic value of 47.62% which mean the seedlings are widely used within Ibadan metropolis, followed by Tree crop seedlings with 42.86% economic value and forest tree species had 9.52% economic value as the lowest (Table 2). Ornamental plants ranked the highest as a result of its patronage and accrued profit. The rate of returns (RORT) which is the ratio of money gained from an investment relative to the amount of money invested was high with the highest returns on Umbrella tree (N1,000), King palm (N900), Queen palm (N900), Golden palm (N900), Step tree (N900), Flamboyant (900), and Ficus (N900). The highest quantities of seedling species produced per year were Ixora (3000) and the lowest seedlings produced were Pawpaw and Guava which were 70 in quantity per year. It showed that Juja pine was not among the seedlings with highest returns yet it was produced in higher quantities due to high demand for these species. Forest plantation seedlings are produced in small quantities due to low demand; however, they generate high return whenever sold. This strongly agreed with the findings of Ephraim et al. (2018) who reported that forest plantation seedlings generated high returns whenever sold.

Table 2: Mean Values of economic Analysis for seedling Produced in the Study Area

Seedlings species	Quantity sold Per annum	Production cost (N)	Selling price/ seedling (N)	Total Revenue (N)	Gross Margin (N)	RORT
Tree crops (42.86%)						
Coconut	100	80,000	2000	200,000	120,000	150

Source: field survey, 2020

Table 4 shows the major factor affecting nursery establishment in the study area. The table revealed that only 47.4% of the respondents with variable constraint on inadequate fund. While the remaining constraints listed had mostly severe constraints on major factors affecting nursery establishment as follows: water shortage 51.3%, poor transportation 48.7%, lack of labour 43.59%, lack of technical know-how 43.59, marketing of the products 51.28, high costs of labour 46.2%, and inflation had severe constraints. This result agrees with the finding of Onyekwelu (2001), there is need to reform government policies, incentives, extension service, provision of seeds. Also tackling others problems like inadequate fund, water shortage, inflation and poor transportation during raining season.

CONCLUSION

Based on this study, plant nursery enterprise is a viable means of income in Nigeria, which one can engage in as a mean of self-employment instead of depending on Government for white collar jobs. Most of the nursery operators and owners were young and agile individuals. Twenty-one species; 10 Ornamental species, 9 tree crops species and 2 forest species were identified in the study area. These species were considered indicators of marketable seedlings species in the study area. Employment and income generation were the major reason why most of the respondents engaged in seedlings production. Apart from income generation, nursery as a business is another means of conservation of plant species and it has a great role in the control of environmental problem. The economic analysis from this study shows that the rate of returns (RORT) was high with the highest return on Umbrella tree (N1,000), King palm (N900), Queen palm (N900), Golden palm (N900), Step tree (N900), Flamboyant (N900), and Ficus species (N900). Thus, commercial nursery business in the study area can be greatly improved upon, since it is concentrated mostly in the hands of young individuals. There is great need for adoption of this enterprise in order to reduce unemployment and enhance economic status of the farmers in the study area. It can also be concluded that many of the farmers are however faced with some problems which influence their productions of seedlings production as rightly stated in the results. It is therefore recommended that land acts are to be reformed by government to get more people to engage in seedlings plant production and there is need for Government and NGOs to assist nursery operators with loan to start up or expand the existing nursery business.

Table 3: Factors affecting nursery establishment

ABSTRACT

Tomato and ginger are front line vegetables in Nigeria serving daily culinary and health needs of the populace. However, being highly perishable crops they are exposed to high post-harvest losses. Thus, this underscores the need for strengthening capacity of producers, marketers and processors in order to curb this wastage. A training program was organised with different modules to address identified needs. A total of 67 participants consisting of women and youths (male and female) along the value chain were trained. Majority (64.2%) of the participants were males, within 21-30 years (44.4%) and an average age of 27.7years. Most (68.7%) of the trainees were involved in farming as major occupation with an average of 10 years farming experience (75%). The mean pre-score in tomato production was 1.48±1.599 while the post-assessment score was 2.49±1.561. The pre and post- assessment score in ginger processing was 0.45±0.610 and 0.99±1.022. The result of the t-test showed a significant difference in the knowledge of the participants in tomato production (t= 4.312, p= 0.00), marketing and record- keeping (t= 9.079, p<0.00). Tomato and ginger value chains in Nigeria can be positioned for the desired boost towards achieving economic diversification when capacity of major actors are strengthened.

Key words: Horticulture, value chain, vegetables, spices and capacity building

INTRODUCTION

Vegetables are important for human health because of their vitamins, minerals, phytochemical compounds, dietary fiber content (thehumanisia.com., 2021) and also other health benefits such as: improved digestive health, lower blood pressure, lower risk of heart disease, diabetes control. (WebMd, 2020). Vegetables are considered as protective supplementary food. They produce taste, increase appetite and protect against degenerative diseases. They can neutralise the acids produced during digestion of proteins and fats. (Venkatesh, 2020). Vegetables are an important feature of Nigerian's diet that a traditional meal without it is assumed to be incomplete (Badmus and Yekini, 2011). Vegetable crops are grown in many parts of the world contributing significantly to income security and the nutritive diet of many households. Vegetable crops such as tomatoes, okra, pepper, cabbage etc. are widely cultivated in most part of the Sub-Sahara Africa, particularly by small scale farmers in most states of Nigeria (Adeolu and Taiwo 2009; Giroh et al., 2010). In Nigeria, vegetable production has been on-going for decades, providing employment and income for the increasing population especially during the long dry season. However, production is constrained by inadequate infrastructure, agronomic and socio-economic variables (Sabo and Zira, 2009).

Spices on the other hand are dried seed, fruit, root, bark or vegetative substance used in nutritionally insignificant quantities as a food additive for the purposes of flavoring. (NIHORT, 2009). They are functional foods, that can be demonstrated to have a beneficial effect on certain target functions in the body beyond basic nutritional requirements (Lobo et al., 2010). Spices occur in a variety of flavor, color, and aroma contributing a wide range of nutrients to foods (Mann, 2011). They enhance and complement flavor in foods with no detrimental effect on the organoleptic quality of the food (Kaefer and Milner, 2011).

Tomato is a very healthy crop used to prepare so many delicacies in Nigeria which makes it an important crop in Nigeria. While some eat it raw, others use it to cook stew, jollof rice, salad, and so many other delicacies. (Agricincome.com, 2019). Tomato value chain development is one of the best agricultural investment option in the country due to high demand and guaranteed good returns on investment. Commercial tomato production has contributed to employment in the country (Infoguide Nigeria, 2021).

Ginger is one of the important crops for export, food and nutrition security in Nigeria. The Nigerian ginger has been adjudged one of the best in the world, and is highly regarded in the international market for its quality and highly medicinal value. Specifically, its aroma, purgency and high oil and aleoresin content are other distinct features of ginger products from Nigeria.The active ingredient, gingerol is known to help fight infections, lower blood sugar and reduce heart risks. It is also used in the brewery/beverage, cosmetic and the cooking industries (Statistics,2020).

Nigerian farmers can tap into the $3billion global ginger market to earn foreign exchange as the country explores opportunities to grow its non-oil exports opportunities. Nigeria's ginger production is put at 31 million metric tons while demand is put at 65 million MT, leaving a supply-demand gap of 34 million MT. According to Egugozie,2021 the overall policy objective of the ginger production programme includes increase in productivity and to promote small, medium and large-scale (SME) commercial production of the crop. Globally, the face of the farmer has been changing over the past 30 years to reflect rural demographics, as well as evolving gender and generational dynamics. Women in developing countries produce 80% of household food (World Bank, 2014) and play a key role in household food security (Meinzen-Dick et al., 2011). Yet women – as well as youth – have less access to productive resources, capital, and fewer opportunities to apply their skills and knowledge (FAO, IFAD & ILO 2010; World Bank & IFPRI, 2010). A significant proportion of rural youth in particular are underemployed or unemployed, have marginal income, or limited career prospects (AGRA, 2015; Bennel, 2007). Thus, there is a pertinent need to build capacity of stakeholders to enable them key into economic diversification plan of the Federal Government. A training program was therefore organised for unemployed youths and women with the overall aim of enhancing capacity of trainees on tomato and ginger production and value addition, and with the following specific objectives:

1. To determine pre and post training knowledge of participants.
2. To identify socio-economic characteristics of respondents

MATERIALS AND METHODS

The training and empowerment program was organised for selected beneficiaries in Bagauda, Kano State, North West agricultural zone of Nigeria. Crops of focus which were tomato and ginger had comparative advantage in the zone. Training modules included improved nursery practices of tomato, value addition of tomato and ginger and record keeping. Sixty-seven trainees comprising unemployed youths and women along the value chain were trained. Structured questionnaires were used to elicit information on social characteristics, pre and post knowledge of participants. Data obtained was subjected to descriptive and inferential statistics.

RESULTS AND DISCUSSION

Socio-economic characteristics of respondents

Most (67.2%) of the respondents were from Kano state followed by Kaduna (31.4%) while only very few of the respondents were from Kebbi and Taraba states (1.5%). Majority of the participants were within 21-30 years with an average age of trainees of 27.7years. This is an indication that the trainees are young, and may be open to innovations in agricultural value chain development. Most (64.2%) of the participants were male while 35.8% were female. This indicates the dominance of the male folks in the tomato and ginger value chain. This is expected considering the cultural practices in the area in which men are actively involved in agricultural value chain. Almost all the respondents were educated with one form of education. Most (47.8%) of the trainees had tertiary level of education, secondary (41.8%) and primary (9.0%). The education level may help them to understand improved practices in agricultural value chains. Most (50.7%) of the respondents were single with a family size of <5 and 6-10 persons in their respective households (39.5%). The major occupation of the participants was farming (68.7%), student (14.9%) and 11.9% of the trainees were unemployed. Most of the trainees had 6-10 years of farming experience with an average of 10 years. More than half (53.7%) of the trainees belonged to society such as cooperative society (Table 1)

Pre and post training knowledge of trainees

The mean pre score in tomato production was 1.48±1.599 while the post-assessment score was 2.49±1.561 indicating an increase in knowledge of the trainees in tomato production. The pre and post-assessment score in tomato marketing and record-keeping was 0.99±1.981 and 5.57±3.594. An increase in knowledge was also observed on aspects taught in ginger value chains. The pre and post- assessment score in ginger processing was 0.45±0.610 and 0.99±1.022. There was also an increase in the knowledge of the participants in ginger marketing and record keeping. The overall pre assessment score was 5.13 while the post score was 16.64. This showed improvement in the knowledge of the trainees in tomato and ginger value chains (Table 2).

Test of difference between pre and post training knowledge of participants in tomato and ginger value chain

The result of the t-test showed a significant difference in the knowledge of the participants in tomato production (t= 4.312, p= 0.00), marketing and record- keeping (t= 9.079, p<0.00) (Table 3). This indicated an increase in knowledge of the trainees in tomato production and marketing. A significant difference was also observed in the knowledge level of the participants in ginger processing (t=4.029, p<0.00) and ginger marketing (t= 8.068, p=0.00). There was also a significant difference in the overall knowledge score of the participants (t=9.784, p=0.00). This indicated improvement in the knowledge of the participants in the commodities value chain. Olajide-Taiwo *et al*, (2018) also observed a significant difference in participants' knowledge after training on ginger and turmeric value chains. Chang (2015) also emphasized that most of the issues in agricultural value chains may be addressed by equipping smallholder farmers with the necessary skills through education and training. Loiruck (2013) stressed the importance of skills, technical and financial support in enhancement of agricultural production.

Table 3: T test of difference between pre and post training assessment score among the trainees

Variables	Mean	Standard deviation	Standard error mean	T value	DF	Sig value

CONCLUSION AND RECOMMENDATION

The study concluded that majority of the participants were indeed youths and males with one form of education or the other. They were experienced in farming as well as marketing and processing depending on which of the value chain they are involved in. There was an increase in the knowledge of the respondents on tomato production, marketing and record keeping. In the same vein there was increase in knowledge of ginger production across the value chain. Therefore, specialized training programs should be incorporated as part of economic diversification package so as to increase the knowledge and skill of the stakeholders involved in horticultural value chains to boost their livelihoods.

ABSTRACT

Marketing of raw cashew nuts (RCNs) in Nigeria is not properly coordinated due to the activities of middle men and liberalization policy on commodity crops. This results in market failure and reduction in price of nuts thereby affecting farmers' income. The study addressed marketing problems of raw cashew nuts in order to enhance farmers' livelihood. A multistage sampling procedure was adopted to purposively select 132 cocoa farmers from Dekina, Ofu and Ankpa Local Governments Areas of Kogi State. Data were collected with interview schedule and analysed using descriptive and inferential statistics. The mean age of respondents was 44 years. Majority (61.3%) of the respondents sold 80kg bag of raw cashew nuts for between N50,000-59,000 in 2017, 34.9% sold at N30,000-39,000 in 2018 and majority (90.1%) sold below N20,000 in 2019. This suggests a sharp drop in the prices of RCNs. Fraud from local buyers and absence of organized market were found to be major factors affecting marketing of RCNs. A significant relationship exists between the activities of middle men buying raw cashew nuts and income realized from sales of cashew nuts by farmers ($r=0.146$, $p=0.038$ at $p\leq0.05$). The role of the middlemen in the cashew marketing process is responsible for low pricing of RCNs which reduced the income accruable to farmers. Recommendation was that the National Cashew Association of Nigeria and the Federal Government should help monitor the activities of middle men during marketing.

Key words: Marketing, raw cashew nuts, farmers, Kogi State

INTRODUCTION

Agricultural marketing is the performance of all the activities involved in the flow of agricultural products and services from the initial points of production until they reach the hands of the ultimate consumers. Poor trading systems of some crops and their products partly leads to the inherent inefficient agricultural commodity marketing in Nigeria. Cashew earned Nigeria N144.7 billion ($402 million) from the export of raw cashew nuts (RCNs) to Vietnam and other countries in 2017 and the country exported 220,000 tonnes of RCNs in 2017 (Adeniji, 2018). This is about 90 percent of its total production when compared with 160,000 tonnes exported in 2016. Nigeria produced between 200,000 to 240,000 MT of raw cashew nut annually while 20,000 MT are processed within the country (AgWeek, 2020). Nigeria is a major and growing player in the cashew industry with rising market share in global cashew production, with an annual average production increase of 5% (NEPC, 2018). The export value of cashew nuts supplements the income of about 50,000 farmers and an additional 55,000 people who are employed along the value chain (Adeigbe *et al.,* 2015). Cashew nuts worth N5.26 billion were exported in Nigeria in the fourth quarter of 2020.

The marketing of RCNs involves several players and channels in the value chain. Major players consist of farmers, local buying agents, processors, exporters, sub sector associations, cooperative societies and other service providers. It starts from the sale of raw cashew nuts by gatherers and farmers to the local buying agents, retailers, wholesalers, processors and the exporters. Majority of raw cashew nuts are exported. There are around 11 Nigeria based exporters of raw cashew nuts. They buy nuts from licensed buyers and exporters, make arrangements with License Buying Agents (LBAs) in different locations before start of a new cashew season. Olam Nigeria Limited is the largest exporter of cashew from Nigeria that accounts for more than 30% of the total raw nuts exports. Century Exporters Ltd, Elephant Group, Colossus Investments and ITP Ltd are the other emerging raw cashew nuts exporters among others. The marketing of raw cashew nuts is not well organized in Nigeria due to the activities of middle men and the liberalization policy of the commodity value chains. This results in market failure and price volatility. Market failure is a condition in which a market does not efficiently allocate resources to achieve the greatest possible consumer satisfaction. It manifests in four forms; public good, market control, externality and imperfect information (NSW Market failure guide, 2017). In Nigeria, foreigners' encroachment at the farm gates is posing serious limitations in the proper marketing of cashew nuts. Foreign buyers are mostly exporters which influences the local buyers to exploit the farmers. This has led to price chaos that destabilises the procurement system and improper post-harvest practices particularly drying of raw nuts.

Farmers are compelled to sell their nuts to buyers at reduced prices dictated by local traders. However, products of cashew tree (kernel and apple) are grossly under utilised for income generation, food and nutrition security. In Nigeria, farm gate price of traded nuts in 2021 lies between 380-450 Naira per kg (AfriCashewSplits, 2021). However, the aforementioned price range is a bit better than the situation two years back when cashew was sold at around N20,000 per 80kg bag which discouraged most cashew producers. This study was demand driven because of recent interaction with cashew farmers in Kogi State. The farmers complained of low pricing of raw cashew nuts, search for reliable buyers during harvesting. In the 4th edition of the World Cashew Convention and Exhibition held in Macau China 2018, it was reported by Adeniji that Nigerian farmers were among those paid low price for RCNs when compared with other major producing countries. If this trend and imbalance continues, farmers will shift attention from cashew production to other businesses and this will affect market supply. This scenario is likely to lead to drop in quality and destroy the overall value chain of cashew.

It is against this backdrop that the study was designed to address the factors affecting marketing of raw cashew in order to enhance income of farmers in their farming enterprise.

The specific objectives were to:

1. Describe the socio-economic characteristics of farmers in the study area.

2. Examine income generation trend of farmers from raw cashew nuts.

3. Investigate the factors faced by farmers in marketing of raw cashew nuts.

Statement of Hypothesis: H_O: There is no significant relationship between the activities of middle men buying raw cashew nuts and income realised from the sales of cashew nuts by farmers.

MATERIALS AND METHODS

Study Area: The study was conducted in Kogi State and it is well known for cashew production. Other farm produce grown include: cocoa, oil palm, maize, cassava, yam, melon and rice. Agriculture is the mainstay of the state with capital at Lokoja. The State is located on the intersecting point of longitude 70 49'N and latitude 60 44'E on the map of Nigeria. Kogi State Government (2021).

A multistage sampling technique was adopted. Kogi State was chosen because it is the highest cashew producing State in Nigeria. The next stage was to select three Local Government areas from the eastern zone of the state due to the high concentration of cashew production and marketing activities in these areas. A systematic random sampling was used to select 48 farmers from Dekina, 44 from Ofu and 40 from Ankpa Local Government areas based on a list of cashew production from the Kogi State branch of the National Cashew Farmers Association of Nigeria (NCAN). Farmers were selected from two villages each from the LGAs. In all, 132 respondents were selected. Data were collected from the respondents with interview schedule and analysed using descriptive and inferential statistics.

RESULTS AND DISCUSSION

Socio-economic characteristics of respondents

Table 1 reveals that greater percentage of the respondents (61.3%) were between the age categories of 31-50 years, while minority of the respondents (21.2%) were above 50 years of age. The mean age of respondents was 44 years. This age distribution implies that most respondents were still in their youthful age in producing cashew. It was discovered that 67.4% of the respondents were males with 32.6% female. Male farmers dominating cashew production is probably due to the nature of intense and time consuming activities. A large proportion of the respondents were married (95.5%). This is expected as majority of the respondents were adults. Thirty percent of the respondents had no formal education while 23.5% and 37.1% had primary and secondary education respectively with 10.6% of the respondents having tertiary education. This result is supported by Adebayo *et al*, (2020). They reported that age and educational qualification had influence on the marketing of raw cashew nuts among cashew farmers in Kwara State of Nigeria. A mean of about 18 years of farming experience was obtained. This shows that cashew farmers in the study area were experienced in the business. The mean household for the farmers was 9 persons with average farm size of 6.6 hectares. Household size provides cheap labour for agricultural activities.

Source: Field survey, 2019

In Table 2, majority (61.3%) of the farmers sold bag of raw cashew nuts for N50,000-59,000, in 2017, 34.9% of farmers sold bag of cashew for N30,000-39,000 and majority (90.1%) sold bag of cashew below N20,000 in 2019. This is reflected in the mean of N13,607 which is also low for 2019. This suggests that there was a sharp drop in the prices of cashew in the study area in the years under consideration. This is low especially when compared with the cost of production coupled with rising inflation affecting goods and services. The implication of this result could be as a result of major factors identified in this study which was reflected in Table 4. It could also be related to cheap price paid for Nigerian RCNs at the international market. This attests to why Indians and Vietnamese buyers are always in the country during every cashew trade season. The finding was supported by Adeniji (2018) in the 4th edition of the World Cashew Convention and Exhibition held in Macau China.

Table 2: Money sold per bag of raw cashew nuts in 2017, 2018 and 2019

Price per 80kg bag of raw cashew nuts in Naira (N)	2017		2018		2019	
	F	%	F	%	F	%

Factors affecting marketing of raw cashew nuts

The distribution of respondents according to factors determining marketing of raw cashew nuts is shown in table 3. The result revealed that majority of the respondents had mean values of 1.88, 1.80, 1.76, 1.74 and 1.66 which follows the respective order: fraud from local buyers, no organized market for selling cashew nuts, poor marketing information, lack of training on cashew nuts marketing and no value addition to raw nuts as major factors determining marketing of raw cashew nuts in Cross River State. The result suggests that the aforementioned variables impact marketing of raw cashew nuts in the study area. This result is supported by a market information system (MIS) expert with the African Cashew Alliance (ACA), Fitzpatrick, (2021). He reported that poor market information in cashew causes low farm gate prices which affect the income and livelihood of farmers.

Table 3: Factors affecting marketing of raw cashew nuts N=132

Factors	Major Factor		Minor Factor		Not a Factor		Mean
	F	%	F	%	F	%	
a. Fraud/insincerity from local buyers	120	90.9	8	6.10	4	3.00	1.88
b. Poor quality of raw cashew nuts	30	22.7	34	25.8	68	51.5	0.71
c. No value addition to raw cashew nuts	103	78.0	13	9.80	16	12.1	1.66
d. Lack of training on cashew nuts marketing	95	72.0	21	15.9	16	12.1	1.74
e. Poor marketing information	106	80.3	15	11.4	11	8.3	1.76
f. No organized market for selling cashew nuts	113	85.6	12	9.10	7	5.30	1.80
g. Poor farm road network to transport cashew nuts	68	51.5	34	25.8	30	22.7	1.35

Activities of middlemen buying raw cashew nuts from farmers

The result of the activities of middlemen buying raw cashew nuts from farmers shows that buyers motivate farmers to sell raw cashew nuts to them coupled with insincerity and buying cashew nuts at lower prices (Table 4). The motivation is in form of providing inputs and loan advance which is a commitment for selling RCNs to the buyers during harvesting season. This system makes farmers to accept whatever price they are offered. This finding is in line with Premium Times (2021) who reported that middlemen decide the priced they are willing to buy cashew nuts from farmers. Also, Fitzpatrick (2021) added that buyers take advantage of the uncoordinated system to exploit cashew farmers by offering them lesser prices for RCNs during purchase.

Table 4: Activities of middlemen buying raw cashew nuts from farmers

Activities of middlemen	Percentage
1. Insincerity of cashew buyers	92.4
2. Buyers motivating farmers to sell raw cashew nuts	98.5
3. Buyers pre-funding cashew farmers	48.5
4. Buying raw cashew nuts at lower prices	97.7

Source: Field survey, 2019

Correlation between activities of middlemen marketing raw cashew nuts and income realised by farmers

The result in table 5, shows that a significant relationship exists between the activities of middle men buying raw cashew nuts and income realized from sales of cashew nuts by farmers. This implies that the more the middle men were insincere in buying cashew nuts from farmers, the lesser the income that will be realized by farmers. This finding is also similar to a study conducted by Adebayo et *al* (2020). They reported that unstable price was a major challenge to cashew marketing in Nigeria. Also, Agbongiarhuoyi *et al* (2020) reported that low prices offered to farmers could affect sustainability of cashew in Nigeria. In terms of household size which was also significant, means that the higher the household size, the more the income that will be used for labour to do cashew farm operations. However, the income realized by farmers in this study was low.

Table 5: Correlation between activities of middlemen marketing raw cashew nuts and income realised by farmers

Variables	r value	P value
Activities of middle men buying cashew	-0.146	0.038**
Household size	0.188	0.009**

Source: Field survey, 2019

CONCLUSION AND RECOMMENDATION

It could be inferred from the study that most cashew farmers had primary and secondary education with small scale farm sizes. The major factors affecting raw cashew nuts marketing of farmers were fraud from cashew buyers, lack of organized market for selling raw cashew nuts, poor marketing information, and lack of training on cashew nuts marketing respectively. The role of the middlemen in the cashew marketing process is responsible for low pricing of RCNs which reduced the income accruable to farmers. It is therefore recommended that NCAN and the Federal Government should help monitor activities of middle men during marketing. They should be empowered by the two bodies to add value to RCNs in order to improve farmers' livelihood.

ABSTRACT

The study was carried out to analyse wholesale tomato marketing in Yamaltu-Deba Local Government Area, Gombe State, Nigeria with the objective of estimating the market margin of tomato as well as identify the challenges facing the business. A multistage sampling technique was used to select fifty tomato marketers from the study area. Information was obtained from the sampled marketers through the use of a structured questionnaire. Descriptive statistics and Shepherd-Futrel model for marketing efficiency were used for data analysis. The result revealed that 56% of the respondents were male, married (84.00%) and were between the age of 31 to 50 years (64%) with the mean age of 40 years. Most (60%) of the respondents had less than 10 years of marketing experience in tomato. Marketing analysis result showed that average revenue, cost, gross margin, market margin and coefficient of marketing efficiency were ₦523,264.32, ₦442,452.80, ₦80,811.52, 39.85 and 84.56%, respectively implying that tomato marketing was profitable in the study area. Although the business was profitable, yet it faced some challenges which include perishability, low pricing and seasonality of tomato. Addressing these challenges will further increase the profit made by the marketers.

Key words: Tomato, market margin, efficiency, cost.

INTRODUCTION

Tomato (*Lycopersion esculentum* mill) is one of the leading vegetable crops in Nigeria. The production of tomato in Nigeria increased from about 2, 632,500 tons in 2016 to 3,816,009 tons in 2019, making it one of the highest producing countries in Africa (FAOSTAT, 2019). The crop is of high nutritional values and it is rich in vitamins, mineral and fibre. It is widely used in varieties of dishes as raw, cooked or processed products in Nigeria. Marketing of agricultural produce covers the services involved in moving the products from the farmgate to consumer. It enables farmers as well as middlemen to earn income with which they purchase other useful goods and services (Ebe, 2007). However, marketing of vegetable crops, including tomato, is quite complex and risky due to perishable nature of the produce, seasonal production and bulkiness (Meena and Singh, 2014). Market efficiency is the maximization of input-output ratio in marketing. It can also be defined as the movements of crops and livestock from producers to consumers at lowest cost content with the provision of services consumer desires (Ejiola, 2001). The inputs of marketing are the various resources employing in performing the various marketing services and the costs of these services are marketing costs. While the outputs are the benefits or satisfaction created or value added to the commodity as it passes through the marketing system (Giroh, 2010). Efficiency in marketing is an indication of productive utilization of resources, and, could help to harmonize demand and supply and stimulate production. A market is efficient if the ratio of value of output to value of input is maximized through marketing system (Giroh, 2010). Considerable attention has not been given to marketing of tomato in Yamaltu-Deba Local Government Area, hence, this study was carried out to analyze the wholesale tomato marketing in the LGA. In order to achieve the main objective of the study, the following specific objectives were set. one, to describe the socio-economic characteristics of tomato marketers; two, to determine the index of marketing efficiency; three, to identify the challenges faced by tomato marketers.

MATERIALS AND METHODS

Study Area

The study was carried out in Yamaltu-Deba Local Government Area (LGA), Gombe State. Yamaltu-Deba is one of the eleven Local Government Areas in the State with its headquarters in Deba. According to NBS (2009), the result of 2006 census indicated a population of 255,726 for Yamaltu-Deba LGA. The LGA covers an area of about 1,981 square kilometers and lies at latitude 11^{0}31' N and longitude 11˚24' E with the temperature ranges from 20^{0}C to 31^{0}C. The LGA hosts parts of the lake

Dadinkowa. It shares boundaries with parts of Borno State to the North, Balanga LGA to the South, Gombe and Akko LGAs to the East (Erie *et al*, 2019). Yamaltu-Deba LGA has a vibrant trade sector and hosts a number of markets (Manpower, 2021). The target population was tomato marketers.

Sampling technique

A multistage sampling technique was used in the choice of individual respondent. The first stage was purposive selection of Yamaltu-Deba LGA from eleven LGA in Gombe state. Yamaltu/Deba was selected because it is known for production of tomato and hosts one of the major markets for the commodity in the state. The second stage was random selection of five food markets in the LGA based on size of tomato sales-Kwandon, Dadin-kowa, Zambuk, Deba and Kuri markets. The third stage involved random selection of ten wholesale tomato marketers from each market, making a total of fifty.

Data source and analysis

Primary data were used for this study. Data were collected by the use of well-structured questionnare. Respondents were asked to indicate socio-economic characteristic (sex, age, marital status, educational level, year of marketing experience, quantity purchased and sold, prices, various costs i.e. transportation, stall rent, and challenges encountered in tomato marketing. Data analysis involved the use of descriptive and budgetary analysis. The descriptive analysis was used to analyze socio-economic characteristics of marketers and challenges to tomato marketing (Objectives I and III) while marketing efficiency analysis was used for Objective II. Descriptive analysis involved the use of frequency counts, percentages, mean and charts. In order to identify the challenges faced in tomato marketing, the marketers were asked to indicate the severity of each problem on 3-pont rating scale. The values were assigned to point as follows: Very severe=3, Severe= 2 and Not severe=1. The challenges were ranked based on the mean score. Marketing efficiency was estimated following Shepherd-Futrel model, as used by Ugwumba, 2009 and Layade *et al*, 2017. The model is considered as an accurate measure of marketing efficiency. It is expressed as the coefficient of total cost of marketing to total revenue expressed in percentage term. The coefficient of market efficiency (CME) indicates the percentage of sale revenue absorbed by costs. The lower the CME, the higher the level of efficiency and value added and vice-versa.

$$CME = \frac{TC}{TR} \times 100 \quad \text{...(1)}$$

Where,

CME= Market efficiency

TR=Total Revenue

TC=Total Cost

RESULTS AND DISCUSSION

Socio-economic characteristics distribution of respondents

Findings in table 1 revealed that most of the marketers were within the age range of 31-50years with mean age of 40years. This is an indication that tomato marketing in the study area enjoys involvement of young matured persons who can engage in marketing activities of tomato. Fifty-six percent of the respondents were male, indicating that men engage more in the wholesale marketing of tomato in the study area. This is in conformity with finding of Adeoye and Ibe (2015) who reported that 67.5% of the wholesale tomato marketers were male. Over 84% of those engaged in tomato marketing were married, implying that most of the respondents have responsibilities. 70% of the respondents had formal education while 30% did not. The result indicates that majority of respondents were literate and this could assist them in effective communication in doing their business (Asogwa and Okwoche, 2012). In term of experience, 60% had between less than 10 years in the business, indicating a relatively high knowledge in tomato marketing. This suggests that year of experience in tomato marketing will help the marketers to envisage, understand and manage the risk in business. Similarly, the result is in support of Nse-Nelson *et al* (2016) who stated that the greater the year of marketing experience, the more knowledgeable the marketer in minimizing costs and maximizing the benefits.

Table 1: Socio-economic characteristics of tomato marketers in the study area

Variable	Frequency	Percentage
Sex		
Male	28	56.00
Female	22	44.00
Total	50	100.00
Marital status		
Single	08	16.00

Years of experience in tomato marketing		
Less than 10	30	60.00
10-19	12	24.00
20-29	05	10.00
30-39	01	02.00
Above 39	02	04.00
Total	50	100.00

Source: Field survey, 2020.

Cost and return analysis of tomato

In table 2, Coefficient of marketing efficiency obtained indicates that 84.56% of the total revenue was absorbed by marketing cost. This implies that the marketing efficiency in the study area is low (15.44%). It could be further inferred that the value added was 15.44% and this is the productivity of resources invested in the tomato marketing. In order to increase efficiency of fresh tomato marketing system in the study area, those measures that will increase revenue and reduce marketing cost could be adopted.

Table 2: Summary of Costs and return of tomato per month

Variable	Amount
Average Quantity Sold (kg)	6824
Average price of tomato per kg	76.68
Average Total Marketing Cost (₦)	442,452.80
Average Total Revenue (₦)	523,264.32
Gross Margin (₦)	80,811.52
Market margin (%)	39.85
Coefficient of Marketing Efficiency (%)	84.56

Source: Calculation from field survey data 2020.

Challenges facing okra marketing

In table 3, the challenges experienced by tomato marketers in descending order are high perishability nature of tomato, low pricing, insufficient capital for their business, inadequate supply due to seasonality, and high transportation cost. Perishability remains one of the major problems of agricultural produce which makes it difficult to keep fresh the produce for long period and this is also linked to problem of seasonality (Nse- Nelson, 2016). Measures to ameliorate these problems should be implemented by relevant authorities.

Table 3: Challenges facing tomato marketing in the study area

S/N	Challenges	Not severe	Severe	Very severe	Mean score	Standard Deviation	Mean rank
1	High perishability nature of tomato	16(32.00)	25(50.00)	9(18.00)	1.84	0.69	1st
2	Low pricing	18(36.00)	27(54.00)	5(10.00)	1.74	0.63	2nd
3	Insufficient capital for business	26(52.00)	18(36.00)	6(12.00)	1.60	0.69	3rd
4	Seasonality	29(58.00)	15(30.00)	6(12.00)	1.54	0.71	4th
5	High transportation cost	32(64.00)	17(34.00)	1(2.00)	1.38	0.53	5th

Source: Field survey, 2020.

CONCLUSION

The study revealed a low marketing efficiency in the study area, as larger percentage of their revenue is gulped by costs of marketing. In order to increase efficiency of fresh tomato marketing system in the study area, efforts should be targeted towards increasing efficiency of tomato marketing system in the study area by putting in place measures that will increase revenue and reduce marketing cost.

ABSTRACT

The study investigated the efficiency of coffee marketing and farmers Linkage in Nigeria, two local government areas of kogi state were purposively chosen and data from thirty coffee farmers in each of the local government where collected using structured questionnaire and focused group discussions. Result analysis show that majority are male (90.2%) and of average age of 69years and most has no formal education. The farms are old and most of them have over 50years of farming experience. Most of them sold to coffee agent buyers who buy at critical low price. There is low demand for coffee due to low price and low quality of coffee produced. The price offered, the perceived amount by farmers and the buyers are critical factors that affect market efficiency of coffee. Furthermore, there is little or no efficiency in the marketing of coffee in the study area. Good and efficient market should be organized for the farmers as well as educate and encourage the youths to go into coffee production.

Key words: Coffee farmers, efficiency, market, coffee buyers

INTRODUCTION

Coffee is rated second in trade volume in the world after oil nevertheless; records have shown that the Productivity level and income in the Nigeria coffee farm household have been too low over the years. Coffee growing and drinking started in Ethiopia in the 9th century. Today, it is an important commodity and a popular beverage in the world. Over 2.25 billion cups of coffee are consumed in the world every day (Ponte Stefano, 2002). Over 90% of coffee production takes place in developing countries, while consumption happens mainly in the industrialized economies. Worldwide, about 25 million small producers rely on coffee for a living. In spite of coffee demand globally and known to be second to oil in world trade volume and despite over 110 varietal coffee plants available in the Mambila plateau, Nigeria coffee production has been on decline over the years as compared with her counterpart producing countries whose output has been on the increase (Lewin et al., 2004). Statistics also shows that coffee contribution to Nigeria's agriculture has been on decline ICO (2015). A study carried out on West and Central Africa coffee production shows that while Cameroon and Côte d'Ivoire produce 48,240 tons from 175,000ha of land and 171,000 tons from 480,000ha respectively, Nigeria records 5,400tonnes from a 3,750ha. A critical factor in the rather low and declining coffee productivity in Nigeria is a serious lack of market demand for Nigeria coffee, which is a critical factor in the stimulation of coffee production in Nigeria. Furthermore, the coffee marketing in Nigeria has been found to be inefficient due to small buyers of coffee who influence coffee price at the detriment of the farmers, also lack of adequate financing, imperfect market information, low quality coffee/ quality differentiation among others are the determinant factors affecting the efficiency of coffee marketing in Nigeria (Ayoola, 2012).

Nestlé Nigeria dominates coffee sales in Nigeria. The company's Nescafé is popular among coffee consumers in Nigeria because it was the first coffee brand in the country and has built up strong brand loyalty. These attributes gave the company a dominant 84% share of off-trade volume sales in 2011(Euromonitor international, 2012). As such there is the need to collaborate with the company and with government intervention through CRIN to form a good link between the processors and manufacturers and farmers so as to make the coffee market more efficient and thus making coffee production more desirable. Nigeria is blessed with the natural and human resources to produce coffee. Low market demand for coffee is believed to have led to the abandonment of coffee plantation in Nigeria. It is the lack of understanding of the efficient market for coffee produced in Nigeria that necessitates this study.

Against the above background therefore, the study seeks to:

1. Ascertain the various factors that are affecting the efficiency of coffee marketing in Nigeria, with

the bid to increasing coffee output and enhancing the livelihood of the farmers

2. Determine the socioeconomic characteristics of the coffee farmers in the study area

3. To make policy recommendations that will enhance coffee demand in Nigeria and put the country on top as one of the coffee producing nation, particularly that there exists a great potential in natural and human resources for achieving such fit.

MATERIALS AND METHODS

Kogi State was purposively chosen for the study. The study is targeted at coffee producers in the chosen State. In carrying out the study, primary data was used in collecting relevant data through questionnaire administration and focus group discussion. Two local governments (kabba and Ijumu) were purposively sampled in the state. Thirty coffee producers were randomly sampled in each of the local government to make a total of sixty respondents. The data collected were analyzed using both descriptive and quantitative method of analysis

Data Analysis

Descriptive Statistics (mean, standard deviation and simple frequency tables), was used in the analyses of the socio-economic variable and agronomic practices while partial correlation analysis was used to ascertain the factors that affects the market efficiency of coffee marketing in the study area.

DISCUSSIONS

Table 1 show the socioeconomics characteristics of the coffee farmers in the study area. Results analyzed shows that majority (90.2%) of the respondents are male farmers and most of them (31.1%) only acquire adult education. This implies that most do not have formal education therefore may not readi.ly adopt new innovation improving coffee production. Of the total respondents, 73.8% constituting the majority farms both cash and arable crops. This has to a very large extent help in improving the livelihood and food security of the farmers. The result further shows that most (61.3%) of the coffee farmers have between 21-30ha of coffee farms. However, most of the plots are not optimally utilized for coffee production mainly due to low coffee demand. Majority are primarily farmers with an average age of 69 years of age and with majority (54.1%) having farming experience of above 50 years. This shows that most of the farmers are aged and well above productive age hence low coffee productivity for coffee in the study area. These findings corroborate with Ayoola (2012) that the majority of the coffee farmers (about 53 percent) were above the age of 50 years and about 72 percent had been involved in coffee production for at least 15 years and none of the farmers had any formal training in coffee production. This equally indicate the reason for the low outputs of which majority produce between 1-5bags of 80kg jute bags between the 2016-2018 cropping season.

Most (29.5%) of the farmers source their coffee seedlings from the agricultural development project (ADPs) hence the agency is much closer to the farmers as compared to other agencies such as IITA, CRIN etc. Further analysis indicates that most (43.2%) of the farmers are faced with the problem of low demand for their coffee while (38.3%) attest to the fact that low/poor price of coffee was a major reason for low production. Farmers therefore where not motivated to produce coffee due to low demands for farmers' coffee and which is as a result of poor quality of processed coffee (most of the farmers practiced dry coffee processing of which wet processing is highly desirable) this also adduced to the fact that majority could not sell their coffee produce.

Furthermore, the result on table 1 shows the descriptive statistic of the farmers. The table shows that the farmer receives between an average of sixty-four naira and ninety-five naira on a kilogram of coffee between the 2016-2019 seasons. This is far low compared to the international coffee price and could therefore not compensate for farmers' expenses in the coffee production and processing.

Table 2 shows the correlation analysis carried out to show that the amount coffee farmers receives has significant effect on the distance to market at 1% level of significance implying that the farmers really go to market due to far distance (3-5km) and perhaps old age (average of 69 years), hence there are chances that the farmers receives low price for the coffee hence showing in efficiency in the marketing of coffee. Furthermore, the correlation between who buys coffee and the amount offered is significant at 10% while the perceived reasonable amount by farmers and the farmer's age is significant at 1% indicating a very strong variable affecting the efficiency of coffee marketing. Thus the marketing of coffee is not as efficient as expected due to the critical factors affecting the farmer's price for coffee, unorganized market, age of farmers etc.

CONCLUSION AND RECOMMENDATION

The study carried out shows that the coffee farmers has no organized and efficient market for their coffee and this has affected the price /amount the farmer receives for coffee per kilogram and thus by extension low coffee production. It is therefore recommended that government /agencies should help in the organization of good market for the farmers, encourage youths to go into coffee since there is high demand globally as well as provide extension training for the farmers furthermore, price sensitization is highly recommended for the farmers through there cooperatives and extension agents.

ABSTRACT

This study was conducted to examine the skill gap in appropriate coffee processing method among coffee farmers in Nigeria and deduce effective method for good market drive. Specifically, the farmers' socio-economic characteristics were identified with their knowledge and practices in three processing methods available. Two hundred and twenty twenty-five (225) coffee farmers were randomly selected and interviewed through the use of structured interview schedule, from five coffee producing states. Frequency counts and percentages were used in describing the data collected, while Pearson's Correlation Co-efficient (r) was used to determine the relationship between their knowledge and practice of the processing methods in use. Prominent practice sequence in the appropriate processing method (wet processing) revealed; harvesting (100%), sorting (87.6%), pulping (15%), soaking (15.8%), washing (16.2%) and drying to12% Moisture Content (74.5%). However, the following knowledge in processing methods were revealed; wet processing (18%); semi wet processing (25%) and dry processing (85%). More so, the study revealed positive and significant relationship (r=.181; p<0.01) between the knowledge of processing method and practice. It was however deduced that the major problem of coffee marketing is inadequate knowledge in appropriate wet processing method. Hence there is a skill gap in the knowledge of wet processing. More training on wet processing method is required for Nigeria Coffee farmers to compete favourably in the World Market.

Key words: Coffee, Skill gap, Processing, and Market

INTRODUCTION

The genus *Coffea* contains more than 100 species, only two of which, *Coffea arabica* L (*Arabica* coffee) and *Coffea canephora* Pierre (*Robusta* coffee) are commercially cultivated. It is an economic important crop grown in over 70 countries of the World and consumed throughout the world (Opeke, 2012). In Nigeria, Arabica and Robusta coffees account for about 4% and 94% of the total production respectively (Alli; *et al*, 2021). Coffee is one of the major cash crops produced in Nigeria for which very little information is available. In this circumstance, the International Coffee Organization (ICO) and other related organizations have for long been basing the production, processing methods and export figures for Nigerian coffee on mere estimates and assumptions. However, the production is faced with soil depletion, prevalence of pests and diseases, inappropriate processing technology, which has resulted in poor marketing and consequently led to abandonment by farmers. Improper post-harvest processing and poor handling of coffee have been identified as the major cause of poor coffee quality which leads to the problem of coffee marketing in Nigeria. As a result of poor marketing, the income of the coffee farmers has drastically reduced. Hence, many of the coffee farmers have either abandoned their farms or replaced coffee plants with other economic crops (such as castor oil plants). Coffee bean of lower quality cannot attract good premium in the coffee international market. In fact, in actual coffee market crisis, quality is the best guarantee for negotiating a better price. It is estimated that 40% of the quality of coffee is determined in the field, 40% at the post-harvest primary processing, and 20% at secondary/export processing and handling including storage. In order to enhance quality and market value of Nigerian coffee, improved primary processing by the farmers at the village level is a prerequisite (Kamard and Kalita, 2017).

There are three major Coffee processing methods that determine the qualities of coffee beans for the World Market (CoffeeAM.com, 2021).

a. Processing by the Wet Method: This involves harvesting, sorting, pulping, soaking in water (wet fermentation), washing, and drying to moisture content of about 12%.

b. Processing by the Semi- Wet Method: This involves harvesting, sorting, pulping, heaping in basket (dry fermentation), washing, and drying to moisture content of about 12%.

c. Processing by the Dry Method: This involves harvesting, sorting and drying to moisture content of about 12%.

Justification

Despite the favourable climatic conditions, and long history of Robusta production in Nigeria, green coffee beans quality is declining from time to time due to improper pre-and post-harvest management practices. At this backdrop, it is important to determine the skill gap in processing among Nigeria coffee farmers to enhance quality coffee bean for a sustainable coffee production and improved livelihood.

Objectives

1. Identify socioeconomic characteristics of respondents

2. Ascertain respondents' knowledge on three processing methods of coffee

3. Establish respondents' coffee processing method

4. Determine the constrains faced by respondents in practicing wet processing method in the study area

MATERIALS AND METHODS

Thirteen states are known for coffee production in Nigeria. Though it has been established that all the 22 states where cocoa is being grown can also grow coffee, hence the remaining nine are considered as emerging states (CRIN, 2010). For the purpose of this study, 13 states are considered as the growing States. Multistage sampling procedure was engaged in selecting the respondents:

Stage 1: Five states were purposively selected from the 13; Ekiti, Kogi, Osun, Plateau and Taraba states, being areas currently known for coffee growing on commercial level

Stage 2: During Cocoa Research Institute of Nigeria sensitization program in each of the State, 45 respondents were randomly selected from the list of attendance using the first 45 odd numbers. The data were subjected to descriptive analysis and Pearson Correlation to determine relationship between knowledge and practice of the farmers processing method.

Skill gap analysis was carried out by identifying the respondents' level of skill as against the appropriate stages of wet processing methods.

RESULTS AND DISCUSSION

The result in Table 1 show a mean age 45 $\pm$ 12 years of respondents, which is an indication that middle aged people are gradually involved in farming as against previous studies (Agbongiarhuoyi, *et, al*; 2006) that Nigerian farmers were made up of aged people. However, majority (85%) of the respondents were male while 84% were literate, able to read and write. The ability to read and write enhances performance through training; though majority (88%) have never been trained on wet processing.

Table 1: Showing some respondents' socio-economic characteristics

Farmers' practices

Figure 1 shows the respondents' stage by stage practices in appropriate method of coffee processing. From the results, activities involving dry processing, harvesting (100%), sorting (87.6%) and drying to 12% moisture content (74.5%) were highly carried out, while activities that involve wet processing; pulping (15%), soaking (15.5%) and washing (16.2%) were not seriously practiced. However, Goto and Fukunaga (1986) and CoffeeAM (2021) differently asserted that pulping, soaking and washing add value to coffee bean.

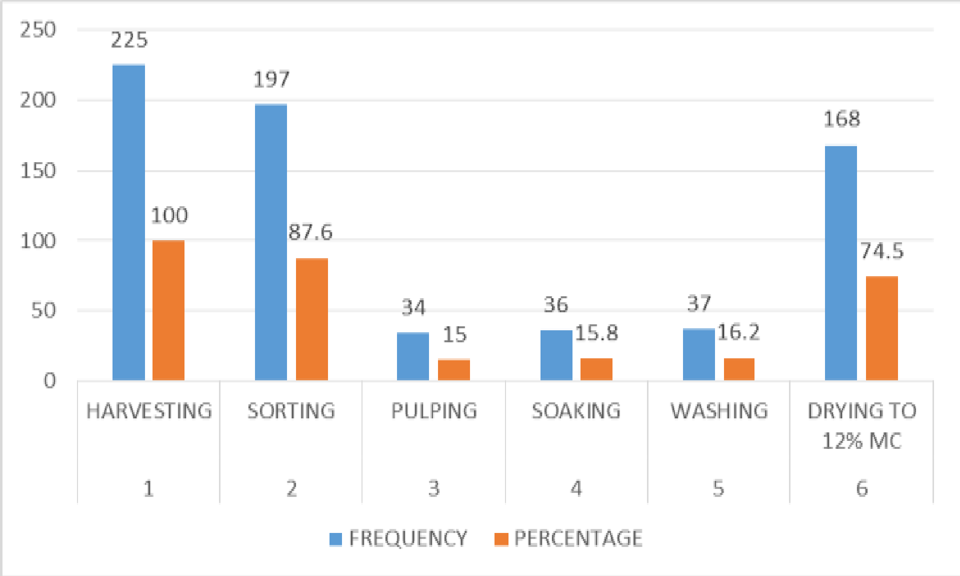

Figure 1: Respondents' practices in wet processing sequence

Source: Field survey, 2019

Knowledge in processing method

Figure 2 shows comparison between respondents' knowledge and practices in the three processing methods among coffee farmers. Among the farmers, dry processing was prominent with Majority (85%) having knowledge on dry processing, with about (25%) having knowledge on semi wet while only (18%) had knowledge on wet processing. However, it only indicated that only 10% of the respondents practice wet processing. This low knowledge in wet process is evident in their responses to their practices wet processing sequence.

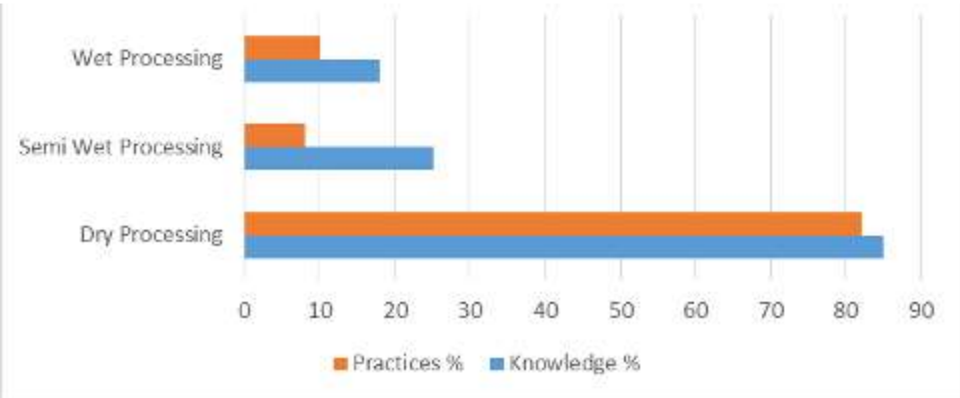

Figure 2: Respondents' knowledge and practices in the three processing methods among coffee farmers

Source: Field survey, 2019

Relationship between Knowledge and practices

The result on Table 2 shows a positive and significant relationship at r=0.181; p<0.01 between knowledge of processing and farmers practices; when knowledge increases good and appropriate practices increase.

Table 2: Pearson correlation describing relationship between respondents' knowledge and practise of processing method

Variable	r	r^2
Coffee processing Methods	.181	.007

Source: Field survey, 2019

CONCLUSION

The study concludes that though majority of the respondents were literate with no training on wet processing method and practise dry processing method.

IMPLICATIONS AND RECOMMENDATIONS

Consequent to the result of the study, coffee farmers will be facing more challenges at both the local and international market. The more cherished green coffee from wet processing accrues premium prices and improves farmers' livelihood. However, to improve quality of bean and consequent good market value, there should be creation of awareness of profitability in coffee production, establish Public Private Practice, through market driven coffee production, building farmers' capacity on wet processing through participatory and learning Action.

ABSTRACT

This study investigated the effects of Covid–19 on the demand and supply of vegetables in Kabba, Kogi state. Data were randomly collected from 60 vegetables sellers through well-structured questionnaires and interview. Measure of central tendency such as mean, frequency, percentage as well as likert-scale analysis was used. Result from the analysis revealed that majority (90%) of the respondents were male while 10% were female, with a mean age of 30 years. Majority (75%) of the sellers were illiterate, with an average selling experience of 7 years. Majority (90%) of the respondents do not belong to social organization. Majority (100%) of the respondents had no extension contact. Majority (95%) of the sellers had no access to credit, with a mean income of 147,000 naira. During the pandemic (80%) vegetables consumption and sales was very low. Effects of Covid–19 on the demand–side shock include job losses, reduced income of the consumers, price of the commodities, depleted purchasing power, insufficient savings, high demand and size of the population while on the supply –side shock include price of the commodity, labour shortages, cost of transportation, government policy, goals of the seller, disruptions to transportation and distribution networks, disruptions due to movement and travelers restrictions, created food insecurity and thickening of border. As cases of contagion increase, governments take more drastic measures to stop the spread of the virus, also influencing the global food system. Therefore, it is recommended that sellers should form a cooperative in other to access inputs to increase marketing efficiency and improve their livelihood and to avoid the impact of COVID-19 on sellers, government must increase its support towards (loans or inputs) sellers as well as all the vulnerable households that directly depend on agriculture products for survival.

INTRODUCTION

Vegetables such as cabbage, cucumber and carrot are important vegetables known to mankind for over 4,000 years. Record show that the Ancient Greeks, Romans, Indians and Chinese all valued and used them greatly. Collectively, these vegetables deliver leaf, flower and root vegetables that are eaten fresh, cooked and processed: used as folder and forage, sources of protein and oil used in low fat edible products, for illumination and industrial lubricants, condiments such as mustard, herbs and other flavorings: and soil conditioners as green manure and composting crops and very rich in vitamins. As the COVID-19 pandemic of 2020 unfolds, considerable attention has focused on the resiliency of food supply chains in a time of crisis. Food supply chains have needed to adjust rapidly to demand side shocks, including panic buying and changes in food purchasing patterns, as well as plan for any supply side disruptions due to potential labor shortages and disruptions to transportation and supply networks (Breen, 2020). The COVID-19 pandemic is getting worse day-by-day, with interruptions in human activities, a huge death toll, and a direct hit on the global economy. Baum and Robertson (2020) argued that the wreaking havoc due to COVID-19 is not a surprise since pandemics viz Spain flu, Polio, HIV, Severe Acute Respiratory Syndrome (SARS), Zika, the Middle East Respiratory Syndrome (MERS), and Ebola are the recent realities of the modern world. Abdelhed and Zouari (2020) reported that in the past century, death due to viral diseases was far more than the major armed conflicts. The COVID-19 prevention measures such as lockdown, stay-at-home order, mass quarantine, and transport halt are highly challenging in those societies. Many developing countries imposed a short state emergency when the first case was confirmed. The movement of imports and exports is becoming slower or even stopped in some cases. During this economic crisis, the countries have to depend on emergency packages, which might not be adequate to cushion them and their vulnerable population. The transport sector has also halted operations owing to lockdown imposed in several countries and this has disrupted the supply chain for essential goods, especially food (Sachs, 2020; Reardon et al., 2020) and humanitarian aid donated by different agencies.

As the COVID-19 pandemic of 2020 unfolds, considerable attention has focused on the resiliency of food supply chains in a time of crisis. Food supply chains have needed to adjust rapidly to demand-side shocks, including panic buying and changes in food purchasing patterns, as well as plan for any supply-side disruptions due to potential labor shortages and disruptions to transportation and supply networks.

The COVID-19 prevention measures such as lockdown, social distancing, isolation, stay-at-home order, mass quarantine, and transport halt are highly challenging in those societies. Many developing countries imposed a short state emergency when the first case was confirmed. The movement of imports and exports is becoming slower or even stopped in some cases. During this economic crisis, the countries have to depend on emergency packages, which might not be adequate to cushion them and their vulnerable population. The transport sector has also halted operations owing to lockdown imposed in several countries and this has disrupted the supply chain for essential goods, especially food and humanitarian aid donated by different agencies, increase in price of items, increase in perishability of produce amongst others. Most studied on the subject matter have been on foreign land and none in the study area which this study aims to achieve.

MATERIALS AND METHODS

The study was carried out in year 2020 in Kabba town, Kogi State. It is an agrarian community located within the southern guinea savannah ecological zone of Nigeria and is known to have a tropical savannah climate with distinct wet and dry seasons. The study investigated the effects of Covid–19 on the demand and supply of vegetables in Kabba town. Two stages sampling technique were adopted for the study. First, kabba town was purposely selected because of the high rate of demand and supply of these vegetables. Secondly, sixty (60) vegetable marketers were randomly selected. Primary data and secondary data were used in this study. The primary data were collected by the use of structured questionnaires, using face to face interview schedule and information observation with the sellers who engage in selling cabbage, carrot and cucumber. Secondary data was obtained from text books, journals, bulletins, internet and other relevant literature. Data were analyzed using descriptive statistic and likert scale.

Model Specification

$$\text{Percentage (\%)} = \frac{\text{observed frequency x 100}}{\text{Total No frequency}}$$

Mean(x) = $\sum x/n$

Where: $\sum$ = summation, X = individual observation, N = No of observations.

Likert Rating Scale Technique

The effects of Covid –19 on demand-side and supply-side shocks on food supply chains were estimated using the four likert rating scale technique. The mean score of 2.5 was used as the cut off points. Thus the mean score of 2.5 and above was considered serious and very serious while those with mean score below 2.5 are not serious and not very serious.

This can be summarized with the equation become

$$X = \frac{\sum fn}{n} \quad \text{........(4)}$$

Where; X = mean score, $\sum$ = summation, N = frequency

$$\sum fn/n = \frac{1+2+3+4}{4} = 2.5$$

Decision Rule

0.5 - 1.50 = Strongly disagree, 1.51- 2.49 = Disagreed, 2.50-3.00 = Agreed, 3.09 – 4.00. Strongly agreed

RESULTS

Socio economic characteristics of the vegetable marketers in the study area (Table 1) shows that shows that most (83.33%) of the respondents were male while 16.67% were female. Majority (66.67%) of the respondents are between 20-30 years, with a mean age of 30 years. Most (75%) of the marketers sampled were illiterate but cannot be cheated in carrying out their selling activities. Majority (66.67%) of the respondent had between 1 - 10 years marketing experience with a mean marketing experience of 7 years. Most (83.33%) of the respondents do not belong to social organization such as cooperative society while 16.67% belong to vegetable seller's union in the study area. 100% of the respondents had no extension contact. 91.67% of the marketers had no access to credit while 8.33% had access to credit. About (66.67%) of the marketers had between 101,000 – 150,000 yearly income with a mean income of 147,000 naira.

Effects of Covid–19 on demand side shock of vegetables in the study area (Table 2) shows that before the pandemic, vegetables consumption (55%) was very high, while during the pandemic it (77.33%) was very low. Effects of Covid – 19 on the demand –side shock include job losses, reduced income of the consumers, price of the commodities, deplete purchasing power, insufficient savings, high demand and size of the population respectively.

Effect of covid–19 on supply side shock of vegetables in the study area (Table 3) reveals that before the pandemic, vegetables sales (55.67%) was high while during the pandemic (75%) was very low. Results revealed that the effects of Covid – 19 on the supply – side shock include price of the commodity, labour shortages, cost of transportation, government policy, goals of the seller, disruptions to transportation and distribution networks, disruptions due to movement and travelers restrictions, created food insecurity and thickening of border.

Covid–19 coping strategies adopted by the marketers during the period in the study area (Table 4). The respondents adopted getting help from people, going outside to work, selling of assets, spend savings, borrow loan for survival and borrowing from friends and relatives for survival during the period. It is a taboo for them and their households to engage in begging, thuggery and prostitution. Several social prevention strategies and Policies were adopted by the government to cope with Covid–19 (Table 5) such as school closing (SC), workplace closing (WPC), cancel public events (CPE), restrictions on gathering (ROG), close public transport (CPT), stay at home requirement (SHR), restrictions on internal movement (RIM) international travel controls (ITC) and lockdown, isolation and social distancing (LISD) were the measures identified as very strict. On the other hand, income support (IS) was considered less strict (rejected) in the study area.

DISCUSSION

COVID-19 disease has a great effect on the actions and activities of humanity and the various preventive measures taken to control the spread of the pandemic hinder the production and distribution of agricultural products. United Nations Sustainable Development Goals (UNSDGs) (UNDP, 2014) noted that 55% of the global population with a majority from developing countries do not have access to social protection. Fraser (2020) added that this vulnerability will aggravate socio-economic losses whose effects will spill to human rights, educational sectors, and to depriving the poor and marginalized of food and proper nutrition. Vegetables marketing, food demand, supply and thus food security is greatly affected due to mobility restrictions, reduced purchasing power, reduced income, job losses, and with a greater effect on the most vulnerable population groups. As cases of covid-19 increase, governments take more drastic measures to stop the spread of the virus, also influencing the global food system. Sachs (2020) reported the measures taken by governments to tackle the spread of covid-19. The halting of the transportation sector owing to the lockdown disrupted the supply of foods and vegetables. Grant (2020) concluded that although the levels of implementing these measures vary, their effects in controlling COVID-19 has been considerably successful.

Majority of the people in the study area are in the active age group of 20-30 years and this will increase marketing in the study area (economically active age brackets). Glauber *et al.,* 2020 stated that consideration should be given socio-demographic characteristics such as gender and identity, age, education, migrant status, employment status, ability status, and household composition as they give deeper insights of how COVID-19 may affect consumer demand for food in Nigeria. The pandemic recorded decrease in demand for vegetables which agrees with the analysis of FAO (2019) that during pandemic, demand for food decreased due to uncertainty and the reduction of people's spending capacity, although this decrease is slight; the situation could worsen if the pandemic continues for a long time, due to reduced income and job losses. Imman (2020) also reported job losses, reduced income of the consumers, deplete purchasing power, insufficient savings and convenience as effects of Covid–19 on the demand side shock.

Supply side shocks identified in this study include price of the commodity, labour shortages, cost of transportation, government policy, goals of the seller, disruptions to transportation and distribution networks, disruptions due to movement and travelers restrictions, created food insecurity and thickening of border agrees with Imman (2020) who reported labour shortages, cost of transportation, government policy, goals of the seller, disruptions to transportation and distribution networks, disruptions due to movement and travelers restrictions, created food insecurity and thickening of border as effects of Covid – 19 on the supply side shock.

The marketers adopted getting help from people, going outside to work, selling of assets, spend of savings, loan for survival and borrowing from friends and relatives respectively as survival strategies during the period. Majority of them did not belong to any cooperative society, seller's union nor had contact with extension services. Saito and Spurling (1993) reported that inadequate access to agricultural information and innovations is a major problem for women in agriculture.

RECOMMENDATION

Extension workers should intensify efforts in disseminating improved marketing information to sellers. Vegetable marketers should form a cooperative in other to access inputs to increase marketing efficiency and improve their livelihood. To avoid the impact of COVID-19 on marketers, the government must increase its support (loans or inputs) towards marketers as well as all the vulnerable households that directly depend on agriculture products for survival. The government should create an enabling socio-economic environment through the provision of social amenities to facilitate economic growth and improve health facilities, thereby increasing local produce, creating job opportunities and increasing GDP.

EMPIRICAL ESTABLISHMENT OF THE PRODUCTIVITY OF CRIN COCOA HYBRIDS TC_1-TC_8 IN NIGERIA

*Adedeji, A.R., Lawal, J.O., Famuyiwa, B.S., Taiwo, O.A., Orisasona, T.M. and Ayegboyin, K.

Cocoa Research Institute of Nigeria (CRIN) Ibadan

ABSTRACT

The study investigated the performance of CRIN Cocoa hybrid Tc_1 – Tc_8 on farmers' farm compared with established on–station performance at CRIN. It specifically explained the variations of performance across the states in the study area, along with farmers' adherence with Good Agricultural Practices (GAP). Using a multistage sampling technique, random selection of 288 tree across 48 cocoa farms that received Cocoa hybrid pods in 2011 for farm establishment in 4 Cocoa producing States were achieved in Cross River, Ondo, Osun and Ogun States of Nigeria. The ages of cocoa trees included in the study were between 5 to 8 years, while farmers were trained to take data for one year. Descriptive statistic was used to analyse the data. Results revealed majority (68.4%) of the respondents exhibiting Fair knowledge of GAP, while about 49.6% practiced GAP. The mean pod yield per tree was 130±14.0 pods with 35±4.0 mean beans per pod. The yield per tree across the States varied in the study area. The study deduced that CRIN hybrid cocoa is significant to sustainable cocoa production, increase in productivity and consequently improved farmers' livelihood in Nigeria.

Key words: Cocoa, productivity, CRIN hybrid, Nigeria

INTRODUCTION

The importance of agriculture to the Nigerian economy cannot be under estimated. In Nigeria, Cacao occupies about 0.6 million hectares and production stands at 383,000 tonnes in 2012 (FAOSTAT, 2014). The average cocoa yield in West Africa is about 0.5 tonnes/ha while for Nigeria it is around 0.4 tonnes/ha. This suggests that yield in Nigeria is low compared to the world average. Cocoa remains the highest foreign exchange earner of all agricultural export crops in Nigeria, cocoa output has declined and one of the factors responsible for this was the fact that soils of cocoa growing agro-ecologies are inherently poor in fertility, rapidly degraded of properties, acidic due to the nature of the parent materials and leached of nutrients due to high rainfall intensity. After its introduction into the zone of West Africa sub- region in 1890, the area planted to cocoa increased rapidly to its present 0.7 million hectare and yield increased to peak of 310,000 tons in 1965 (Daramola, 2004). Many studies have attributed this yield decline essentially to soil nutrients imbalance and poor planting materials (Ayanlaja, 2002 and Ojeniyi, 2010).

Problem Statement

Despite the vast hectares of land been used for Cocoa farming in Nigeria, the productivity has been low. The Cocoa Research Institute of Nigeria (CRIN) introduced new cocoa hybrids named (TC_{1-8}) to the farmers but the empirical determination of the average number of bean per Kg, actual number of dry bean per Kg , number of pods that make on Kg of dry beans and number of pods per tree yield /year per hectares of cocoa hybrids TC_l to TC_8 has not been established in order to determine the simple but very vital information for sustainability, profitability and constraints of its production in Nigeria. To this end, it is essential to determine these parameters at the CRIN headquarter and at the farmers' farms. Therefore, the urgent need to examine critically the yield parameters of these varieties of cocoa. Specifically, this study was based on the objectives to determine average number of cocoa bean in a pod and evaluate number of pod yield per tree per year.

MATERIALS AND METHODS

The study was carried out in four States, purposive sampling technique was used for selection of four states namely Ondo, Ogun, Oyo and Cross River State. In each of the state, 6 local Government areas were selected for sampling. In Ondo state, the local Government area that were covered were Owena, Ile-Oluji/Okeigbo, Idanre, Akure south, Irele and Akure North and for Ogun state; Ijebu North, Ijebu East, Egbado North, Egbado South, Obafemi Owode/Ota and Abeokuta North. While in Oyo state; Oluyole, Atiba, Afijio, Ido Akinyele, and Ogo-oluwa and for Cross River state the local Government areas that were captured are Ikom, Etung, Boki, Obubra, Ogoja and Akamkpa. A total of 24 LGAs were used for the study. However, two farmer's (farm) were randomly selected from the list of those that collected hybrid cocoa pods from

CRIN in 2011 and six trees were tagged from each farmer's farm for the purpose of the study. The respondents were asked to harvest and record the identified Tc1-8 to achieve the study's objectives. In all, 48 farmers' farm were sampled and 288 trees tagged for the study. The farmers were trained on how to take data from the tagged trees, while relevant data on bean in a pod and actual number of pods per tree yield per year were collected to achieve the aims and objectives. The data collected were analyzed using descriptive statistics.

RESULTS AND DISCUSSION

Respondents' knowledge of Good Agricultural Practices

Table 1 shows the respondents' knowledge of GAP, Majority (68.4%) indicated that they have fair knowledge of GAP, while only 14.9% had high knowledge. This is an indication that majority of the farmers who collected the hybrid materials did not follow Good Agricultural Practices, which are requirements for optimum performance of the hybrid. Hence this can contribute to the farmers' low yield.

Table 1: Respondents' knowledge of GAP

Knowledge Level	Scores	Frequency	Percentage
High Knowledge	>46.27	43	14.9
Fair Knowledge	>13.4<46.27	197	68.4
Low Knowledge	<13.4	48	16.7

Source: Field survey, 2020

Yield of pod per tree per year

Figure 1 shows average yield per tree per year. The mean yield per tree per year was 130 pods, while Osun recorded the highest yield (172) and Cross Rivers (156) pods per tree per year however, the least was recorded by Ondo state. This result may be as a consequence of the farmers' knowledge in agricultural practices and handling of the hybrid materials.

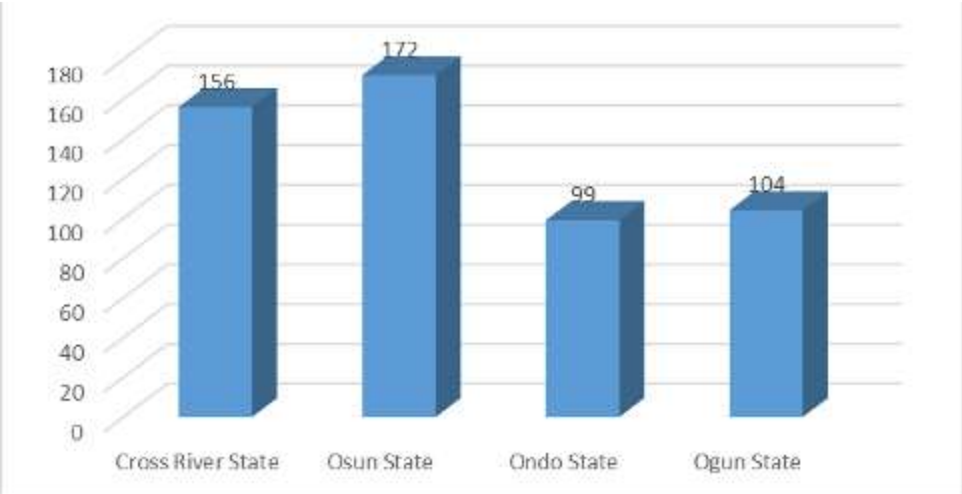

Figure 1. Average yield per tree per year

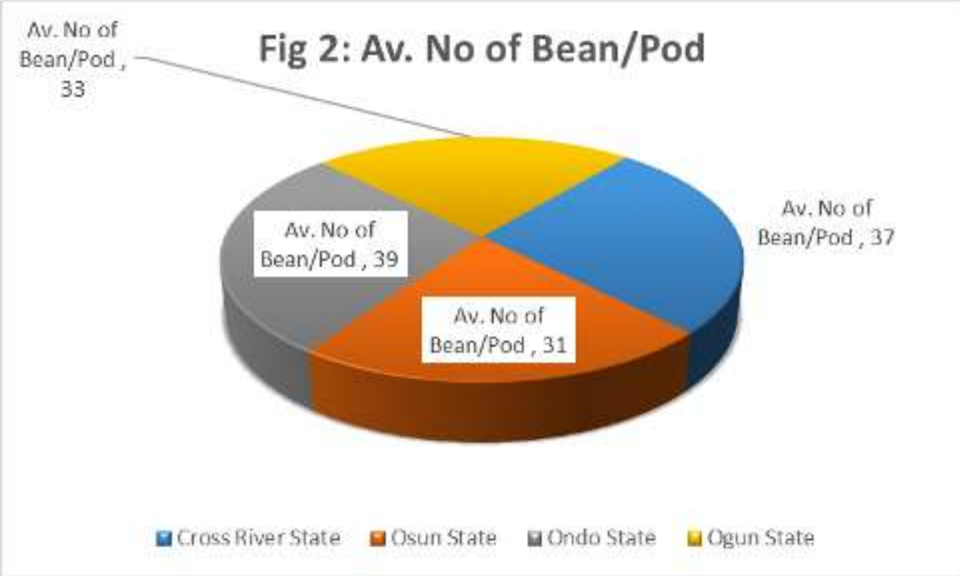
Source: Field survey, 2020

Average Number of Bean per pod

Figure 2 shows the average number of bean per pod recorded from each state. The highest (39 beans/pod) was recorded from Ondo followed by Cross River (37 beans/pod), while the least was Ogun with 31 beans /pod. However, the mean bean per pod from the study area was 35 beans per pod, this correspond with the quality identified by CRIN 2011.



Source: Field survey, 2020

CONCLUSION

It was concluded that though the majority of the farmers had fair knowledge on Good Agricultural Practices of the hybrid materials, yet the average yield per tree per year (130 pods) while the average bean per pod was recorded to be 35 bean. The results correspond with CRIN assertions on the qualities of the hybrid materials; Tc1-8

RECOMMENDATION

More awareness and training should be made available to the farmers, while the hybrid materials should also be available to the farmers to improve their yield and consequently increase their livelihood

ABSTRACT

An experiment was conducted at the National Horticultural Research Institute Dadin-kowa Experimental Station, Gombe State to determine the performance of poultry manure and NPK 15:15:15 on growth and yield of watermelon, during 2019-2020 dry season. A randomized complete block design (RCBD) was used consisting 4levels of poultry dropping manure (0, 1, 2, and 3ton/ha) and 3 levels of NPK fertilizer (0, 40, and 60kg/ha), these were replicated 3 times. The parameters observed were vine length, number of leaves, number of branches, fruit weight per plant, fruit diameter and fruit weight per hectare. The result showed that there was significant difference among the treatments used. It further revealed that the combination of 3tons of poultry manure and 60kg of NPK fertilizer was superior in enhancing vine length, number of branches and fruit yield followed by other treatments while the control gave the least of the values.

Key words: Watermelon, poultry manure and NPK 15:15:15. fertilizer

INTRODUCTION

Watermelon is an important vegetable crop in the tr opics; it has its origin from the hot, dry regions around the Mediterranean. Its cultivation has extended to tropical and subtropical regions on the American continent. However, watermelons grown in humid areas are less sweet and tasty than those from hotter drier climates (Anon, 2006). By the 10th Century, watermelons were being cultivated in China, and are today the world largest producer of watermelon. It was believed that African slaves introduced watermelon into the United States of America. Watermelons have the following contents: 73% water. 2.25% protein, 0.2% fat, 9.7% carbohydrate, and 0.8% ash (Purseglove, 1999). The consumption of the edible parts has been reported to promote digestion and help prevent constipation (Fatoken, 1979). Watermelon also use to compliment staple food since it is a good source of vitamin, minerals, and protein (Funso and Bassir, 1998) In general, high nitrogen under high temperature condition promote maleness in flowering and the seeds are rich in fat and protein (Anon, 2005). By world healthiest food (2013), increase in vine length, number of leaves, leaf area and watermelon as well as number of branches were recorded with increase in lycopene, phenolic antioxidants and fertilizer application. This study was designed to evaluate the effect of organic and inorganic fertilizer for the growth and yield of water melon in the study area.

MATERIALS AND METHODS

The trial was conducted during the dry season of 2019/2020 at National Horticultural Research Institute (NIHORT), Dadin-Kowa station, (Latitude 110 14' N and Longitude 110 8' E) with altitude 440m above sea level in Sudan savannah ecological zone of Nigeria. The area is characterized by a mono modal rainfall pattern with medium rainy season period which usually starts in May and extends to October. Treatments used consisted of 4 different levels of poultry manure (0, 1, 2, and 3tons/ha) and 3 levels of NPK 15:15:15fertilizer (0, 40, 60kg/ha). The treatments were in factorial, arranged in a Randomized Complete Block Design in 3 replications. The watermelon was planted at 1.0m by 1.0m, inter and intra-row spacing respectively. Poultry manure was incorporated in to the soil two weeks before planting. Data collected were vine length, number of leaves, number of branches, fruit weight, fruit diameter and fruit yield, these were subjected to analysis of variance (ANOVA) at 5% probability.

RESULTS

The results of the soil analysis of the experimental site showed that the soil textural class was loamy sand (Table 1). The soil pH was slightly acidic (6.2) with low organic carbon of 4.79g kg^{-1} soil. Total N content of was very low. The available phosphorus was low (0.015g kg-1). Mg content was high while K and Ca content were moderate. The CEC of the analysed soil was moderate and ranged between 6.67 to 7.18cmol K^{-1} soil.

Table 2 shows the effect of NPK and poultry manure on vine length of water melon. The application of 60kg/ha NPK resulted to significant vine length which was however at parity with application of 40kg/ha NPK at 4WAP. Poultry manure usage effect was significant throughout the sampling periods.

Table 2. Effect of poultry manure and NPK 15:15:15 fertilizer on vine length of watermelon in Dadin-kowa, 2019/20 season

Treatments	2 WAP	4WAP	6 wap	8 WAP
NPK (Kg/ha)				
0kg	8.48c	18.92c	29.99c	54.99c
40kg	10.65b	24.76b	36.03b	71.05b

Poultry manure and NPK 15:15:15(Kg/ha)	**	**	**	**

All means followed by the same letters in the same column are not significantly different using DMRT. NS=Notsignificant

The use of poultry manures at 3t/ha recorded significantly lengthy vines compared to other treatments. The control resulted to the least number of leaves (Table 3). Application of 3t/ha poultry manure at 4WAP produced significant number of leaves compared to other treatments. Treatment with 1, 2 and3t/ha poultry manures resulted to statistically the same number of leaves at 6 and 8 WAP. Generally, there is increase in number of leaves of watermelon with increase in quantity of poultry manure. Table 4 contains the results on yield and yield parameters as influenced by NPK and poultry manures. Fruit yield increased with additional increase in quantity of NPK. Application of 3t/ha NPK produced statistically lengthy fruits while the control recorded the shortest fruit. Poultry manure application at 1, 2 and 3t/ha were statistically the same and better than the control. The fruit yield was significantly affected by NPK and poultry manure. Higher dosage of NPK and cow dung results in increased yield of watermelon while lower yield was observed for the control.

DISCUSSION

The experiment was designed to evaluate the effect of poultry manure and NPK 15:15:15 fertilizer at different rates for the growth and yield of watermelon while specific different opinions have been expressed with regards to watermelon fertilization using organic manure like poultry manure and cow dung by different authors. Schippers (2000**).** recommended the use of poultry manure for crop production which; was consistent with Kogbe's (1995). Poultry manures have been found to produce higher watermelon fruit yield than cow dung manures. This was attributed to the higher content of nitrogen and phosphorus in poultry manures in addition to its ability to furnish the soil with more magnesium and some trace elements (Purseglove 1995). The influence of fertilizer and manures applications are that fruit yield by fertilizer application are significantly higher compared to the control. This is in accordance with the fertilizer level with the findings of Efediyi (2009) who reported a response to NPK application showed better performance in watermelon flowering to no fertilizer application. It is important to note that spacing has significant effects on watermelon plants in the study area. Therefore, the combination of cowdung and NPK leads to releasd of mineral el ements that established and maintained optimal soil physical condition for plant growth (Enujeke *et al.,* 2013). Bamikole *et al.* (2011) also reported that combination of organic an d inorganic fertilizers significantly increased crop gr owth parameters and yield and attributed it to high l evel of nitrogen supplied by the combination which i s an essential plant nutrient for growth. This is in conformity with the findings of Dean (2004), who reported that, vegetative growth and yield parameters are under the influence of plant spacing. while final fruit weight of watermelon

CONCLUSION

Therefore, it can be further concluded that watermelon farmers are advised to embark on production and application of poultry manure and NPK 15:15:15 fertilizer that will significantly increase the production of watermelon in their farms in the study area.

ABSTRACT

A training by CRIN in 2014 in three major Cocoa agro-ecologies in Nigeria exposed cocoa farmers to various rehabilitation techniques viz: Partial replanting; Complete replanting; Phased farm replanting; Planting under old trees; Side grafting; Top grafting and Coppicing of old stands. To evaluate the adoption of the methods and establish the preference by farmers for the rehabilitation techniques, a post training survey was carried out in 2019 through administration of structured questionnaires on farmers' socio-economic characteristics, level of adoption and preference for the rehabilitation techniques. Results revealed that 75.71% of the respondents were below 50 years an indication of vibrant Cocoa farmers' population. 91.90% of the respondents are married which may ensure availability of labour in production activities. On-farm experience, 78.1% of farmers has more than 10 years' experience in Cocoa production. Majority of farmers (83.3%) are formally educated though only 14.29% had tertiary education while 21.43% had secondary education. On knowledge of rehabilitation techniques, 33.81% of the respondents claimed planting under old trees was known to them, while 7.62% claimed they know all the rehabilitation techniques. 9.05% claimed they were taught complete farm replanting. On the source of the rehabilitation knowledge, 58.57% stated they got the knowledge through CRIN, 12.38% through the State Tree Crop Units (STCU) while 11.43% got theirs through friends. On adoption of rehabilitation methods taught 85.24% indicated they have started practicing one form of the rehabilitation techniques or the other. 54.76% of the respondents have adopted planting cocoa seedlings under old plantation, while 15.71% have adopted coppicing method. On preference for the rehabilitation methods, 61.43% prefers planting improved seedling under old plantation while 21.43% prefers coppicing technique. This study has showcased the need for massive rehabilitation of over 600,000ha of cocoa plantations in Nigeria through replanting of improved cocoa hybrids from CRIN for increased cocoa productivity thereby reducing further encroachment into the remaining forest land.

Key words: Cocoa, rehabilitation, adoption, preference, replanting

INTRODUCTION

Cacao (*Theobroma cacao L.*) is an important export commodity crop in Nigeria making her ranked fourth among producing countries in West Africa. It has remained a leading export commodity crops among countries producing it. In Nigeria, more than 200,000 households from 14 active producing States earn their livelihood from the crop (NCDC, 2008). There are however 8 additional emerging States producing the crop (Famaye, 2013). The crop is regarded as the second highest foreign exchange earner after petroleum contributing 38.54% to the national GDP (NEPC, 2011). As important as this crop is to the national economy, production has decline to as low as 450Kg/ha. The decline is as a result of several factors such as old age of plantations, pests' incidence, low yielding genotypes, nutrient depletion(Ibiremo *et al* 2017) and outright plantations abandonment (Adeyemi *et al*, 2017) especially since the advent of oil boom in the 70s. A plot is considered unproductive if the yield has declined to about the quarter of what is obtainable at the peak period of 10-25 years (Olaiya, 2001) while Oduwole (2001) based his own recommendation on the cost/benefit ratio of the plot. In order to bring an unproductive plot into life, rehabilitation processes have to be carried out on the plot. Generally speaking, rehabilitation is defined as the process of bringing an unproductive cocoa plot back to economic productivity (Oluyole *et al,* 2015). Some rehabilitation techniques include: partial replanting; complete replanting; phased farm replanting; planting under old cocoa trees; side grafting; coppicing and top grafting. These practices were demonstrated to farmers in the study areas about six years ago. Therefore, the objective of this study was to post-evaluate these practices on the farmers' farms and to evaluate the extent of adoption of these techniques by the farmers in the study areas.

MATERIALS AND METHODS

The study was carried out in the three cocoa producing States in the southern part of Nigeria, specifically Ondo, Cross River and Osun States.

These are the States where rehabilitation techniques were earlier demonstrated among cocoa farmers. In each of the States, two cocoa producing Local Government Areas (LGAs) were selected making a total of six LGAs selected for the study. There were 35 questionnaires for each community totaling 70 per each State Purposive sampling technique was used to select the 210 respondents from the study area. Structured questionnaire was used to elicit information from the selected respondents. The information collected from the respondents were analyzed with the use of descriptive analysis such as frequency and percentages.

RESULTS AND DISCUSSION

Table 1 shows that 75.71% of the total respondents were of the age 50 years and below showing that the highest proportion of the respondents were still in active age to carry out rehabilitation on their farms. Also 91.90% of the respondents were married indicating that there may be more farm hands to rehabilitate the farms. This is a good development as labour is a major factor in carrying out rehabilitation process. Majority (78.1%) of the farmers are highly experienced on farm work as the proportion has been on farm work for not less than 10 years. However, 83.33% of the farmers are formally educated though only 14.29% had tertiary education while 21.43% completed secondary school education. All these are good indicators towards good adoption of the rehabilitation techniques that were taught. The role of Farmers Field School in information dissemination has also been pointed out (Nwagbue and Akinbile, 2012). Table 2 also indicates that 58.57% of the farmers claimed that they got the knowledge of rehabilitation techniques from CRIN while 12.38% received the knowledge from States Tree Crop Units, this is an indication that the training exercise by CRIN was effective especially the one that will not tamper with harvesting from existing stands. CRIN has been involved in all aspects of cocoa production especially training activities (NEPC, 2011). However, 11.43% of the total farmers got the knowledge of rehabilitation techniques from their friends; training on cocoa rehabilitation has been a recurring activity as most farms are moribund. Meanwhile Table 3 reveals that 85.24% of the farmers have started practicing rehabilitation techniques on their farms after they have been taught. This is a good development as majority of the respondents adopted the techniques. Table 4 indicates that of all the rehabilitation techniques taught, 54.76% of the respondents practiced planting under old trees in their farms while 15.71% practiced coppicing and 1.90% practiced side grafting. This shows that planting under old trees is mostly adopted among the farmers in the study area. There is therefore the need for CRIN to generate enough seedlings of improved cocoa hybrids to be distributed to farmers to rehabilitate the unproductive farms (CRIN, 2017). As shown in Table 6 regarding the rehabilitation methods preferred among the farmers, 61.43% of the farmers preferred planting under old trees than any other rehabilitation techniques and 21.43% preferred coppicing. The former option will discourage further encroachment into the remaining forest land in Nigeria for cocoa production

As revealed in Table 7, 73.33% of the farmers confirmed that they have started harvesting from their rehabilitated plot between 2-3 years after rehabilitation while 12.38 % started harvesting after a year. Table 9 reveals the plot in which planting of new hybrids were planted under old trees, harvesting of pods was carried out as claimed by 55.71%, this is in support of their precocious nature followed by coppicing (16.67%). The low interest in coppicing is that farmers find it difficult to wait for 2-3 years before coppiced plot comes into bearing hence they prefer methods that will still sustain some returns from old stands while the plots are rehabilitated. Table 8 shows poor response to side grafting techniques because they are afraid to take risk; the methods are too technical. Sodre and Gomes (2019) had reported that this technique is not yet well understood despite many studies particularly the mechanisms involving the physiology of the graft and root stock.

CONCLUSION

Knowledge of cocoa rehabilitation techniques have been imparted into the consciousness of cocoa farmers in the study areas viz: complete replanting, coppicing, planting under old trees, side grafting and top grafting. Of all the techniques, planting under old trees was mostly acceptable; followed by coppicing while the least accepted was side grafting. Top grafting was not adopted at all. We recommend that the two adopted techniques be concentrated upon for now. The former can be achieved through massive production and distribution of seedlings of our new hybrids to farmers in the producing areas to replace old, moribund and unproductive trees. The methods that are being adopted by cocoa farmers will stem the tide of further encroachment into existing forest land in the study areas. The 33.81% of farmers describing the new CRIN cocoa hybrids as higher yielding and none response of 54.29% to the hybrids suggest more sensitization by CRIN and other stakeholders at popularizing the cocoa hybrids.

ABSTRACT

Plant population affects growth and yield of leafy vegetables; they determine the efficiency of light use, nutrient uptake, water balance and land maximization. A field experiment was conducted at the Federal University of Agriculture, Abeokuta, in 2021 to determine the effects of plant population on leaf area and proximate composition of Amaranth. Treatments comprised of 3 plant populations: 400,000, 200,000 and 100,000 plants/ha using a spacing of 5, 10 and 20 cm intra-row and a constant inter-row spacing of 50 cm, replicated 4 times. Data were collected on number of leaves, leaf area and proximate composition (Moisture, dry matter, ash, carbohydrate, crude fibre and crude protein content) using standard procedures. Data collected were subjected to Analysis of Variance and treatment mean separated using least significant difference (p≤0.05). The number of leaves were similar all through the growing period, ranging from 10 – 11 leaves at 3WAP and 23 – 27 leaves at 4WAP. The leaf area was similar all through the growing period, ranging from 1.25 – 1.59 cm^2 at 2WAP and 42.10 – 51.60 cm^2 at 4WAP. Plant population of 200,000 plants/ha had more carbohydrate (23.89%) and dry matter (11.96 g) content with plants grown at 100,000 plants having the least dry matter (11.4 g) content and the fattest (2.79%). Amaranth planted at 400,000 plants/ha had more ash (29.5%), crude fibre (24.51%) and crude protein (21.33%) content with plants grown at 200,000 plants/ha having the least ash (28.7%), crude fibre (24.01%) and crude protein (20.67%) content. Planting at 100,000 plants/ ha is best for herbage yield. Planting at 200,000 plants/ha is best for optimum carbohydrate and dry matter content, while plants grown at 400,000plants/ ha is best for optimum ash, crude fibre and crude protein content.

Key words: Plant population, leaf area and proximate composition.

INTRODUCTION

Amaranthus cruentus (Linn) is a vegetable crop belonging to the genus *Amaranthus*, of the family *Amaranthaceae* and order *Caryophyllates* (Grubben, 2004). There are two kinds of amaranths i.e. vegetable and grain amaranths (Vorster *et al*., 2008). The center of origin for *Amaranthus* has been considered to be Southern Asia (Indo-Burma region) and Central and South America for most of the varieties that have been held under cultivation since time immemorial (De Candolle *et al*.,1984). Cultivation of amaranths contributes to the vitality of farmlands as they used as pioneer species for the colonization of disturbed lands (NRC, 2006). This characteristic is partly attributed to their C4 mode of photosynthesis, which involves efficient water use. They are photoperiod sensitive and are known to flower during shorter day lengths (Ebert *et al*.,2011). The dry matter content is high (9–22%). The average composition of *Amaranthus cruentus* per 100g edible portion is (averages of about 40 samples): water 84.0 g (78.4–91.3), energy 176 kJ (42 kcal), protein 4.6 g (3.2–6.0), fat 0.2 g (trace–0.6), carbohydrate 8.3 g, fibre 1.8 g (0.4–6.4) (Grubben, 2004). Plant population is the total number of plants present per unit area of land. The yield of a crop is directly influenced by population of plant. Plant height is increased, in high plant concentration due to competition for light. The thickness of leave may reduce due to high plant population, leaf geometry is also altered due to high population pressure (Nazer *et al*., 2016). Amaranthus cruentus is an important leafy vegetable in Nigeria, but the cultivation is erratic and not fixed at a particular population. Experimented reports are sparse on population effects on the leaf development and proximate composition of *Amaranthus cruentus.* The objective of this study was to assess the effects of plant population on leaf development and proximate composition of amaranth; which will serve as a way of improving the nutritive qualities of Nigerian foods.

MATERIALS AND METHODS

The experiment was conducted between May and July 2021, at the research farm of the Federal University of Agriculture Abeokuta (FUNAAB). Soil samples taken randomly up to 15 cm depth from 5 core spots, using soil auger were bulked to have a composite sample. This was air dried and analysed to determine the soil nutrient status. Twelve raised beds of 2.0m x 2.0m each were made. The treatments were arranged in a Randomised Complete Block Design (RCBD) having 3 treatments: 400,000, 200,000 and 100,000 plants/ha using a spacing of 5, 10 and 20 cm intra-row and a constant inter-row spacing of 50 cm, replicated 4 times, making a total of 12 experimental plots. Seeds were planted on beds using the drilling method and later thinned to the different intra row spacings based on the required treatment. Leaf area was determined using non-destructive method developed by Pearcy *et al* (2000): Y = 0.5(L x B) where Y = Leaf area (cm^2), L= Length, B= breadth. Data was collected on number of leaves per plant. Proximate composition: percent moisture, dry matter content, crude fibre, crude protein, carbohydrate content, fat and ash content were determined using the methods of Association of Official Analytical Chemists (AOAC, 2005).

RESULTS AND DISCUSSION

Leaf development

There were no significant differences in the number of leaves between 2 and 4WAP (Fig. 1). However, at 2WAP, the number of leaves per plant was the same (6 leaves/plant). At 3WAP, plants grown at 400,000 plants/ha had about 11 leaves/ha compared to plants grown at 200,000 and 100,000 plants/ha that had 10 leaves/ plants each. At 4WAP, plants grown at 100,000 plants/ha had about 27 leaves/ha compared to plants grown at 400,000 and 200,000 plants/ha with 24 leaves/plant each (Fig. 1). The lowest population had the highest number of leaves with the highest population having the least number of leaves which is in accordance with the report of Innocent *et al*., (2015). At higher planting population competition for sunlight, moisture, nutrient and space si greatly increased which can lead to reduced number of leaves.

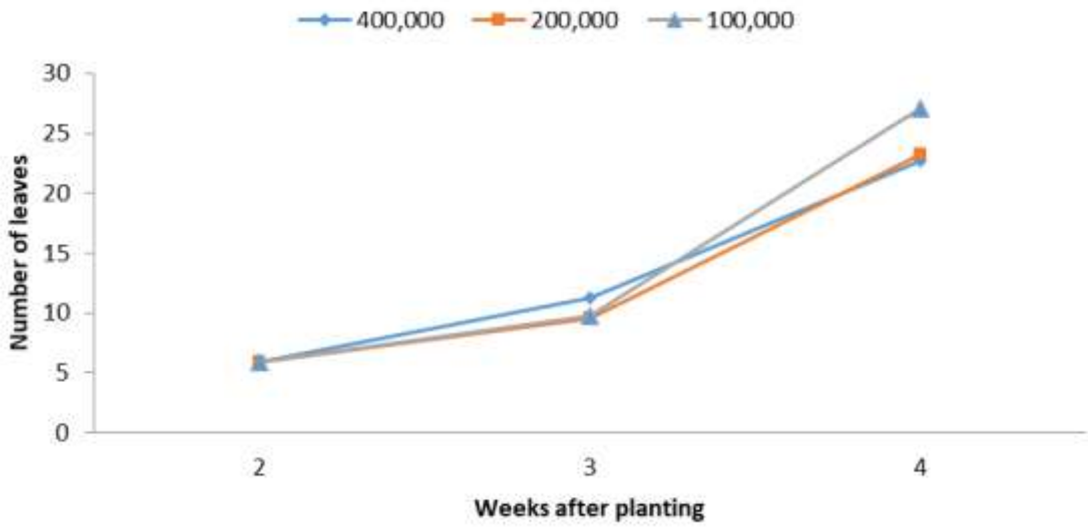

Figure 1: Effects of plant population on number of leaves of *Amaranthus cruentus*

Also, there were no significant differences in leaf area per plant between 2 and 4WAP (Fig. 2). However, at 2WAP, plants grown at 100,000 plants/ha had the widest leaves of 1.56 cm^2 compared to plants grown at 200,000 plants/ha with 1.25 cm^2 wide leaves and 400,000 plants/ha that had 1.56 cm^2 wide leaves. At 3WAP, plants grown at 400,000 plants/ha had the widest leaves of 21.50 cm^2 compared to plants grown at 200,000 plants/ha with 13.80 cm^2 wide leaves and 100,000 plants/ha that had 13.70 cm^2 wide leaves. At 4WAP, plants grown at 100,000 plants/ha had the widest leaves of 51.60cm^2 compared to plants grown at 400,000 plants/ha with 42.10cm^2 wide leaves and 200,000 plants/ha that had 43.20cm^2 wide leaves (Fig. 2). The lowest population size having larger leaves and higer population having smaller leaves is in agreement with the report of Innocent *et al*. (2015). The lowest population having larger leaves may be attributed to nutrient partitioning within the plant;

ISSN: 2814-0508

with the nutrients being used for leaf development rather than shoot development. Plants compete for necessary growth factors: sunlight, moisture and soil nutrient; the competition for these growth factors are further amplified by the increase in plant population.

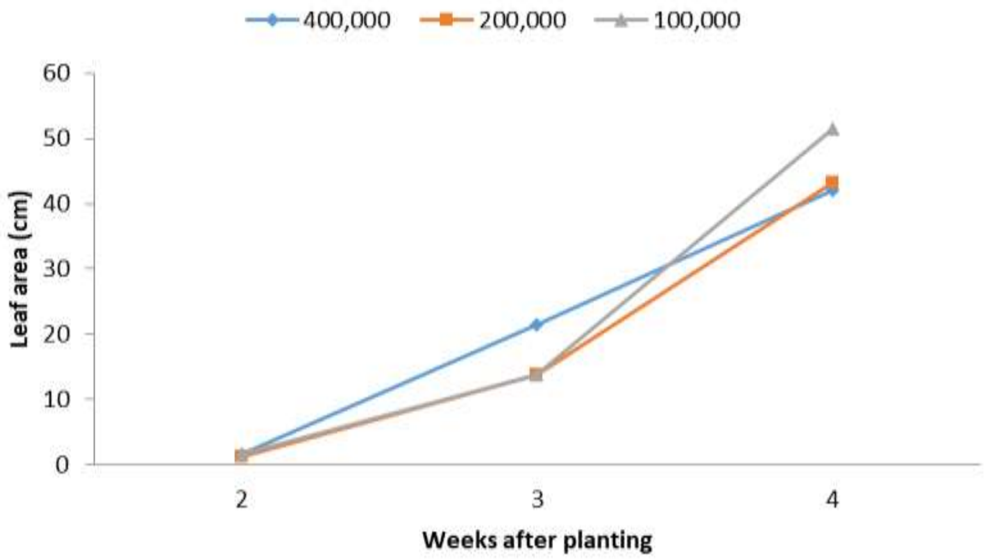

Figure 2: Effects of plant population on leaf area of *Amaranthus cruentus*

Proximate composition

Plants grown at 400,000 plants/ha had significantly higher ash content compared to plants grown at 200,000 plants/ha, but similar to those grown at 100,000 plants/ha (Table 1). The ash content indicates its high inorganic components which contain essential nutrients needed by humans (Asaolu *et al*., 2012). The treatments had no significant effects on the moisture content, fat content, crude protein and dry matter content. However, plants grown at 100,000 plants/ha had higher moisture content and fat content compared with the other plant populations. Plants grown at 200,000 plants/ha had higher dry matter content when compared with the other plant populations while plants grown at 400,000 plants/ha had higher crude fibre and crude protein when compared with the other plant populations (Table 1). Dietary fibre helps to lower cholesterol level, risk of coronary heart diseases, constipation and diabetes (Ebun-oluwa et al., 2007). The crude fat analysis shows that leafy vegetables are poor in lipids and this confirms their relevance as good diets for healthy living (Oluwole *et al*., 2019). Plants grown at 200,000 plants/ha had significantly higher carbohydrate content when compared to plants grown at 400,000 plants/ha, but similar to those grown at 100,000 plants/ha (Table 1). Carbohydrate constitutes a major class of organic compounds which are important for the maintenance of life and also provide raw materials for many industries (Sena *et al*., 1998).

Table 1: Effects of plant population on proximate composition of *Amaranthus cruentus*.

Plants/ha	Moisture	Dry matter	Ash	Fat	Crude fibre	Crude protein	CHO
	% ←						→
400,000	88.20	11.8	29.5	2.72	24.51	21.33	21.94
200,000	88.04	11.96	28.7	2.73	24.01	20.67	23.89
100,000	88.60	11.4	29.41	2.79	24.28	20.87	22.65
lsd (0.05)	NS	NS	0.45	NS	NS	NS	1.46

*NS = Not Significant

CONCLUSION

From this experiment it can be concluded that plant population up-to 400,000 plants/ha had significant positive effect on the ash, crude fibre and crude protein content of *Amaranthus cruentus* which are needed by the body for growth. Plant population of 200,000 plants/ha had significant positive effect on the carbohydrate and dry matter content of *Amaranthus cruentus* with 100,000 plants/ha being optimum for herbage yield.

ABSTRACT

Soil is the most important source and an abode for many nutrients and micro flora. Due to rapid depletion of agricultural areas and soil quality by means of ever-increasing population and an excessive addition of chemical fertilizers, an urgent attention needed to maintain sustainable approaches in agricultural crop production. Biochar is the solid, carbon-rich material obtained by pyrolysis using different biomasses. Biochar have been found in soil around the world as a result of vegetation fires and historic soil management practices and have been thought to poses long term carbon sequestration potential which help combat global warming by holding carbon in the soil. Biochar is also used primarily as a soil amendment to make soil more fertile by increasing soil organic matter, improving soil physical and chemical properties, enhancing plant nutrient availability and increasing soil microbial population and activities thus boosting higher crop yield which in turns result in food availability and preserves arable land diversity. This paper explained the role of biochar in plant nutrition and food security.

Key words: Soil, Biochar, Plant, Nutrition, Food security and Covid-19

INTRODUCTION

The world's population is expected to reach 9 billion by 2050 with the most populated continents of Asia and Africa expected to have a more significant surge in population than other continents ofthe the world (Godfray *et al*., 2010), it will require an increase of 50% in agricultural supply to meet the growing demand (Mueller *et al*., 2012; FAO 2013a; Paul *et al*. 2009; FAO 2009). Agriculture constitutes the backbone of most developing economies. It is the largest contributor to gross domestic product (GDP) the biggest source of foreign exchange, accounting for about 40% of the continent's foreign currency earnings, and the main generator of savings and tax revenues. In addition, about two-thirds of manufacturing value added tax is based on agricultural raw materials. Agriculture remains crucial for pro-poor economic growth in most African countries particularly Nigeria, as rural areas support 70-80 % of total population. More than in any other sector, improvements in agricultural performance have the potential to increase rural incomes and purchasing power for large numbers of people to lift them out of poverty (NEPAD, 2002; Wiggins, 2006). Agriculture is important for food security in two ways: it produces the food people eat and perhaps even more important it provides the primary source of livelihood for 36 % of the world's total workforce. In densely populated countries of Asia and Pacific region, this share ranges from 40-50 % and in sub-Saharan Africa, two-thirds of the working population still make their living from agriculture (ILO, 2007). If crop production in the low-income developing countries of Asia and Africa is adversely affected by climate change, lack of quality inputs such as fertilizers, seeds, herbicides, insecticides and insufficient technical knowledge on best crop production practices by rural farmers in these countries, where the livelihoods of a large numbers of the rural poor will be put at risk and their vulnerability to food insecurity increased. Generally crop growth and development are strongly influenced by various biotic and abiotic stresses such as pest, weeds, drought, high salinity, extreme temperature and soil quality(Thalmann *et al*.2017).Soil is also contaminated by heavy metals through various human activities (Moon *et al*. 2013), such as mining and mineral exploration which negatively affects plant growth and development and ultimately brings low yielding cropping systems(Al-Farraj 2013 and Noman *et al*.2017).The strength of soil is directly related to nutrient availability. Plants require a number of soil nutrients like nitrogen (N), phosphorus (P), and potassium (K) for their growth, but soil nutrient levels may decrease over time after crop harvesting, as nutrients are not returned to the soil. In most developing countries, the soil is not only deficient in micronutrients like NPK but also in secondary nutrients (example sulfur, calcium, and magnesium) and micronutrients (e.g. boron, zinc, copper, and iron),(Pathak *et al*.2010).Thus, to fulfill the shortage, a large amount of chemical fertilizers is added to the soil; however, only a small percent of water soluble nutrients are taken up by the plants and the rest are converted into insoluble forms, making continuous application necessary. The extensive use of chemical fertilizers has led to the deterioration of the environment causing infinite problems. It lowers the nutrient composition of the crops and also degrades the soil fertility in the long run (Harriprasad *et al*.2013 and Yargholi *et al*. 2014).

Besides fertilizers, pesticides are also the basic evil for agriculture, and the adverse effects of pesticides on the environment are truly responsible for influencing the microbial properties of soil. High inputs of fertilizers and pesticides and their long persistence in the soil adversely affect the soil microflora, thereby disturbing soil health and significantly reducing the total bacterial and fungal biomass (Prashar *et al*.2016). Due to long-term treatment with inorganic fertilizers (N and NPK) and/or organic manures, a shift in structural diversity and dominant bacterial groups in agricultural soils has been recorded by (Wu *et al*.2012). Biofertilizers, on the other hand, can reenergize the soil by improving the soil fertility and hence can be used as a powerful tool for sustainable agriculture, rendering agro-ecosystems more stress-free. Additionally, the application of organic amendments to soils, from a remedial point of view, has typically been justified by their relatively low cost, which normally requires other forms of disposal (burial in a landfill, incineration, etc.). Soil amendments must possess properties such as high binding capacity and environmental safety and should have no negative effect on the soil structure, soil fertility, or the ecosystem on the whole (Paz-Ferreiro *et al*., 2013). The use of biochar has been accepted as a sustainable approach and a promising way to improve soil quality and remove heavy-metal pollutants from the soil (Lahori *et al*., 2017). Biochar is a carbon-rich organic material, an organic amendment, and a by-product derived from biomass by pyrolysis under high-temperature and low-oxygen conditions. Biochar is produced through a process called pyrolysis, which basically involves heating of biomass (such as wood, manure, or leaves) in complete or almost complete absence of oxygen, with oil and gas as co-products. However, the quantity of these materials produced depends on the processing conditions. Recently, it has been reported that biochar obtained from the carbonization of organic wastes can be a substitute that not only influences the sequestration of soil carbon but also modifies its physicochemical and biological properties (Garcia *et al*. 2016 and Zhang *et al*.,2017). Biochar has the potential to produce farm-based renewable energy in an eco-friendly way. Specifically, the quality of biochar depends on several factors, such as the type of soil, metal, and the raw material used for carbonization, the pyrolysis conditions, and the amount of biochar applied to the soil (Dabela *et al*., 2012). In addition, the biochar amendment to the soil proved to be beneficial to improve soil quality and retain nutrients, thereby enhancing plant growth (Bananoni *et al*., 2017). Since biochar contains organic matter and nutrients, its addition increased soil pH, electric conductivity (EC), organic carbon (C), total nitrogen (TN), available phosphorus (P), and the cation-exchange capacity (CEC) (Dume *et al*.2016). Earlier, Verheijen *et al*. (2009) reported that the biochar application affected the toxicity, transport, and fate of various heavy metals in the soil due to improved soil absorption capacity. The presence of plant nutrients and ash in the biochar and its large surface area, porous nature, and the ability to act as a medium for microorganisms have been identified as the main reasons for the improvement in soil properties and increase in the absorption of nutrients by plants in soils treated with biochar (Nigusse *et al.,* 2012). Chan *et al*. (2008) reported that biochar application decreased the tensile strength of soil cores, indicating that the use of biochar can reduce the risk of soil compaction. A lot has already been discussed on the benefits of inoculation of rhizobacteria in soil, but the addition of biochar can also provide more nutrients to the soil, thus benefiting the agricultural crops. The mixing of the plant growth-promoting microorganisms with biochar was referred to as the best combination for growth and yield of French beans by Saxena *et al*. (2013). Addition of biochar in the soil can be extremely useful to improve the soil quality, as well as to stimulate the plant growth, and thus, biochar can play an important role in developing a sustainable system of agriculture. Several uses and positive effects of biochar amendment have currently been considered as an effective method to reclaim the contaminated soil (Placek *et al.,* 2016), and to achieve high crop yields without harming the natural environment. The positive influence of biochar on plant growth and soil quality suggests that using biochar is a good way to overcome nutrient deficiency, making it a suitable technique to improve farm-scale nutrient cycles. Therefore, a complete focus is being made to explore the positive effects of biochar amendment on plant nutrition and promotion of food security.

Covid-19 was caused by the virus SARS-CoV-2 which was first identified in Wuhan, Hubei province, China in December 2019 (WHO 2020). As of July 6 2020 more than 11 million cases were recorded with 537,419 death related to covid-19 have been reported in 213 countries (Hopkins, 2020). In Africa, over 470,000 cases have recorded with more than 29,000 cases from Nigeria (Hopkins, 2020). The virus is typically spread from one person to another via respiratory droplets and contact with contaminated surfaces (Guan *et al*., 2020). Covid-19 has led to unprecedented local and global public health measures, such as obligatory movement restrictions, social and physical distancing and prolonged closures of schools and leisure centers among others

Food Security

The 1996 World Food Summit defined food security as "a situation that exists when all people, at all times, have physical, social and economic access to sufficient, safe and nutritious foods that meets their dietary needs and food preferences for a healthy life." (Barrett, 2010) This definition incorporates several needs: availability of food, access to food, and for the food to be culturally appropriate. There are many factors in today's global environment that exacerbate food security. It is true, we live in an age where we are growing and producing more food than ever before. We have enough food to feed the world's population, but it is not distributed properly nor is all food culturally appropriate across the globe. Local food access differs dramatically and the greatest difference exists between developed and developing countries (Havas *et al*., 2011). The primary reason for this inequity is an income-related difference between these populations (Hazell and Wood, 2008). It must be stated though, that in every country of the world there is hunger, and this often falls along economic and social lines. The underprivileged – be it individuals or countries –often have less. There are three areas of global concern that impact food security: overpopulation, climate change and urbanisation. Areas of the world with the highest birth rates and population such as the developing countries, where demand often exceeds supply, also have the greatest levels of hunger and disease. Local ecosystems provide the resources a population needs for food production, health, environmental management and water. Examples include rangeland, fertile soil, nutrient cycling, and wildlife for hunting, among others. The local ecosystem has a certain carrying capacity, and once this is exceeded the ecosystem becomes stressed and begins to break down. This is defined as ecosystem vulnerability (Ericksen, 2008). The results can include over-farmed soils, denuded grazing lands and dried up or contaminated wells, all of which contribute to an underfed population.

Biochar Production

The ancient method for producing biochar as a soil additive was the "pit or trench" method which created terra preta, or dark soil while this method is still a potential to produce biochar in rural areas, it does not allow the harvest of either the bio-oil or syngas and release a large amount of Carbondioxide, black carbon and other Green house gases (GHGs) into the air (Laird, 2008). Biochar production processes can utilize most urban agricultural or forestry biomass residues such as wood chips, corn Stover, rice or peanut hulls, tree bark, paper mill sludge, animal manure, and recycled organics. In modern times Biochar can be manufactured on a small scale using low-cost modified stoves or kilns or through large-scale, cost-intensive production, which utilizes larger pyrolysis plants and higher amounts of feedstocks. Biochar is produced from several biomass feedstocks through pyrolysis a thermal decomposition of biomass in an oxygen-limited environment, generating oil and gases as by-products (Zhu *et al*., 2018). The dry waste obtained is simply cut into small pieces to less than 3 cm prior to use. The feedstock is heated either without oxygen or with little oxygen at the temperatures of 350–700°C (662–1292°F). Pyrolysis is generally classified by the temperature and time duration for heating; fast pyrolysis takes place at temperatures above 500°C and typically happens on the order of seconds (heating rates ≥ 1000°C/min). This condition maximizes the generation of bio-oil. Slow pyrolysis, on the other hand, usually takes more time, from 30 min to a few hours for the feedstock to fully pyrolyze (heating rates ≤ 100°C/min) and at the same time yields more biochar. The

ISSN: 2814-0508

temperature range remains at 250–500°C (Brown *et al*., 2011).

The type of biochar produced depends on two variables: the biomass being used and the temperature and rate of heating. High and low temperatures have an unequivocal effect on char yields. It has been noticed that at low temperature (<550°C), biochar has an amorphous carbon structure with a lower aromaticity than the biochar produced at high temperature (Joseph *et al*., 2010). High temperature leads to lower char yield in all pyrolysis reactions (Antal *et al*., 2003). Peng *et al*. (2011) reported the effect of charring duration on the yield of biochar; yield showing a decrease with increasing duration at the same temperature. The pyrolysis process seriously affects the quality of biochar and its potential value to agriculture in terms of agronomic performance or in carbon sequestration. The yield of biochar from slow pyrolysis of biomass has been stated to be in the range of 24–77% (Dutta, 2010 and Stoyle, 2011). The pyrolysis process can be shown as follows:

Biomass (Solid) → Biochar + Liquid or oil (tars, water, etc.) + Volatile gases (CO2, CO, H 2)

Biochar Properties

Biochar is a stable form of carbon and can last for thousands of years in the soil (Shenbagavali and Mahimairaja 2012). It is produced for the purpose of addition to soil as a means of sequestering carbon and improving soil quality. The conditions of pyrolysis and the materials used can significantly affect the properties of biochar. The physical properties of biochar contribute to its function as a tool for managing the environment. It has been reported that when biochar is used as a soil amendment, it stimulates soil fertility and improves soil quality by increasing soil pH, increasing the ability to retain moisture, attracting more useful fungi and other microbes, improving the ability of cation exchange, and preserving the nutrients in the soil (Ajema, 2018). Biochar reduces soil density and soil hardening, increases soil aeration and cation-exchange capacity, and changes the soil structure and consistency through the changes in physical and chemical properties. It also helps to reclaim degraded soils. It has shown a greater ability to adsorb cations per unit carbon as compared to other soil organic matters because of its greater surface area, negative surface charge, and charge density (Liang *et al.,* 2006), thereby offering the possibility of improving yields (Lehmann, 2007). The physical characteristics of biochar are directly and indirectly related to how they affect soil systems. Soils have their own physical properties depending on the nature of mineral and organic matter, their relative amounts, and how minerals and organic matter are related. When biochar is present in the soil mixture, its contribution to the physical nature of the system is significant, affecting the depth, texture, structure, porosity, and consistency by changing the surface area, pore and particle-size distribution, density, and packing (Blanco-Canqui, 2017). The influence of biochar on physical properties of soil directly affects the growth of plants, since the depth of penetration and accessibility of air and water in the root zone is determined mainly by the physical composition of the soil horizons. This affects the soil's response to water, its aggregation, and work ability in soil preparation, dynamics, and permeability when swelling, as well as the ability to retain cations and response to changes at ambient temperature. The smaller the pores on biochar, the longer they can retain capillary soil water. The addition of biochar can reduce the effects of drought on crop productivity in drought-affected areas due to its moisture-retention capacity (Jiyoti Rawat *et al*., 2019). Most research findings on the effect of biochar on soil physical properties point to the improvement of soil bulk density with biochar application (Karhu *et al.,* 2011, Haryani and Gunito 2012, Masulili *et al.,* 2010); water-holding capacity also increased (Karhu *et al.,* 2011). Biochar has high porosity, which allows high water-holding capacity. However, it is hydrophobic as it is dry due to its high porosity and light bulk density. Adding biochar to the soil also improves soil physical property, water permeability, and aggregate stability. Peng *et al*. (2011) reported that, compared with chemical fertilizer application, biochar amendment to a typical Ultisol resulted in better crop growth.

As far as its chemical properties are concerned, biochar reduces soil acidity by increasing the pH (also called the liming effect) and helps the soil to retain nutrients and fertilizers (Lehmann, 2006). The application of biochar improves soil fertility through two mechanisms: adding nutrients to the soil (such as K, to a limited extent P, and many micronutrients) or retaining nutrients from other sources, including nutrients from the soil itself. However, the main advantage is to retain nutrients from other sources. In most cases, the addition of biochar only has a net positive effect on the growth of crops if nutrients from other sources, such as inorganic or organic fertilizers, are used. Biochar increases the availability of C, N, Ca, Mg, K, and P to plants, because biochar absorbs and slowly releases fertilizers (Deluca *et al*. 2015). It also helps to prevent fertilizer drainage and leaching by allowing less fertilizer use and reducing agricultural pollution in the surrounding environment (Cao *et al*.2018). Biochar alleviates the impact of hazardous pesticides and complex nitrogen fertilizers from the soil, thus reducing the impact on the local environment. Good healthy soil should include a wide and balanced variety of life forms, including bacteria, fungi, protozoa, nematodes, arthropods, and earthworms. Recently, biochar has been reported to increase the microbial respiration of the soil by creating space for soil microbes (Slapakova *et al*.2018), and in turn the soil biodiversity and soil density increased.

Benefits of applying Biochar to the Soil

The amendment of soils for their remediation aims at reducing the risk of pollutant transfer to waters or receptor organisms in proximity. The organic material such as biochar may serve as a popular choice for this purpose because its source is biological and it may be directly applied to soils with little pretreatment (Beesley *et al*.2011). There are two aspects which make biochar amendment superior to other organic materials: the first is the high stability against decay, so that it can remain in soil for longer times providing long-term benefits to soil and the second is having more capability to retain the nutrients. Biochar amendment improves soil quality by increasing soil pH, moisture-holding capacity, cation-exchange capacity, and microbial flora (Mensah and Frimpong, 2018).

The addition of biochar to the soil has shown the increase in availability of basic cations as well as in concentrations of phosphorus and total nitrogen (Glaser *et al*., 2002 and Lehmann *et al*., 2003). Typically, alkaline pH and mineral constituents of biochar (ash content, including N, P, K, and trace elements) can provide important agronomic benefits to many soils, at least in the short to medium term. When biochar with a higher pH value was applied to the soil, the amended soil generally became less acidic (Yaun *et al*., 2011). Acidic biochar could also increase soil pH when used in soil with a lower pH value. The pH of biochar, similar to the other properties, is influenced by the type of feedstock, production temperature, and production duration. Another valuable property of biochar is suppression of emissions of greenhouse gases in soil. Spokas *et al*.(2009) reported reduced carbon dioxide production by addition of different concentrations of biochar ranging from 2 to 60% (w/w), suppressed nitrous oxide production at levels higher than 20% (w/w), and ambient methane oxidation at all levels over unamended soil.Bonanomi et al.(2015) reported that biochar is effective against both air-borne (e.g. Botrytis cinerea and different species of powdery mildew) and soilborne pathogens (e.g. *Rhizoctonia solani* and species of *Fusarium* and *Phytophthora*). The application of the biochar derived from citrus wood was capable of controlling air-borne gray mold, *Botrytis cinerea* on *Lycopersicon esculentum*, *Capsicum annuum* and *Fragaria ananassa*. Although there is a shortage of published data on the effects of biochar on soil-borne pathogens, evidence given by Elmer et al. (2010) has shown that the control of certain pathogens may be possible. The addition of biochar in 0.32, 1.60, and 3.20% (w/w) to asparagus soils infested with Fusarium has augmented the biomass of asparagus plants and reduced Fusarium root rot disease (Elmer *et al*.2010). Similarly, Fusarium root rot disease in asparagus was also reduced by biochar inoculated with mycorrhizal fungi (Thies and Riling, 2009). The application of biochar to soil can influence a wide range of soil constraints such as high availability of Al, soil structure and nutrient availability, bioavailability of organic and inorganic pollutants, cation-exchange capacity (CEC), and retention of nutrients. Biochar can also adsorb pesticides, nutrients, and minerals in the soil, preventing the movement of these chemicals into surface water or groundwater and the subsequent degradation of these waters from agricultural activity.

The consequence of biochar addition on plant productivity depends on the amount added. Recommended application rates for any soil amendment should be based on extensive field testing. At present, insufficient data are available for obtaining general recommendations. In addition, biochar materials can vary greatly in their characteristics, so the nature of the particular biochar material (e.g. pH and ash content) also influences the application rate. Several studies have reported a positive effect of using biochar on crop yields with rates of 5–50 tonnes per hectare with appropriate nutrient management (Jyoti *et al*., 2019).

The experiments conducted by Rondon *et al*. (2007) resulted in a decrease in crop yield in a pot experiment with nutrient deficient soil amended with biochar at the rate of 165 tonnes per hectare. An experiment conducted in the United States showed that peanut hull and pine chip biochar, applied to 11 and 22 tonnes per hectare, could reduce corn yields below those obtained in the control plots with standard fertilizer management (Gaskin *et al*., 2010). Thus, the control of the rate of application of biochar is necessary to prevent the negative impact of biochar.

The Combination of Biochar with other Soil Amendments

The combination of biochar with other soil amendments such as manure, compost, or lime before soil application can improve efficiency by reducing the number of field operations required. Since biochar has been shown to sorb nutrients and protect them from leaching (Major *et al*., 2010 and Novak *et al*., 2009), mixing of biochar may improve the efficiency of manure and other amendments. However, Kammann *et al*. (2016) acknowledged in their recent review that very few studies that directly combined organic amendments with biochars were available. They found that co-composted biochars had a remarkable plant growth-promoting effect as compared to biochars when used pure, but no-systematic studies have been done to understand the interactive effects of biochars with non-pyrogenic organic amendments (NPOAs). Biochar can also be mixed with liquid manures and used as slurry. Additionally, combined biochar and compost applications have numerous advantages over mixing of biochar or compost with soil separately. These benefits, according to Liu *et al*. (2012), include more efficient use of nutrients, biological activation of biochar, an enhanced supply of plant-available nutrients by biological nitrogen fixation, reduction of nutrient leaching, and the contribution of combined nutrients in comparison to a single application of compost and biochar. Rubab *et al*. (2017) reported in their study that addition of biochar could decrease the use of Inorganic fertilizers by improving the quality and yield of crops because in their findings they reported that biochar at the rate of 1% and Nitrogen at the rate of 50% provided an optimum output minimizing the economic cost of production. Application of organic fertilizers and biochar showed significantly higher N absorption than sole urea application. Frequent application of organic fertilizers and biochar resulted in significantly higher N absorption than one-time application of organic fertilizers (Widowati *et al*., 2012).

Effects of Biochar on Plant growth, Nutrition and Food security

Several reports have shown that biochar has the capability to stimulate the soil microflora, which results in greater accumulation of carbon in soil. Besides adsorbing organic substances, nutrients, and gases, biochars are likely to offer a habitat for bacteria, actinomycetes and fungi (Thies and Riling, 2009). It has been suggested that faster heating of biomass (fast pyrolysis) will lead to the formation of biochar with fewer microorganisms, smaller pore size, and more liquid and gas components (Nartey et al.2014). The enhancement of water retention after biochar application in soil has been well established (Busscher *et al*., 2010), and this may affect the soil microbial populations. Biochar provides a suitable habitat for a large and diverse group of soil microorganisms, although the interaction of biochar with soil microorganisms is a complex phenomenon. Many studies reported that addition of biochar along with phosphate solubilizing fungal strains promoted growth and yield of Vigna radiata and Glycine max plants, with better performances than control or those observed when the strains and biochar are used separately [Saxena 2013, Saxena 2016 and Saxena *et al*., 2017).

The use of biochar increased mycorrhizal growth in clover bioassay plants by providing the suitable conditions for colonization of plant roots (Solaiman *et al*.2010). Warnock *et al*. (2007) summarized four mechanisms by which biochar can affect functioning of mycorrhizal fungi: (i) changes in the physical and chemical properties of soil, (ii) indirect effects on mycorrhizae through exposure to other soil microbes, (iii) plantfungus signaling interference and detoxification of toxic chemicals on biochar, and (iv) providing shelter from mushroom browsers.It was found that biochar increased the biological N2 fixation (BNF) of Phaseolus vulgaris (Rondon *et al*.2007) mainly due to greater availability of micronutrients after application of biochar. Lehmann *et al*. (2003) reported that biochar reduced leaching of NH4+ by supporting it in the surface soil where it was available for plant uptake. The direct beneficial effects of biochar addition for the availability of nutrients are largely due to the higher content of potassium, phosphorus, and zinc availability and, to a lesser extent, calcium and copper (Lehmann *et al*., 2003). Field and green house research have confirmed the safety and practicability of recycling biochar on arable land in sub Saharan Africa. It has shown that biochar has a lining effect of between 80 and 90 % of the total neutralizing power of lime and can increase plant growth up to 45%. Most soils in Africa are infertile due to acidity and low inorganic matter, therefore continuous cultivation requires many soil additives to correct these deficiencies and the fact that additions such as nitrogen fertilizer often increase the soil pH makes the addition of neutralizing agents such as biochar a necessity on most infertile soils. Biochar has added advantage of being able to replace many of the macro and micro nutrients removed during plant growth and harvest. A number of studies have shown that biochar can increase soil pH, cation exchange capacity (CEC), total N, available P, exchangeable Ca, magnesium, etc. and can reduce Al availability.

Widowati *et al* (2012) reported that biochar application decreased N fertilizer requirement. They also found that organic carbon was increased by biochar application. Similar results were seen with different types of biochar and soil in various regions (Rondon *et al* 2007, Novak *et al* 2009, Cui *et al* 2011, Masulili *et al* 2010, Laird *et al* 2010). The increase in soil carbon through biochar application is attributed to the stability of biochar in the soil, which persists despite microbial action. Sukartono *et al*. (2011) reported that application of biochar improved soil fertility status, especially soil organic C, CEC, available P, exchangeable K, Ca, and Mg of the sandy soils in Lombok, Indonesia. Since biochar is highly porous and has a large specific surface area, its impact on soil CEC and other nutrient that have correlation with CEC is very important. Besides the direct/indirect effect of biochar on soil fertility characteristics, application of biochar contributes to the interaction of soil with microelements such as lead and cadmium. Jiang *et al*. (2012) reported that incorporation of biochar increased Pb(II) adsorption by variably charged soils. Biochar amendment significantly decreased extracted Cd in the soil by 17-47%. Some types of biochar also appear to reduce the mobility of heavy metals such as Cu and Zn (Hua *et al.,* 2009). Novak *et al*. (2009) reported that most soil micronutrient concentrations were not influenced by biochar addition; however, biochar application decreased exchangeable acidity, S, and Zn. Application of organic manure and biochar significantly affected the soil's total N content after harvest. The use of organic fertilizer and biochar increased soil organic matter content and cation exchange capacity which increases the negative charge that contributes to greater absorption of the released nutrients (N urea). These conditions exist as biochar is better at storing nutrient N than organic fertilizers.

Yield was higher when maize was grown on biochar-treated soils. With biochar application, yields obtained with fertilization rates between 90 and 180 kg N ha-1 were similar to each other; less N was used to obtain the same level of yield, which was achieved at maximum dosage. Unused N at maximum dosage was absorbed into the soil because of biochar. The results imply that biochar can play a role in lowering N dosage for maize production (Wani Hadi Utomo and Titiek Islami, 2013). Biochar can increase the value of non-harvested agricultural products (Major *et al*.2005) and promote the plant growth (Lehmann 2003, and Oguntunde *et al*.2004). A single application of 20 t ha^{-1} biochar to a Colombian savanna soil resulted in an increase in maize yield by 28–140% as compared with the unamended control in the 2nd to 4th years after application (Major *et al*. 2010). With the addition of biochar at the rate of 90 g kg^{-1} to tropical, low-fertile ferralsol, not only the proportion of N fixed by bean plants (Phaseolus vulgaris) increased from 50% (without biochar) to 72%, but also the production of biomass and bean yield were improved significantly (Shenbagavalli and Mahimairaja, 2012). When biochar was applied to the soil, a higher grain yield of upland rice (Oryza sativa) was obtained in northern Laos sites with low P availability (Asai *et al*., 2009 and Silber *et al*., 2010). Palansooriya *et al*., (2019) reported that yield of various upland crops which are usually a stable food for most developing countries can be enhanced by biochar-induced increases of nutrients availability and top soil retention/recovery. They went to report that biochar can assist in controlling unsuitable soil acidity, alkalinity, salinity and remediating a contaminated soil while increasing the retention of soil organic carbon, water content and higher crop yield.

Chan *et al.* (2008) reported that increased crop yield is largely attributed to the ability of the biochar to increase N availability. N levels, which were high after the first season, can increase the absorption and efficiency of fertilizer N in the second season (biochar manure and organic waste biochar). The high soil N levels in the second season can increase the absorption and efficiency of fertilizer N in the third season (organic waste biochar). Up to the third season, the soil N level of biochar is still higher than that of organic fertilizers. Biochar application combined with chicken manure could improve some properties of peat and acid sulfate soils. In peat soil, application of biochar (6.25 t ha^{-1}) and chicken manure (1.25 t ha^{-1}) increased soil pH and available soil K. In acid sulfate soil, biochar (5 t ha^{-1}) + chicken manure (0.5 t ha^{-1}) increased soil pH and available soil P and also decreased soluble Fe and iron toxicity symptoms of the rice plant. Improvement of soil properties resulted in an increase of rice growth and yield in swamplands of Indonesia (Nursyams *et al*. 2013). Based on a Soil Research Institute study in Indonesia, the addition of biochar from cocoa skin to maize and padi gogo (as much as 2.5 and 5 t ha^{-1}, respectively) increased yield by 281% (from 0.37 to 1.41 t dried corn grain ha^{-1}) and 150% (from 0.4 to 1 t dry milled rice ha^{-1} (Nurida, 2012).

CONCLUSION

Plant nutrition-based research activities are indispensable in meeting food security needs in the 21st century. The fact that at least 60% of the presently cultivated soils globally have several mineral problems, like toxicities of Al, Mn and Na, and deficiencies ofN, P, K, S, Fe and Zn, makes plant nutrition-based research a major promising research area needed to meet the demand for massive increases in food production required for the growing world population. One of the high priority objectives of plant-nutrition research will be ensuring a long-term sustainable nutrient management system for crop production, and developing more efficient mineral nutrient uptake by crop plants and improving intra and intercellular use of nutrients without detrimentally affecting the environment through the use organic fertilizers such as biochar .Creation of asynergy between plant nutrition and sustainable organic agricultural practices is required to assure a rapid progress towards alleviating food insecurity issues in developing countries this 21st century. Literatures reviewed in this article showed that biochar has high potential in improving soil physical, chemical and biological properties. In an agroindustrial land of most developing countries where most of people work as farmers, there are sufficient amounts and kinds of biomass materials for biochar production. The application of biochar to agricultural land seems suitable. This necessitates further studies to ensure the wide use of this important resource (biochar) by farmers in developing countries to produce quality and healthy food for its populace.

ABSTRACT

The research studied the effect of sowing dates on two sesame (Sesamum indicum L.) varieties in Jigawa North East Zone, conducted in two different seasons 2019 and 2020 both at Binyaminu Usman Polytechnic Hadejia Teaching and Research Farm during 2019 and 2020 raining season. The treatments consisted of two varieties (E8 and Ex-Sudan) and three sowing dates (early July, mid-July and late July). A randomized complete block design (R C B D) with three replications was used. The results showed that in 2019, sesame varieties recorded significant variation; Ex-Sudan produced highest mean values for growth and yield parameters than E8. While early July sowing date recorded significantly higher growth and yield parameters. In 2020, Variety Ex-Sudan produced the highest mean values than E8 for all parameters. Early July sowing resulted in significantly higher growth and yield parameters of the two varieties. Significant interaction was also observed between variety and sowing date in both seasons. It is recommended that farmers at Jigawa North East should adopt Ex-Sudan as their sowing material, early July sowing date is suggested for increasing sesame production in the study area.

INTRODUCTION

Sesame (*Sesamum indicum* L.) belongs to the plant family Pedaliacea and is commonly called beniseed in Nigeria. It is an important oilseed crop believed to have originated from tropical Africa, where there is the greatest genetic diversity. It was later taken at a very early date to India where a secondary centre of diversity was developed (Purseglove., 1996; Nwalem., 2015). The four major states that produce this commodity in Nigeria are Taraba, Jigawa, Nasarawa and Benue. Nigeria is the largest producer of sesame seeds in Africa, and the third largest in the world, with about 580,000 tonnes produced in 2017 (FOA., 2018).

Sesame seeds (approximately 50 percent oil and 25 percent protein) are used in baking, candy making, in cooking and salad oil and margarine. The oil can also be used in manufacture of soaps, paints, perfumes, insecticides and pharmaceuticals. Sesame meal, left after the oil is pressed from the seed, is an excellent high protein (34-50 percent) feed for poultry and livestock (Oplinger*et al.,* 2007; Nwalem., 2015). As a raw export commodity, sesame seed from Nigeria is enjoying a rising profile in the world market where overall global demand has risen to 3.3 million tons. Sesame, like other raw agricultural communities, has over 15% margin in terms of value added products compared to other crops (RMRDC, 2004; Nwalem, 2015).

BOTANICAL DISCRIPTION

Sesame is an annual herb that can grow to heights of 0.3m to 2. 2m (Kafriti and Decker. 2002). The flower is about 3 to 4 cm long, auxiliary with one flower and two exra-floral necteries per leaf axil (Robert, 2002). Some varieties are highly branched, while others are not and they tend to be variable in number depending on the environmental factors. (Alegbejo *et al.*, 2012; Down *et al.*, 2012; Olinger, 1990). The capsules are oblong, 2 to 5 cm long, containing wingless 1.5 to 4 mm long seed with white, yellow, grey, light brown, red brown or black testa with a smooth or reticulate surface (Kafiriti and Decker, 2002). The petiole is about 1.0 to 1.5 cm long (Down *et al.*, 2012). Oplinger *et al.* (1990) observed that the fruits are deeply grooved capsule 3.5 cm in length and contain between 50 to 100 or more seeds. The number of capsule per plant depends on variety and environmental condition. The seed is very small, light in weight (1000 grain weighing 2 to 4 g) and can be white, grey, brown, chocolate or black in colour. Sesame matures in 90-120 days when the plants drop their leaves and the stems and seed capsules turn yellow-brown. This is the time to harvest the plants and dry them in the sun in a sack. As the sun bakes the capsules, they pop open and release their seeds. Threshing the capsules inside a sack gets most of the seeds from the capsules. Finally, the chaff is winnowed from the seeds, and they're ready to be stored.

MATERIALS AND METHODS

The experiment was conducted during 2019 and 2020 rainy season at Teaching and Research Farm of Binyaminu Usman Polytechnic Hadejia, situated at latitude 12^0 27'N and 12 24" N and 7^0 46'E and 10 E and 400 meters' elevation above sea level. The treatment consisted of three sowing dates (early July, mid-July and late July), and two varieties of sesame (E8 and Ex-Sudan). E8 is an early maturing variety and is ready for harvesting within 90 days after sowing. The seed is light brown in colour and seed size is about 3.6mm. Ex-Sudan is a relatively older variety than E8 and originated from Sudan. The seed is white in colour and late maturing variety about (120 days). The treatments were combined and laid out in a Randomized Complete Block Design (RCBD) replicated three (3) times. The mean annual temperature is between 27^{0}C to 30.6^{0}C and soil type is sandy – loam. Composite soil sample from the experimental field was collected at random using soil auger at 0-30cm depths. The soil samples were air dried, sieved and analyzed for physical and chemical properties (pH, Texture, Organic Carbon, Cation Exchange Capacity and Available Phosphorus as described by Black (1965). Information about rainfall maximum and minimum temperature, relative humidity wind speed and sunshine hours of the growing seasons was obtained from metrological station of the Department of General Studies Binyaminu Usman Polytechnic Hadejia Jigawa State. The Data was subjected to Analysis of Variance (ANOVA) as described by Snedecor and Cochran (1967) using SAS. Significant treatment means were separated at 5% level of probability using SNK. Simple and partial correlation studies were also carried out to determine the relationships between various parameters and yield as well as the contributions of the different parameters studied to the grain yield. Plot size was 3m x 2m (6m^2), An alley of 0.5m and 1m was left between plots and replicates, respectively. The land was ploughed and harrowed, to obtain a fine tilt. Ridges 40cm high and 75cm inter row was erected and marked out into replications and plots according to the experimental design. Sesame seed were sown according to the treatments; Early July sowing was done on 1st of July, Mid July sowing was carried on 15th of July and the late July sowing was conducted on 29th of July both at 2019 and 2020 raining season respectably at the experimental sites using 7.0 kg seed rate /ha. The fertilizer was applied using side placement method. Each plot was given N.P.K. 15: 15: 15: fertilizer at the rate of 60: 30: 30 kg ha^1. A based application of the fertilizer at the rate of (30:30:30) kg ha was applied at 3WAS and Urea (45%N) was used to supply the remaining 30 kg N ha^1 at 6 WAS. Weed control was done manually using hoe and hand picking at 3, 6, and 9 WAS. Major pests of sesame are weevil, termites, leaf-feeding caterpillars and rats while its main diseases are Mycoplasma (little leaf disease) and Soil-borne fungal diseases. But no major pest and diseases were encountered during the period of this experimental research. Data were collected from the following characters from the five tagged plants at 6, 8, and 10 WAS the mean values were recorded Plant height, Number of branches per plants, Fresh weight per plant (g), Plant dry weight, Leaf area, and number of capsules per plant at maturity were determined by counting all the capsules of five tagged plants from each plots and the mean values were recorded, Days from sowing to 50% flowering in each plot were noted and recorded, Days from sowing to maturity were noted from each plot and recorded, 1000 seeds of sesame were counted and weighted from each plot and the mean value was recorded, Seed yield per plot within the net plot were harvested and allowed to sundry for two weeks, and was kept in bags upside down in order to avoid seed loss when the capsule open. It was later threshed and weighed and the means values were recorded for each plot, Seed yield per hectare (kgha^1), Harvested plants from the net plot was threshed and add to gross plot to obtain yield per hectare.

RESULTS

The effect of sowing date on plant height at 6, 8 and 10WAS in 2019 and 2020 is presented in table 1. In 2019 the result show that there is no significant effect at 6 and 10WAS for both varieties while at 8WAS Ex-Sudan had significantly higher than E8 per plant while in 2020 E8 variety at 6 and 10WAS is significantly higher than Ex-Sudan and no significant difference at 8WAS in plant height. The table also shows that sowing date had significant effect on plant height both seasons; in 2019, late July produced significantly higher plant height at 6WAS, higher than Mid July while Early July produce significantly shorter plants. At 8WAS however, seeds planted early July produced significantly shorter plants, while the rest of the sowing dates produced significantly higher and similar plant heights. At 10WAS, Mid July sowing produced significantly taller plants then the rest of the sowing dates. Meanwhile, in 2020 raining season considering early and mid-July at 6WAS produced higher plant heights, mid-July at 8WAS and early July at 10WAS. However late sowing date produced significantly shorter plants at 6, 8 and 10WAS.

Days to 50% flowering and Days to Maturity of sesame varieties.

The effect of sowing date on days to 50% flowering and days to maturity of two sesame varieties in 2019 and 2020 raining season is presented in Table 2. In 2019 and 2020 raining season Ex-Sudan variety had higher significant difference than E8 which were ranked second at both season for days to 50% flowering. In 2019 sowing date on days to 50% flowering mid-July sowing date were significantly higher number of days to 50% flowering than early and late July that were statistically similar. While in 2020 sowing dates differed from significantly one another; mid-July sowing date were recorded highest days to 50% flowering and per better than late July sowing date which was recorded second and finally flowed by early July sowing date. The days to maturity on the two varieties Ex- Sudan were significantly at par than E-8 at both two seasons.

Table 3 shows the effect of sowing date on 1000 seed weight, net plot weight and grain yield per hectare of sesame varieties in 2019 and 2020 rainy season. At both seasons variety EX- Sudan performed significantly better than E8 in terms of 1000 seed weight, net plot weight and grain yield per hectare. In 2019, higher 1000 seed weight was obtained from early July sowing date but, mid and late July sowing dates were statistically similar. For net plot weight, early July produced significantly heavier seeds than mid-July sowings while late July sowings significantly produced the lowest seed weight. In 2019 raining season, higher grain yield per hectare was obtained from early July sowing date, mid-July were statistically weighted second and late July significantly produced the lowest grain yield per hectare. While in 2020 raining season variety Ex-Sudan had recorded higher 1000 seed weight, net plot weight and grain yield per hectare than E-8. In 2020 raining season sowing date had significant effect on 1000 seed weight early July were significant heavies than mid-July and late July was significantly recorded lowest. For the net plot weight early July significantly produced heavies weight, mid-July was ranked second and late July was ranked statistically lowest. Grain yield per hectare for sowing date in 2020 raining season early July had resulted significantly higher than mid-July, followed by late July sowing date.

DISCUSSION

The results of the research showed that there was significant difference of sowing date in both 2019 and 2020 where sesame sown at early July and mid-July at 6WAS produced higher plant height in 2020 season and late July produced shorter plant height at 6,8 and 10WAS. This might be attributed to the optimum environmental condition for the growth and development of the crop. This is in line with earlier observation by Aghili *et al.* (2015) who reported that delayed sowing effect plant height (4%) dry matter yield (8.9%). Similar observation was made by Tahir et al. (2012) who found that the yield attributing parameters were significantly affected by different sowing dates. Similarly, Ogbonna *et al.* (2012) stated that the effect of three sowing date had a significant effect of plant height, number of branches and stem girth. In 2019 season, late July sowing produced significant higher plant height at 6WAS than mid-July sowing while early July sowing produced significantly shorter plant. This may be due to the short drought period experienced at that particular year 2020. Ali and Jan (2014) found that sesame sowing was dependent on the rain water and for that reason the yield be effected due to different sowing date and variety characteristic in response to N application. Number of branches per plant respond to sowing date in 2019 at 6WAS, late July produced significantly higher number of branches while mid-July were recorded second and early July produced shorter per plant. At 8WAS mid-July produced higher number of branches per plant and early July was recorded second and late July produced shorter per plant. At 10WAS early and mid-July produced significantly higher number of branches per plant than late July in 2019 season.

Effect of variety on growth and yield of sesame

On days to maturity for two growing season, E8 variety matured early than Ex-Sudan. This is in contrast to findings of Olowe (1999) who stated that

Ex-Sudan is an extra early sesame for Sudan savannah ecological zone while E8 is a medium maturating variety meant for Northern guinea savannah. Number of capsule were significantly affected in 2019. Where EX-Sudan is significantly higher than E8 this might be in line with the fact that with superiority of variety (Ex-Sudan) in term of days to 50% flowing, days to maturity, 1000 seed weight and net plot weight with higher ability. For capsule length in 2019, Ex-Sudan significantly produced longer capsules than E8. While in 2019 there was no significant effect on capsule length. Number of seeds per capsule was significantly influenced by varieties in 2020 where EX-Sudan produced higher number of seed per capsule though temperature, rail fall and good agronomic practices encourages rapid germination, growth and development of the crop (Olowe, 1999). The 1000 seeds weight was significantly affected by variety at both 2019 and 2020 were Ex-Sudan produced heavier seed than E8. This might be due to the optimum days to 50% flowering, days to maturity and accumulation of dry matter by this variety as it observed in this study. Grain yield per hectare were significantly influenced by varieties both in 2019 and 2020 were Ex-Sudan significantly produced higher grain yield per hectare than E8 variety. This might be in line with superiority of variety (Ex-Sudan) in term of days to 50% flowing, days to maturity, 1000 seed weight and net plot weight, which are expected to lead to greater seed yield per hectare.

CONCLUSION

In conclusion the result of the study showed that although E8 variety flowers and matures earlier than Ex-Sudan at both seasons. Ex-Sudan variety and early sowing produced the highest grain yield per hectare both at 2019 and 2020 raining seasons.

RECOMMENDATION

Based on the results obtained from this study Ex-Sudan variety can be recommended. Similarly, early July planting date is suggested for increasing sesame production in the study area.

ABSTRACT

Cashew is an important crop with huge socio-economic potentials capable of improving rural livelihoods, job creation and revenue generation. Its cultivation is plagued by several constraints, prominent amongst the factors is the long horn beetle (LHB), Analeptes trifasciata (Coleoptera: Cerambycidae). The girdling behavior of the LHB leads to breaking off of branches, this usually coincides with the flower initiation period thereby resulting in huge economic loss of yield. Eight cashew accessions namely Brazilian jumbo (BJ), Brazilian extra-large (BeL), Brazilian large (BL), Brazilian medium (BM), Indian large (IL), Indian medium (IM), Indian small (IS) and Indian madras (IMa) in the CRIN cashew germplam plot were evaluated for susceptibility to LHB for two years. Data were taken on number of LHB and damage intensity, thereafter subjected to ANOVA and susceptibility index. IL (0.4) and IM (0.5) accessions recorded highest mean insect count/tree, significantly different from others. BL and BM recorded the lowest insect count/tree, 0.1 and 0.09 respectively though not significantly different the rest. However, BM had high damage intensity. BJ and BeL recorded insect count of 0.2/tree but had the lowest damage intensity of 0.3/tree, while IM recorded the highest mean damage of 0.8/tree. Based on the susceptibility index, BJ and BeL accessions were categorized as moderately susceptible and the other accessions were categorized as susceptible. Generally, all eight cashew accessions showed susceptibility to the LHB. Therefore, development of new varieties with resistant characters to LHB should be a priority

Key words: long horn beetle, girdling, cashew, accessions, susceptibility

INTRODUCTION

Cashew, *Anacardium occidentale* L, is a resilient and fast-growing evergreen tree species belonging to the family Anacardiaceae. It is an important socio-economic crop with immense potential for job creation and revenue generation. However, its cultivation is affected by several factors such as the *Analeptes trifasciata* F. commonly known as the longhorn beetle (LHB) or stem girdler. The longhorn beetle is an economic insect pest of cashew that causes damage on cashew though its' girdling activities on sapwood of main stems and branches (Adeyemo and Okelana, 1989). This is done to provide suitable breeding material for the larvae, in the form of dead wood. In severe cases of infestation, the stems are completely girdled leaving only a central pillar of about half to one-inch-thick which is inadequate to support the full weight of the branch, this leads to snapping off of the upper stem (Asogwa *et al*., 2008). Unfortunately, the incidence coincides with the period of flowering and fruiting in cashew. As a result of its girdling activities, there is significant loss of inflorescences, pseudo-apples and nuts found on the girdled branches. The current control measure is collection and destruction of the LHB and girdled stems (Igbokwe, 1982) but this has drawbacks. Most farmers do not practice this cultural method because of the difficulty associated with collection of the LHB and hanging stem above hand's height. However, an integrated management system which combines two or more approaches will be most appropriate especially for an insect pest of perennial crops such as cashew. The use of host plant resistance as a means of pest control has been successful for tree crop such as cocoa (Anikwe *et al*., 2009). Cashew is classified based on morphological characteristics such as nut size, form of tree, apple colour, fruit-bearing capacity (Aliyu and Awopetu, 2007). There are eight cashew accessions based on nut size and origin. Personal field observations have indicated disparity in the damage caused by the LHB on the eight cashew accessions (pers. comm. 2016). However, there is no known documented information on cashew accession resistant or susceptible to LHB in Nigeria. This necessitated the search for cashew accession(s) that are resistant or susceptible to LHB as the case maybe. This project therefore assessed the relative susceptibility in eight cashew accessions to *Analeptes trifasciata* on the field.

MATERIALS AND METHODS

The relative susceptibility of eight cashew accessions to *Analeptes trifasciata* was assessed on the field for 2 years on a 2.5-hectare Cashew Germplasm plot at CRIN Headquarters, Ibadan. The location lies between the latitude 7°30'N and longitude 3° 54'E at an altitude of 200 m above sea level. The cashew germplasm plantation was established in 2005 and planted in geometry of 6 m by 6 m with a total of 278 stands. The field contained eight cashew accessions which were: Brazilian Jumbo, Brazilian Extra-large, Brazilian Large, Brazilian Medium, Indian Large, Indian Medium, Indian Small and Indian Madras. The size of the field was 60 m x 255 m and was made up of eight blocks containing an accession in each block. Each accession, which was in a block of 60 m x 24 m containing 40 trees, represented the treatments and was separated by 9 m border row of oil palm trees. From each block of accession, a plot size of 12 m x 12 m containing four trees was marked out and replicated three times. The plot was separated between replicates by 12 m border row of cashew trees. In order to rank the susceptibility level, susceptibility index was conducted according to the method of Navik *et al*., (2019) (Table 1).

Table 1. Susceptibility index used for ranking cashew accessions against damage caused by *Analeptes trifasciata*

Susceptibility status	Damage score
Less susceptible	Accessions with damage level less than (mean (x) –SD)
Moderately susceptible	Accessions with damage level between (mean (x) – SD) to mean (x)
Susceptible	Accessions with damage level between mean (x) to mean (x) + SD
Highly susceptible	Accessions with damage level above mean (x) – SD

Footnote: Susceptibility index adopted from Navik *et al*., (2019) with modifications

Data collection: Once in a month, four randomly selected trees per plot were inspected for damage symptoms and presence of the LHB. Data were taken on the number of *Analeptes trifasciata* found on the cashew trees. To assess intensity of damage, three types of girdled attacks were defined.

Type 1 - Girdled stem: this was made up girdled stem where only the bark has been attacked. Type 2 - Girdled and hanging stem: this included stem on which attack has reached the sapwood but the stem remained attached to the tree though hanging.

Type 3 - Girdled and fallen stem: cut stem which had fallen and laid strewn on the ground.

The attacked stems were counted per tree using the following calculation:

Intensity of attack = NGS/TNST

Where NGS- number of girdled stem(s)

TNST = total number of sampled trees

Data obtained on the number of LHB, damage on the accessions were subjected to analysis of variance and means were separated by Student-Newman-Keuls test (SNK).

RESULTS AND DISCUSSION

The number of adult LHB found on the eight accessions was statistically different from one another. Cashew accessions of Indian large and Indian medium nut sizes had the highest mean count /tree of adult *A. trifasciata*, 0.4 and 0.5 respectively and were statistically similar (Figure 1). Mean number of adults found on Indian medium was significantly different from others, Indian large was only significantly different from Brazilian large and medium accessions; the later recorded the lowest counts of adults, 0.1/ tree (Figure 1). In the same vein, Indian medium (0.26) followed by Indian large (0.19) accessions recorded the highest count of male and were not significantly different. The number of males found on Indian medium was significantly higher than the rest of the accessions (Table 2). A similar trend was observed for the females amongst the accessions, where Indian medium recorded the highest number of female which was statistically different from others except the Indian large accession (Table 2). Both males and females were found on all the cashew accessions but with differing levels of damage.

The girdling intensities of *A. trifasciata* was also observed on all the accessions (Table 2). There were significant differences ($P< 0.05$) in the number of cashew stem girdled amongst the accessions. The mean number of girdled stems only (type 1) on Indian madras accession, 0.19 was significantly different from that of Brazilian jumbo, 0.04, Brazilian extra-large, 0.02 Brazilian large, 0.05 and Brazilian medium, 0.06. Accessions such as Indian madras (0.19/ tree), Indian small (0.17/tree) and Indian medium (0.13/tree) showed higher number of girdled stems and were not significantly different from one another (Table 2). All the accessions were attacked with varying levels of damages.

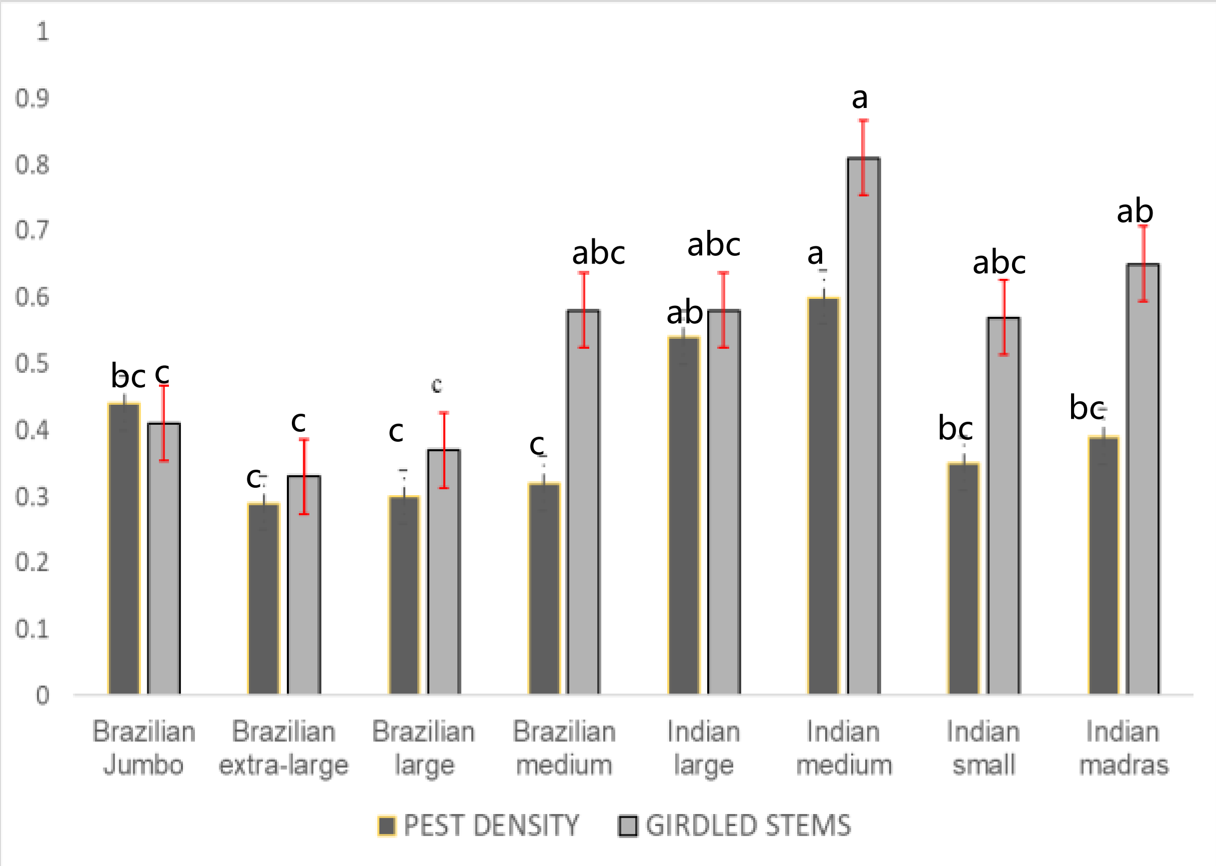

Figure 1. Mean number of *Analeptes trifasciata* and associated girdled stems on eight cashew accessions on the field

Table 2. Mean population density of male and female *Analeptes trifasciata* and girdling intensities on eight cashew accessions

Accessions	Mean nos. of males	Mean nos. of females	Girdled stems	Girdled & hanging stem	Girdled & fallen stem
Brazilian jumbo	0.12b	0.09abc	0.04c	0.2b	0.09a
Brazilian extra-large	0.09b	0.08abc	0.02c	0.18b	0.13a
Brazilian large	0.06b	0.03c	0.05c	0.19b	0.13a
Brazilian medium	0.04b	0.05abc	0.06bc	0.21b	0.18a
Indian large	0.19ab	0.19ab	0.08abc	0.35b	0.14a
Indian medium	0.26a	0.19ab	0.13abc	0.49a	0.18a
Indian small	0.09b	0.09abc	0.17abc	0.29b	0.13a
Indian madras	0.07b	0.07abc	0.19a	0.3b	0.16a

Values with different lower case letter along the columns are significantly different at P<0.05

The number of hanging stems (type 2) showed significant differences (P<0.05) amongst the accessions. For instance, the number of hanging stems recorded on Indian medium accession was the highest and significantly different from others. The highest number of hanging stems recorded in the Indian category was Indian medium accession (0.5), closely followed by Indian large (0.4) and madras accession (0.3). All the Brazilian accessions recorded a mean value of 0.2 hanging branch per tree. The number of fallen stems (type 2) were statistically similar amongst the accessions. Nevertheless, the Indian accessions recorded higher number of fallen stems (Table 2). Generally, the Indian accessions recorded higher damage intensity.

The combination of the girdling activities resulting in damage infestation was highest amongst the Indian accessions with Indian medium accession leading with 0.8 total damaged branch /tree followed by Indian madras accession, 0.7. Indian medium accession was significantly different from all accessions in the Brazilian group except Brazilian medium (Figure 1). Specifically, Indian large and Indian medium accessions recorded more pest density and corresponding high damage intensity such as girdled stems, hanging stems and fallen stems. However, the Brazilian medium with the lowest pest density was observed to have remarkably high damage intensity comparable with all the Indian accessions including Indian medium. The same trend was observed in the case of Indian small and madras. Following the susceptibility index, two categories of susceptibility were identified, namely moderately susceptible accession consisting of Brazilian jumbo and Brazilian extra-large; and susceptible accession category consisting of the rest accessions (Table 3). In a related study, Navik *et al.,* (2019), reported that eighteen cashew cultivars screened for tolerance to apple and nut borer in India showed varying susceptibility status. Furthermore, on the basis of pest density and resultant damage, the Brazilian medium, Indian small and madras accessions can be categorized as highly susceptible. Apart from feeding on the cashew stems, girdling is also done to provide breeding sites for oviposition purpose. The substantial girdling intensity observed on the three highly susceptible cashew accessions further suggests that these accessions are the most favorable accessions for egg-laying, progeny development and survival.

Table 3. Susceptibility status of cashew accessions to *Analeptes trifasciata* on the field

Accessions	Susceptibility status
Brazilian Jumbo	Moderately susceptible
Brazilian extra-large	Moderately susceptible
Brazilian large	Susceptible
Brazilian medium	Susceptible
Indian large	Susceptible
Indian medium	Susceptible
Indian small	Susceptible
Indian madras	Susceptible

CONCLUSION

Generally, all the cashew accessions were susceptible to attack by *A. trifasciata* though in varying levels. While Brazilian jumbo and Brazilian Extra-large were moderately susceptible, the rest of the accessions were susceptible to *A. trifasciata*. The knowledge is expected to have tremendous application in breeding for cashew with better protection against the LHB.

ABSTRACT

To meet global food requirement as a result of the ever-increasing world population is a major problem of humanity. For this reason, there has been an over dependence on pesticide usage to boost agriculture. Consequently, heavy doses of synthetic pesticides are being deposited in the environment. Although, very effective for their particular purpose, synthetic pesticides are eco-unfriendly and toxic to man, domestic and wild-life, non-target organisms as well as enhancing the potential for pesticide resistance development. Thus, there is need for an alternative that will ensure sustainable crop production while mitigating the environment. Allelopathy involves both sympathetic and pathetic interactions between two plants. These qualities could therefore be harnessed and/or augmented to address the weed problems on our farms to increase yield. With this adoption, the use of synthetic herbicides, although cannot be completely discarded, their use could drastically be reduced to an appreciable level. The prospect of allelopathy as a weed control strategy is therefore hereby discussed.

Key words: Allelopathy, Allelochemicals, Allelochemistry, Weeds, Crops

INTRODUCTION

With the increasing population of the world, achieving food security has become a challenge to mankind. Therefore, the use of little agricultural input to maximize production is the solution to this. Although this approach is satisfying the food demand to almost a desirable extent, but is directly and indirectly causing negative impact on quality of the produce, environment and overall human health. Successful breeding for disease and insect resistant cultivars in combination with development of integrated pest management systems have led to a reduction in the demand for fungicides and insecticides, while herbicide use is still increasing worldwide. Weeds are the most aggressive, troublesome and undesirable element of the world's vegetation and cause enormous reduction in crop yield, wastage of resources and human energy and also a health hazard to human being. Weeds cause great problems to humankind by interfering in food production, health, economic stability, and welfare. The overuse of synthetic herbicides for weed control eventually leads to the evolution of herbicide resistant weeds, which also resulted in growing public concern over their impacts upon human health. It is imperative to find out some natural extract to control this menace, thereby minimizing or avoiding the frequent use of herbicides in the future. In this regard, allelopathic effect of different plants is drawing attention of many researchers in the recent past. The phenomenon of allelopathy has existed for thousands of years. Intensive scientific research into the recognition and understanding of allelopathy has only occurred over the past few decades (An *et al*., 1996). These activities have shown significant prospects for the use of allelopathy being utilized for increasing crop productivity and the quality of food for humans. Also it has decreased our reliance on synthetic pesticides and improving the ecological environment. Recent research has demonstrated possibilities of such prospects in reality, especially in weed control.

ALLELOPATHY

The term allelopathy originated from the Greek word 'allelon' meaning 'of each other' and 'pathos' meaning 'to suffer' and means the injurious effect of one organism upon the other. The term 'allelopathy' was first used in 1937 by Austrian scientist Hans Molisch (Willis, 2010). Allelopathy is any direct or indirect effect by one plant, including micro-organisms, on another through production of chemical compounds that escapes into the environment to influence the growth and development of neighbouring plants (Bahadur *et al*., 2015). It is the detrimental effects of chemical(s) or exudates produced by one living plant species on the germination, growth or development of another plant species or microorganism sharing the same habitat. Allelopathy is therefore the influence, usually detrimental of one plant on another by toxic chemical substances from living plant parts through their release when a plant dies or their production from decaying tissue. Allelopathy is described as the beneficial and deleterious biochemical interaction between plants and microorganisms. The bio-chemicals that are released by plant parts, which may have inhibitory (negative allelopathy) or stimulatory (positive allelopathy), effect on each other. Rice (1984) defined allelopathy as any direct or indirect inhibitory effect by one plant including microorganisms on another through the production of chemical compounds that escape into the environment. These chemicals are usually secondary plant metabolites or byproducts of the principal metabolic pathways in plants. They are non-nutritional and can be synthesized in any plant part, i.e. leaves, stems, roots, bark, seeds, etc. Also Lambers *et al*. (1998) defined allelopathy as the growth suppression of one plant species by another due to the release of toxic compounds. Singh *et al.* (2001) opined that allelopathy refers to any direct or indirect effects of plants on other plants through the release of chemicals and plays an important role in many agro-ecosystems. Allelopathy occurs through the release by one plant species of chemicals which affects other species in its vicinity, usually to their detriment. The plant may exhibit inhibitory or rarely stimulatory effects on germination and growth of other plants in the immediate vicinity. Allelopathy involves the synthesis of plant bioactive compounds, known as allelochemicals, capable of acting as natural pesticides (Macias *et al*., 2007) and can resolve problems such as resistance development in pest biotypes, health defects and soil and environmental pollution caused by the indiscriminate use of synthetic agrochemicals (Dayan *et al*., 2009)

Reports as early as 300 BC document that many crop plants (e.g. chick pea, barley, bitter vetch) destroyed weeds and inhibited the growth of other crop plants (An *et al*.,1996) Contemporary researchers have tended to broader the context of allelopathy to include interactions between plants and higher animals (Rizvi and Rizvi 1992), and have suggested that alleloptahy may be part of a whole network of chemical communication between plants and between plants and other organisms, and that such communication may contribute to plant defense.

ALLELOCHEMICALS

Chemicals that impose allelopathic influences are called allelochemicals. They may be largely classified as secondary plant metabolites, which are generally considered to be those compounds (such as alkaloids, phenolics, flavonoids, terpenoids and glucosinolates) which do not play a role in primary metabolic processes essential for a plant's survival and are produced as offshoots of primary metabolic pathways. Allelochemicals are present in virtually all plant tissues, including leaves, flowers, fruits, stems, roots, rhizomes, seeds and pollen. Under favourable environmental conditions, allelochemicals are released into the environment through the processes of volatilisation, leaching, root exudation, and decomposition of plant residues, thereby affecting the growth of adjacent plants (Bonanomi *et al*., 2006). Several chemicals can be released together and may exert toxicities in an additive or synergistic manner.

In a review of the potential use of allelochemcials as herbicides, Putnam (1988) listed 6 classes of allelochemicals namely alkaloids, benzoxazinones, cinnamic acid derivatives, cyanogenic compounds, ethylene and other seed germination stimulants, and flavonoids which had been isolated from over 30 families of terrestrial and aquatic plants. All these chemicals possess actual or potential phytotoxicity. Rainfall causes the leaching of allelopathic substance from leaves which fall to the ground during period of stress; leading to the inhibition of growth and germination of crop plants (Rice, 1974; Mann, 1987). The readily visible effects of allelochemicals on the growth and development of plants include inhibited or retarded germination rate, seeds darkened and swollen, reduced root or radicle and shoot or coleoptile extension; swelling or necrosis of root tips; curling of the root axis, discolouration, lack of root hairs, increased number of seminal roots, reduced dry weight accumulation and lowered reproductive capacity. These gross morphological effects may be secondary manifestations of primary events, caused by a variety of more specific effects acting at the cellular or molecular level in the receiver plants (Rice, 1974). Different allelopathic compound of some crops, important in weed management are presented below:

Allelochemicals of some important crops

Crops	Scientific name	Allelochemicals	References
Rice	*Oryza sativa* L	Phenolic acids	Rimando et al, 2001
Wheat	*Triticum aestivum* L	Hydroxamic acids	Niemeyer, 1988
Cucumber	*Cucumis sativus* L	Benzoic and Cinnamic acids	Yu & Matsui, 1994
Black mustard	*Brassica nigra* L	Allyl isothiocyanate	Weston, 1996
Buck wheat	*Fagopyrium esculentum* L.	Fatty acids	Weston, 1996
Clovers and Sweet clovers	*Trifolium spp* *Melilotus spp*	Isoflavonids and Phenolics	Weston, 1996
Oat	*Avena sativa* L.	Phenolic acids and Scopoletin	Weston, 1996
Cereals	-	Hydroxamic acids	Weston, 1996
Sorghum	*Sorghum bicolor* L.	Sorgoleone	Netzley and Butler (1986)

Ways in which Allelochemcials are released

In order to have any effect on the target plant, the allelochemicals have to be released from the donor plant. This can happen in different ways:

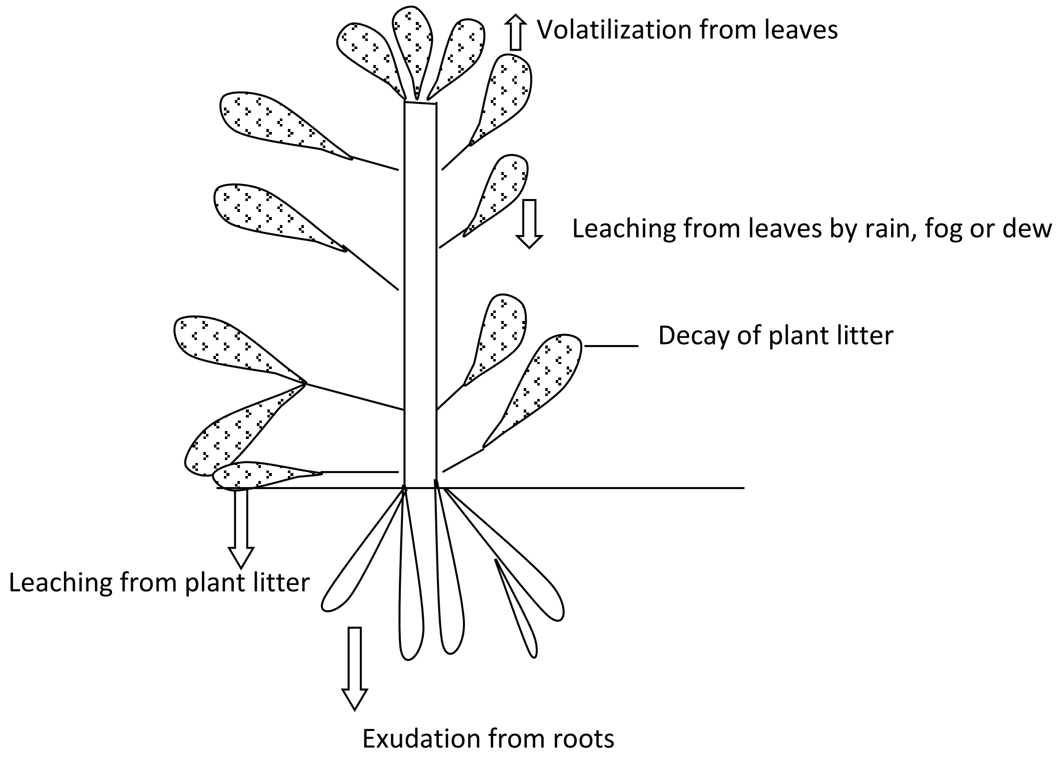
1. Runoff and leachate from leaves and stem of plant. Example, the allelochemicals in the leaves of black walnut, *Juglans nigra*, which are washed off with rain can inhibit the growth of the vegetation under the walnut tree (Bode, 1958).

2. Volatile phytotoxic compounds from the green parts of a plant, e.g. *Salvia leucophylla* and *Artemosia californica* (Halligan, 1973).

3. Phytotoxic compounds from decomposing plant material, such as rye (*Secale cercale*) when used as a mulching material. Apart from shading and keeping the soil moist, rye mulch also inhibits both germination and growth of weeds through release of phytotoxics (Barnes and Putnam, 1986).

4. Phytotoxic compounds released from the plant roots. Rice is an example, where living rice plants are able to suppress weed growth selectively (Navarez and Olofsdotter, 1996).

Source of allelochemicals (Putnam, 1994)



ISSN: 2814-0508

Types of Allelopathy

1**. Alloallelopathy**: It is inter- specific chemical co-action. Allelochemicals are toxic to other species, other than which release it. E.g. maize (*Zea mays*) is allelopathic to *Chenopodium album* and *Amaranthus retroflexus*; Sorghum to *Abutilon theophrasti, Amaranthus hybridus and Setaria viridus;* rye to *Digitaria sanguinalis* and *Chenopodium album.*

2. **Autoallelopathy**: It is intra-specific chemical co-action. Allelochemicals are toxic to same species from which they are released. E.g. wheat, alfalfa, cowpea, rice, apple, clover and sweet potato are autotoxic. The soil where these crops were previously grown is inhibitive to their growth when replanted or their residues proved autotoxic to them when incorporated.

3**. True allelopathy**: It refers to the release into the environment of chemical compound that are toxic the form they are produced by the plant.

4. **Functional allelopathy:** It refers to the release into the environment of chemical compound that are toxic after chemical modification by microorganisms.

5. **Concurrent/ direct allelopathy:** It refers to the instantaneous direct effect of released toxin from the living plant to another growing in vicinity. It is also called 'living plant effect'. E.g. sorghum (*Sorghum bicolor*) suppresses many weeds growing in the vicinity.

6. Residual allelopathy: It is the effect obtained on the plants growing in succession from the decaying residues, leaf litters, stem, and roots of the previous plants. E.g. sorghum is allelopathic to wheat and *Phalaris minor* and sweet potato (*Ipomoea batatas*) to cowpea.

FORMS OF ALLELOPATHIC INTERACTION

Allelopathic interactions between crops and weeds in agro-ecosystems can be of four types as describes below:

Crop against other crops: Crop against crop allelopathic interaction is likely operative in multiple crop culture like intercropping, mixed cropping and agro-forestry. Therefore, selection of suitable pairs of crops having no allelopathic effect with each other is of paramount importance in crop diversification or crop mixture programme. For example, sunflower has been found allelopathic to groundnut under intercropping situations. Similarly, sorghum is allelopathic to wheat and *Phalaris minor* and sweet potato to cowpea. Volatile compounds from the top of soybean, chickpea and beans reduced the uptake of P by corn plants. Allelopathic effects of pearl millet on the germination and seedling growth of wheat, barley, lentil etc. and aqueous root extract of soybean on rape and mustard.

Crop against weeds: Several crop show allelopathic effects on weeds. For example, sorghum releases hydrocyanic/prussic acid (HCN) and suppresses many weeds growing in vicinity. Barley is more competitive to weeds than wheat. Live barley plants and their root exudates were more inhibitory than aqueous leachates of dead roots. Recently some rice genotypes have already been identified which have allelopathic effects on weeds. Allelopathic effect of crops and weeds on other weeds may be applied to develop natural herbicide.

Allelopatic effects of crops on weeds		
Crops	**Weed species**	**Source of inhibitors**
Maize	*Chenopodium album, Amaranthus retroflexus*	Roots
Cassava	*Amaranthus dubius, Digitaria sanguinalis*	Leaves
Sorghum	*Abutilon theophrasti, Amaranthus hybridus, Setaria viridus*	Shoots and foliages
Rye	*Digitaria sanguinalis, Ambrosia artemisiifolia*	Shoots and foliages
Cucumber	*Echinochloa crusgalli*, *Amaranthus retroflexus*	--
Sweet potato	*Cyperus rotundus, Cyperus esculentus*	--

Weeds against crops: Many weeds impose allelopathic influence on certain crops.

Weeds	Crop	Cause/Source	Effect
Quack grass (*Agropyron repens*)	Maize and potato	Ethylene produced by the activity of microorganism on rhizomes	Decrease uptake of manures (N, K) followed by yield reduction
Wild oat (*Avena fatua)*	Wheat, barley and oat	Root exudates	Growth of leaves and roots of wheat
Bermuda grass (*Cynodon dactylon*)	Barley	Decayed grass residues	Seed germination, root growth
Yellow Nut sedge (*Cyperus esculentus*)	Grain crops, soybean and orchard	Vanillic acid, Hydrobenzoic acid in sedge extract	Root and shoot growth of maize and soybean
Johnson grass (*Sorghum halepense*)	Sugarcane, maize and soybean	Root exudates and decaying residues	Root and shoot growth
Gaint foxtail (*Setaria viridis*)	Maize	Roots and leachates of dead roots	Yield reduction
Cogon grass (*Impereta cylindrical*)	Tomato and cucumber	Root exudates	Inhibit growth
Field bind weed (*Convolvulus arvensis*), Canada Thistle (*Cirsium arvense)*	Cabbage, carrot and tomato	Root exudates	Seedling growth

Weed against other weeds: *Parthenium hysterophorus* is allelopathic to many weeds. Whenenever parthenium invades, it forms a territory of its own replacing all existing flora, grasses and broad-leaved weeds mainly because of its allelopathic effect and competition. Very little or no vegetation could be seen in parthenium dominated areas. Similarly, there are many weeds/wild species, viz., *Amaranthus spinosus, Tagetes minuta, Cassia sericea* which pose strong allelopathic effect on parthenium. Weeds against weed allelopathy have enough importance and could be exploited to control some poisonous problematic weeds like parthenium.

Crop against same crop: The importance step towards avoiding/removing the allelopathic effect of some crops on the same crop species is to stop the continous monocropping of the crops over the years and to encourage crop rotation with diverse crop species. Several crops like wheat, alfalfa, cowpea, rice, apple, clover and sweet potato are autotoxic. The soil where these crops were previously grown is inhibitive to their growth when replanted or their residues proved autotoxic to them when incorporated.

Weed against same weed: The allelopathic effect of weed against same weed is another important intraspecific chemical co-action, which results in weaker stand of a particular weed. However, there is equal possibility that chemical autotoxic to a certain weed, may be toxic to other plants specifically crop plants, otherwise, it will accumulate in soil and develop soil sickness in the long run. *Trifolium repens* for example has autotoxicity**.**

Some Crops Whose Residues Have Been Reported To Be Phytotoxic (Putnam 1994; Duke *et al.*, 2002).

Crops	Affected species
Alfalfa	Alfalfa
Apple	Apple
Asparagus	Tomato, asparagus
Barley	White mustard
Bean	Pea, wheat
Black walnut	Tomato
White clover	Radish
Corn	Several weeds
Cucumber	Several weeds
Rice	Barn yard grass
Smooth brome grass	Several
Sorghum	Fescue
Sunflower	Barely, clover, garden cress, lettuce, redroot pigweed, tomato
Wheat	Several weed

Allelopathic Chemistry

Plants produce a myriad of metabolites of no known utility to their growth and development. They are often referred to as secondary plant metabolites and are defined as compounds that have no known essential physiological functions. Secondary plant metabolites, also known as natural products, are regarded by many as "a vast repository of materials and compounds with evolved biological activity including phytotoxicity" (Duke *et al*., 2002). It is proposed that some of these compounds may be useful directly as herbicides or as templates for herbicide development. According to Duke *et a*l. (2002), they often have unique molecular target sites in plants but have not been developed or used much in agriculture or herbicide development. Acetic acid, the primary component of vinegar, is a contact, burning herbicide that can be used selectively in some crops, example onions and sweet corn. Martan 2 is a clove oil product that shows promise as a natural product herbicide (Evans and Bellinder, 2006). In both cases, success depends on the time of application and the growth stage of the crop and weeds.

Allelochemicals vary from simple molecules, such as ammonia, to the more complex quinones, juglone and the terpenes, camphor and cineole, to very complex conjugated flavonoids such as phlorizin (isolated from apple roots) or the heterocyclic alkaloid caffeine (isolated from coffee) (Thompson 1985). Putnam (1985) lists several chemical groups from which allelopathic agents come: organic acids and aldehydes, aromatic acids, simple unsaturated lactones, coumarins, quinones, flavonoids, tannins, alkaloids, terpenoids and steroids, a few miscellaneous compounds such as long chain fatty acids, alcohols, polypeptides, nucleosides, and some unknown compounds. The diversity suggests several mechanisms of action, a multiplicity of effects, and is one reason for the slow emergence of a theoretical framework. The chemistry of allelopathy is as complex as synthetic herbicides chemistry, but it is a chemistry of discovery as opposed to one of synthesis.

Allelopathic compounds isolated from plants (Putman, 1983)

Common name	Chemical class	Natural source
Acetic acid	aliphatic acid	Decomposing straw
Arbutin	phenolic	Manzanita shrubs
Caffeine	alkaloid	Coffee plants
Camphor	monoterpene	Salvia shrubs
Gallic acid	tannin	Spurge plant
Juglone	quinone	Black walnut trees
Phlorizin	flavonoid	Apple roots
Dhurrin	cyanogenic glucoside	Sorghum plants

Production of Allelochemicals

Production of allelochemicals varies with environment and associated environmental stresses. It can occur in any plant organ (Rice, 1974), but roots, seeds and leaves are the most common sources. Source becomes important for exploitation of allelochemicals for weed control. For example, an allelochemical found in flowers or fruits would have less potential value than if it were concentrated in roots or shoots (Putnam, 1985). For control, soil incorporation of whole plants might create proper distribution regardless of which plant part produced the chemical. The amount is important for control purposes, and if specific effects are to be predicted in the field, total quality and concentration must be determined (Putnam, 1985). Evidence shows that allelochemical production may be greater when plants suffer from environmental stress (Rice 1979). Aldrich (1984) stated that production of allelochemicals is influenced by light intensity, quality, and duration, with a greater quantity produced with high ultraviolet light and long days. Quantities of allelochemicals produced are also greater under conditions of mineral deficiency, drought stress and cool temperatures as opposed to more optimal growing conditions. In some cases, plant affected by growth regulators herbicides may increase production of allelochemicals (Aldrich, 1984).

Because stress frequently enhances allelochemical production, it is logical to assume that stress accentuates the involvement of allelo1qpathy in weed-crop interference and that competition for limited resources may increase allelopathic potential or sensitivity of the weed, the crop or both. Thus, weed – crop competition and allelopathy should be regarded as intimately related components of interference in a crop ecosystem.

Prospects for the Application of Allelopathy in Weed Control

As demands increases for sustainable agriculture and concern grows regarding the extensive use of synthetic chemicals, attention is focused on reducing reliance upon synthetic herbicides and finding alternative strategies for weed management. Allelopathy holds great prospect for meeting some of those demands. Allelopathic potential can be used in several ways in agroecosystems.

Enhance crop allelopathic traits for weed suppression: Putnam and Tang (1986) suggested that allelopathic characteristics are more likely to occur in crop predecessors or "wild types" that have evolved in the presence of allelopathic and competitive influence from other species, while the currently used cultivars would be expected to have diminished or reduced allelopathic capacity. Therefore, it is possible to enhance weed suppressive potential of crop cultivars or to transfer allelopathic characteristics from wild types or unrelated plants into commercial crop cultivars through conventional plant breeding method or other genetic recombination strategies. Research on cucumber and rice germplasm has found large differences in allelopathic potentials among accessions. Olofsdotter and Navarez (1996) stated that certain accessions strongly inhibited weed germination and growth. In some cases, up to 70% population of rice weeds, such as duck-salad (*Heteranthera limosa* (Sw) wild), purple ammania (*Ammania coccinea* Rottb, and broadleaf signal grass (*Brachiaria platyphylla* (Griseb) Nash) were controlled by those accessions with strong allelopathic potential (Dilday, *et al*., 1994). More recently Wu *et al*., (1998) found out in their research that some wheat cultivars were found to significantly inhibit both germination and radical, growth of annual ryegrass. The allelopathic potential of wheat cultivars was positively correlated with their allelochemical (total phenolics) contents.

Use of allelochemicals as natural herbicides or pesticides: Example include pyrethrins extracted from a species of Chrysanthernum and cinmethylin derived from the natural product cineol of certain desert plants. By modifying these allelochemicals, the end product could be more active, selective or persistent. In a review of the potential use of allelochemicals as herbicides, Putnam (1988) listed 6 classes of allelochemicals isolated from over 30 families of terrestrial and aquatic plants. These classes are alkaloids, benzoxazinones, cinnamic acid derivatives, cyanogenic compounds, ethylene and other seed germination stimulants and flavonoids. All these chemicals possess actual or potential phytotoxicity. These allelochemicals have been tested and they possess various biological activities and few barriers to synthesis and production, and hence may be another alternative for developing new herbicides from individual plant allelochemicals.

Use of allelopathic plants in companion cropping: Putnam and Duke (1974) suggested that it is possible to utilize a companion plant that is selectively allelopathic against certain weeds and does not interfere appreciably with crop growth. Rice (1984) listed a number of crop species whose presence or leachates have been shown to have inhibitory effects on a number of weeds. The list includes beets (*Beta vulgaris*), lupin (*Lupinus sp*.), corn, wheat, oats, peas, millet (*Panicum sp*), barley *(Hordeum vulgare* L), rye and cucumber. Weeds in cropping systems are most often considered to be detrimental. However, the interaction of weeds with crops may be positive. In a study where controlled densities of wild mustard (*Brassica compestris* L.) were interplanted with broccoli (*Brassica oleracea* Var. Premium crop), crop yield increased as much as 50% compared with broccoli planted alone (Jimenez – Osornio and Sliessman, 1987).

Use of allelopathic crops in crop rotation: Allelopathic weed control can be implemented by growing allelopathic plants in close proximity to weeds which promote production of these chemicals (Tesio and Ferrero, 2010); or by placing the allelopathic materials obtained from dead plants in close proximity to weeds. The decomposing plant material releases allelochemicals which are absorbed by the target weeds. Allelopathic weed control can also be implemented by growing allelopathic plants in a field for a certain period of time, in order for their roots to exude allelochemicals. Crop rotation is the most important example for such allelopathic weed control (Farooq *et al*., 2011).

Use of allelochemicals in liquid solution: Another way to control weeds through allelopathy includes obtaining allelochemicals in a liquid-solution by dipping the allelopathic chaff in water for a certain period of time. Several researchers have advocated using this way of weed control either alone or in combination with other methods of weed control (Jabran *et al*., 2010; Khan *et al*., 2012; Razzaq *et al.,* 2012).

Use of allelochemicals to stimulate weed seed germination: Chang *et al.* (1986) identified a germination stimulant, a p-benzoquinone compound from a natural host (sorghum) for striga. Ethylene was found to be a very effective germination stimulant. Egley and Dale (1970) demonstrated that ethylene would stimulate striga to germinate in the absence of a host. According to EPlee (1975) this gas at about 1.5kg/ha has been used effectively via a soil injection to trigger "suicidal" germination of striga and to deplete the numbers of dormant seeds in soil. Under growth chamber conditions, ethylene induced germination of common cocklebur (*Xanthium pensylvanicum* Wakkr) and redroot pigweed in soil (Egley, 1986).

Plant residue management: Utilizing residue allelopathy as a management tool may be one of the more readily applicable uses of allelopathy in agroecosystems. Of all the possible strategies involving allelopathy for weed control, management of selectively toxic plant residues is the most successful, effective and readily available (Lovett, 1990). Management methods might include incorporating allelopathic crops in crop rotation, applying phytotoxic mulches, and cover cropping with allelopathic plants or smother crops. An *et al.,* (1996) simulated allelopathic phenomena caused by decaying plant residues. Their plant residues may either inhibit or stimulate plant growth, and that inhibition may be confined to a limited period, i.e., the most severe inhibition by plant residues occurs at the early stages of residue decomposition, whereas at later stages the inhibition declines while stimulation gradually emerges. The inhibition and stimulation periods can be manipulated through a wide variety of management means. This approach has significant potential. For example, by analyzing risk manager may avoid the inhibitory period of decaying residues, thus minimizing their negative effects and await the stimulatory effect to crop plants, thereby enhancing the benefits of residues retention on the soil. By extending the inhibitory period of decaying residue and enhancing its effects, weeds may be controlled.

Allelopathy as a tool for weed management: A living cover crop of spring planted rye reduced early season biomass of common lambsquarters 98%, common ragweed 90% and large crabgrass 42% compared to control plots with no rye (Barnes and Putnam, 1983). Wheat straw has reduced populations of pitted morning glory and prickly sida in no-tillage culture. Lieble and Worsham (1983) suggested that wheat produced an allelochemical that inhibited emergence of several broadleaved species. It is reasonable to assume that many plants have allelopathic potential or some susceptibility to allelochemicals when they are present in the right amount, form, and concentration at the appropriate time. Trials in South Dakota showed that fields planted to sorghum had two to four times fewer weeds the following year than similar fields planted to soybean or corn (Kozlov, 1990). It was proposed that reduced weed seed germination was due to phenolic acids and cyanogenic glucosides given off by sorghum. Walker and Jenkins (1986) also demonstrated that sweet potato residues inhibited growth of sweet potato and cowpea. They stated that decaying residues of sweet potatoes reduced uptake of calcium, magnesium and sulphur by other plants.

Plant pathogens and allelochemicals from plant pathogens and other soil microorganisms can be used as bioherbicides. This possibility has been studied for more than three decades (Hoagland, 2001). A good example of a microbial product is the herbicide biolophos (active ingredient phosphinothricin) which is manufactured by fermentation as a metabolite of the soil microbe streptomyces viridochromogenes (Auld and McRae, 1997). Allelopathy may be used in weed suppressing crops by discovering, incorporating or enhancing would be most useful in crops maintained in high-density monocultures, such as turf grasses, forage grasses or legumes.

Another natural herbicide AAL-toxin, is a natural metabolite produced by *Alternaria alternate* f. sp. *Lycopersic*i, the pathogen that causes stem canker of tomato (Abbas *et al*., 1995) the phytotoxic effects of AAL – toxin was tested on 86 crop and weed species (Abbas *et al*., 1995). Monocots were generally immune to its effects. Black nightshade, jimsonweed, all species of tomato tested, and several other broadleaved plants were susceptible at low doses. Other broadleaved species were susceptible but only at higher doses. Abbas *et al.* (1995) proposed that the differential susceptibility of species to AAL – toxin could be exploited for selective weed control.

Limitations of using Allelopathic Effect

There are many limitations in using allelopathic potential as a weed management tool. The limitations are both because of plant itself, producing allelochemicals and the environmental condition.

1. Abiotic and Biotic factors: Inderjit *et al*. (1999) stated that many abiotic and biotic soil factors have influences on phytotoxic levels of allelochemicals. Various abiotic and biotic factors such as plant age, temperature, light and soil conditions, nutritional status and herbicide treatments influence the production and release of allelochemicals, although allelopathy is considered as a genetically influenced factor (Duke, 1985) while moving in the soil, allelochemicals may undergo transformation is various factors regarding soil environment like physical, chemical, biological and physicochemical properties of soil may influence the activity of allelochemicals. According to Inderjit and Dakshini (1995) many studies on allelopathy, however do not involve soil rather involve an artificial soil substrate. Oleszek and Jurzysta (1987) mentioned the influence of soil texture on phytotoxic effects. Inderjit and Pakshini (1994) found that the amount of water-soluble phenolics in *P. lanceolata* leaf leachate amended soil varied depending on the soil textural classes (clay, sandy – loam, sand and silt loam). Clay mineralogy also plays important role in activity of allelochemicals. The action exchange capacity, moisture holding capacity, concentration of inorganic ion etc are dependable on the

type of clay minerals.

2. Inability of synthesizing the allelochemicals: Many allelochemicals are very much expensive to synthesize inspite of having excellent herbicidal properties as for example, tentoxin (Duke *et al*., 2000).

3. Toxicity: Some allelochemicals are toxic to human beings and are carcinogenic, e.g. AAL – toxin and fumonisin are toxic to mammalian cells (Duke *et al*., 2000). Sorgoleone, for example is reported to cause dermatitis (Inderjit and Bhowmik, 2002).

4. Nutrient availability: The amount of nutrient available to the plant and the efficiency of the plant to utilize the nutrient strongly influence the allelopathic potential of rice plant. Sometimes the deficiency of nutrient favours the production of secondary metabolites as mentioned by Hoagland and Williams (1985). As for example in aerobic P – deficient soil, rice roots excrete organic anions particularly citrate to solubilize and enhance phosphorus uptake (Kirk *et al*., 1999).

5. Autotoxicity: Some allelochemicals affect the growth of the plant itself i.e, autotoxic effect which is another problem in the mechanism of allelopathy. Yu and Matsui (1994) identified autotoxins, including some derivatives of benzoic and cinnamic acids from the root exudates of cucumber. Quan Yu (2003) showed the inhibitory effect of root exudates and aqueous root extracts of cucumber (*Cucumis sativus*) and allelochemicals on root antioxidant enzymes and leaf photosynthesis, transpiration and stomatal conductance in cucumber. Therefore, while studying the role of allelopathy in controlling weeds, the autotoxicity of plants should not be ignored.

CONCLUSION

As the development of weed strategies that make use of allelopathic crop plant is receiving increased attention, there is need to enhance allelopathic traits of crop cultivars through breeding programmes such as transferring allelopathic genes into commercial cultivars through modern biotechnology; to enhance their weed – killing capacity, and to identify and characterize those substances involving in strong allelopathic activity and to use them directly as natural herbicides; or as models for developing new and environmentally friendly herbicides. When this is done, Allelopathy will become an important component in the development of future integrated weed management strategies.

ABSTRACT

A screen house experiment was conducted in Cocoa Research Institute of Nigeria, Owena, Ondo state to evaluate the influence of nitrogen fertilizer sources and levels on growth of cocoa seedlings. Treatments were a factorial combination of four nitrogen sources (Cocoa pod husk, Kola pod husk, Chromolaena and NPK) and five nitrogen levels (0, 5, 10, 15 and 20 kg N/ha). The 20 treatments were arranged in a randomized complete block design with three replications. Results indicated that Chromolaena resulted in higher number of leaves and leaf dry matter yield than kola pod husk. Only 10 kg N/ha significantly (P<0.05) increased number of leaves by 14 % when compared with 0 kg N/ha. Nitrogen applied at the rate of 10, 15 and 20 kg N/ha increased plant height by 22 % (68.25 cm), 15 % (64.25cm) and 14 % (63.48 cm) respectively when compared with 0 kg N/ha. Similarly, 10, 15 and 20 kg N/ha resulted to 15 % - 19 % higher stem dry matter yield relative to 0 kg N/ha. All fertilizer levels increased root dry matter yield (6.49 - 7.28 g/plant) when compared with 0 kg N/ha with increases of 15 % - 30 %. Fertilizer applied at the rate of 10 kg N/ha also produced the highest plant height (68.25cm), leaf dry matter yield (19.83 g/plant), stem dry matter yield (24.66 g/plant) and total dry matter yield (49.80 g/plant), which was significantly (P<0.05) higher than all other nitrogen levels. Nitrogen fertilizers irrespective of source enhanced growth of cocoa seedlings. Fertilizer applied at the rate of 10 kg N/ha proved to be the most effective nitrogen level.

Key words: Cocoa seedling, nitrogen fertilizer, growth

INTRODUCTION

Cocoa bean is an importance source of beverage and foreign exchange earnings. In 2019, Nigeria produced 350,146 tonnes of cocoa beans with a yield of 258.6 kg/ha (FAOSTAT, 2019). This was low when compared to Cote d'Ivore and Ghana that produced 2,180,000 and 811,700 tonnes of cocoa beans respectively, with cocoa bean yield of 456 kg/ha and 549 kg/ha respectively (FAOSTAT, 2019). One of the challenges of cocoa production in Nigeria is ageing cocoa plantations and unavailability of fertile top soil to establish new cocoa plantations, arising from competition for land for both agricultural and non-agricultural purposes. Nitrogen is one of the most important nutrient in crop production in Sub Saharan Africa (Okalebo *et al*., 2006) and it is required in the largest quantities by cocoa at its early growth stage (Vliet *et al*., 2015). Its availability in adequate quantity at the early growth stage enhances growth and establishment of cocoa. The use of conventional inorganic fertilizer which is a major nitrogen source is plagued with economic, social and political challenges. This coupled with the epileptic operation of the few fertilizer plants in the country that depend on the importation of major raw materials at high cost has also led to high cost of fertilizer. In the 2014 cropping season, Nigeria imported 180,242 tonnes of NPK fertilizer valued at US $138,413,000, 280,206 tonnes of urea valued at USD $118,391,000 and 22,187 tonnes of muraite of potash valued at USD $10,520,000 (FAOSTAT, 2019). There is therefore need to source for alternative nitrogen sources for cocoa. Cocoa pod husk, kola pod husk and Chromolaena are alternative nitrogen sources. There is need to harness their potentials as alternative nitrogen sources and to establish the most effective nitrogen level that would enhance growth of cocoa seedlings. The objectives of this study were to: 1) Evaluate the effects of nitrogen fertilizer sources on growth of cocoa seedlings and 2) Determine the influence nitrogen fertilizer levels on growth cocoa seedlings.

MATERIALS AND METHODS

The study was conducted in Cocoa Research Institute of Nigeria, Owena, Ondo state in the rainforest ecological zone. Treatments were a factorial combination of four nitrogen sources (Cocoa pod husk (CPH), Kola pod husk (KPH), Chromolaena (CO) and NPK) and five nitrogen levels (0, 5, 10, 15 and 20 kg N/ha). These 20 treatments were arranged in a randomized complete block design with three replications. The soil was air-dried passed through a 2 mm sieve and 5 kg weighed into plastic pots. One pre-germinated cocoa seedling was planted per pot. A sub-sample of the soil was taken and analyzed for some of its chemical and physical properties using standard procedures. Data was collected monthly for 7 months on number of leaves, plant height, stem diameter, leaf, stem, root and total dry matter yield. Statistical analysis was carried out on the data collected using Analysis of variance (ANOVA) and significant means separated using Least Significant Difference (LSD).

RESULTS AND DISCUSSION

Soils of the experimental site in Owena was sandy loam and slightly acidic (5.8). The organic carbon content was low with a value of 14.5 g/kg. Total nitrogen and available phosphorus values were low with values of 0.79 g/kg and 5.13 mg/kg, while soil exchangeable K, Ca, Mg were adequate with values of 0.32 cmol/kg, 5.13 cmol/kg, and 0.82 cmol/kg respectively. *Chromolaena* fertilizer significantly ($P<0.05$) enhanced number of leaves of cocoa seedlings only at 7 MAT when compared with KPH fertilizer (Table 1), while only 10 kg N/ha enhanced number of leaves of cocoa seedlings at 7 MAT when compared with 0 kg N/ha. At 2 MAT, NPK was superior to CO and CPH in plant height (Table 1). However, at 4 and 7 MAT, this effect was not significant. Nitrogen applied at the rate of 10, 15 and 20 kg N/ha increased plant height by 22 %, 15 % 14 % respectively when compared with 0 kg N/ha. Fertilizer applied at the rate of 10 kg N/ha also significantly ($P<0.05$) increased plant height when compared with other N levels. This was consistent with the findings of Ogunlade *et al*. (2008) who reported that CPH alone and CPH fortified with neem enhanced plant height, stem diameter and number of leaves of cocoa seedlings relative to no fertilizer. Similar observation was made by Adejobi *et al*. (2013) who reported that cocoa pod ash increased plant height, stem diameter, leaf area, number of leaves, number of branches and shoot dry matter yield.

At 7 MAT, NPK and CO treatments resulted in higher stem diameter than CPH and KPH (Table 1). The influence of N fertilizer source on leaf dry matter yield was significant (Table 2). At 2 and 4 MAT, NPK fertilizer enhanced leaf dry matter yield of cocoa seedlings when compared with other fertilizer sources (Table 3). However, at 7 MAT, both CPH and NPK treated cocoa seedlings produced higher leaf dry matter yield than KPH treated cocoa seedlings with increases of 10 and 11 % respectively. At 2 and 4 MAT, N levels had no significant influence on leaf dry matter yield of cocoa seedlings (Table 2), whereas at 7 MAT, the influence of fertilizer level was significant ($P<0.05$). Increasing N levels from 0 to 5 kg N/ha increased leaf dry matter yield of the cocoa seedlings but the increase was not statistically significant. Further increase of N level to 10 kg N/ha resulted in significantly ($P<0.05$) heavier leaf dry matter yield when compared with no fertilizer control. Fertilizer applied at the rate of 10 kg N/ha produced heavier leaf dry weight when compared with all other fertilizer levels. At 2 and 4 MAT, stem dry matter yield of cocoa seedlings was not influenced by N fertilizer sources and levels (Table 2). However, at 7 MAT, cocoa seedlings applied with CPH fertilizer performed better than other N fertilizer sources with increases of stem dry matter yield of 13 – 17 %. Chromolaena treatment resulted to higher stem dry matter yield than KPH. At 2 and 4 MAT, N levels had no significant influence on stem dry matter yield of cocoa seedlings. At 7 MAT, the effect of N fertilizer levels on stem dry matter yield of seedlings was however significant. Increasing fertilizer levels from 0 to 5 kg N/ha had no effect on stem dry matter yield. Further increase to 10, 15 and 20 kg N/ha increased stem dry matter yield of cocoa seedlings with increases of 15 – 19 % when compared to 0 kg N/ha. Nitrogen applied at the rate of 10 kg N/ha performed better than other N fertilizer rates. Similarly, (Ogunlade *et al.,* 2006) reported that pace setter organic fertilizer alone and fortified with neem leaf and seed applied at the rate of 10 kg N/ha increased, number of leaves, stem diameter and dry matter yield when compared with no fertilizer and NPK fertilizer.

The influence of N fertilizer source on root dry matter yield was significant only at 2 MAT (Table 2) where NPK enhanced root dry matter yield of cocoa seedlings when compared with all other N fertilizer sources, while CPH and CO performed better than KPH fertilizer (Table 2). The effect of N fertilizer levels on root dry matter yield was significant at 7 MAT (Table 2). All N levels had 15 to 30 % higher root dry matter than 0 N kg/ha. Cocoa seedlings treated with 20 kg N/ha produced 12 % heavier root dry matter yield than cocoa seedlings treated with 10 kg N/ha.

Table 1: Number of leaves, plant height (cm), stem diameter (cm) and crop growth rate (g/day) of cocoa seedlings as influenced by nitrogen fertilizer sources and levels in Owena location soil under screen house condition

The effect of N fertilizer source was significant on total dry matter yield of cocoa seedlings at all the sampled stages (Table 2). At 2 MAT, CO and NPK performed better than CPH and KPH (Table 2). At 4 MAT, only cocoa seedlings treated with NPK enhanced total dry matter yield of cocoa seedlings when compared with CPH and KPH. However, at 7 MAT, cocoa seedlings treated with CPH performed better than all other N fertilizer sources, while CO and NPK performed better than KPH. There was no significant ($P<0.05$) difference between the various N fertilizer levels at 2 and 4 MAT (Table 2). The influence of fertilizer level on total dry matter yield was significant only at 7 MAT (Table 2) were only 10 kg N/ha increased total dry matter yield by 16 % - 24 % when compared with all other fertilizer levels. This was corroborated by Ipinmoroti *et al*. (2006) who reported that CPH, poultry dropping, and cattle dung enhanced number of leaves, leaf area, root length and total dry matter yield (TDMY) of cocoa with TDMY due to the manures being 29.3 - 55.9 % higher than no fertilizer control. Akanbi *et al*. (2014) also reported that oil palm bunch ash and cocoa pod husk ash enhanced growth of cocoa seedling.

Nitrogen fertilizer irrespective of source enhanced growth of cocoa seedlings. The positive growth response of cocoa seedling to N fertilizer can be attributed to the low N status of soil, which was below the soil critical N level of 1 g/kg N required for cocoa (Egbe *et al*., 1989). The need created by this N deficiency in the soil was met by the applied N fertilizers, hence increase in growth of cocoa seedlings. Fertilizer rate of 10 kg N/ha performed better than all the other N rates. This indicates that cocoa growth need was met at the rate of 10 kg N/ha. The application fertilizer at rates below 10 kg N/ha was therefore inadequate to meet the growth need of cocoa, while above 10 kg N/ha had no additional benefit. Hence the fertilizers were best utilized at the rate of 10 kg N/ha.

CONCLUSION

Nitrogen fertilizer irrespective of source enhanced growth of cocoa seedlings, while all nitrogen levels increased root dry matter yield. Fertilizer applied at the rate of 10 kg N/ha proved to be the most effective rate with higher number of leaves, plant height, leaf, stem, root and total dry matter yield than 0 kg N/ha. Fertilizer applied at the rate of 10 kg N/ha also resulted to higher plant height, stem, leaf and total dry matter yield than all other nitrogen levels.
